Abstract. Few studies have examined in detail the sequence of events during the last glacial termination (T1) in the core sector of the Patagonian Ice Sheet (PIS), the largest ice mass in the Southern Hemisphere outside of Antarctica. Here we report results from Lago Edita (47°8' S, 72°25' W, 570 m a.s.l.), a small closed-basin lake located in a valley overridden by eastward-flowing Andean glaciers during the Last Glacial Maximum (LGM). The Lago Edita record shows glaciolacustrine sedimentation until 19 400 yr BP, followed by organic sedimentation in a closed-basin lake and a mosaic of cold-resistant hygrophilous conifers and rainforest trees, along with alpine herbs between 19 400 and 11 000 yr BP. Our data suggest that the PIS retreated at least ~90 km from its LGM limit between ~21 000 and 19 400 yr BP and that scattered, low-density populations of cold-resistant hygrophilous conifers, rainforest trees, high-Andean and steppe herbs thrived east of the Andes during the LGM and T1, implying high precipitation levels and southern westerly wind (SWW) influence at 47° S. The conifer *Podocarpus nubigena* increased between 14 500 and 13 000 yr BP, suggesting even stronger SWW influence during the Antarctic Cold Reversal, after which it declined and persisted until 11 000 yr BP. Large increases in arboreal pollen at ~13 000 and ~11 000 yr BP led to the establishment of forests near Lago Edita between 10 000 and 9000 yr BP, suggesting a rise in the regional tree line along the eastern Andean slopes driven by warming pulses at ~13 000 and ~11 000 yr BP and a subsequent decline in SWW influence at ~11 000 yr BP. We propose that the PIS imposed a regional cooling signal along its eastern,

downwind margin through T1 that lasted until the separation of the northern and southern Patagonian ice fields along the Andes during the Younger Dryas period. We posit that the withdrawal of glacial and associated glaciolacustrine environments through T1 provided a route for the dispersal of hygrophilous trees and herbs from the eastern flank of the central Patagonian Andes, contributing to the afforestation of the western Andean slopes and pacific coasts of central Patagonia during T1.

1 Introduction

The Patagonian Ice Sheet (PIS) was the largest ice mass in the Southern Hemisphere outside of Antarctica during the last glacial maximum (LGM). Outlet lobes from the PIS flowed westward into the Pacific coast south of 43° S and eastward toward the extra-Andean Patagonian plains, blanketing a broad range of environments and climatic zones across and along the Andes. Land biota from formerly ice-free sectors underwent local extinction or migrated toward the periphery of the advancing PIS during the last glaciation until its culmination during the LGM. The PIS then underwent rapid recession and thinning through the last glacial termination (termination 1 = T1: between ~18 000 and 11 000 yr BP) toward the Andes as illustrated by stratigraphic, geomorphic and radiocarbon-based chronologies from northwestern Patagonia (39–43° S) (Denton et al., 1999; Moreno et al., 2015). These data, along with the Canal

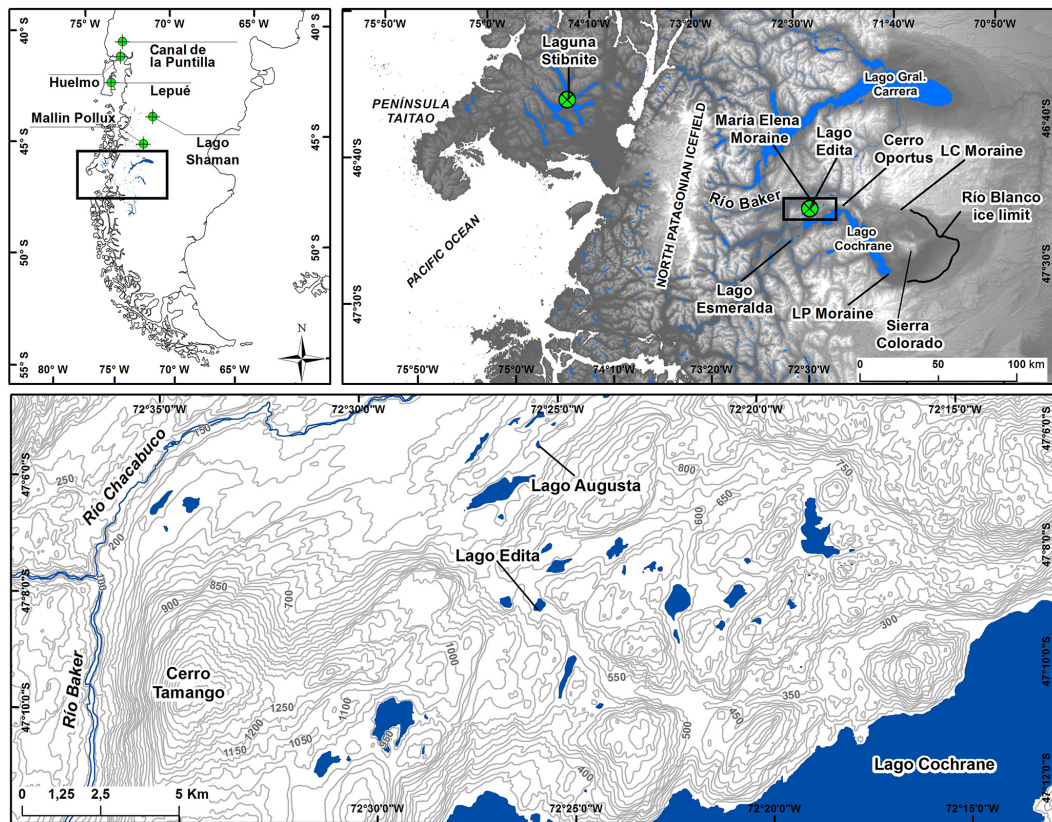

Figure 1. Sketch map of the study area showing the location of central-western Patagonia, the position of Valle Chacabuco relative to the Río Blanco, María Elena, Lago Columna (LC) and Lago Posada (LP) ice limits east Lago Cochrane, and the northern Patagonian ice field and the Taitao Peninsula to the west. We also included Sierra Colorado, Lago Esmeralda and Cerro Oportus for reference. The lower portion of the figure shows a detail on the Cerro Tamango area and the portion of Valle Chacabuco where Lago Edita and Lago Augusta are located. Also shown are palynological sites discussed in the main text (Canal de la Puntilla, Huelmo, Mallín Lago Shaman, Mallín Pollux, Lago Stibnite, Lago Augusta).

de la Puntilla-Huelmo pollen record ($\sim 41^\circ$ S) (Moreno et al., 2015) (Fig. 1), indicate abandonment from the LGM margins in the lowlands at 17 800 yr BP, abrupt arboreal expansion and accelerated retreat that exposed Andean cirques located above 800 m a.s.l. within 1000 years or less in response to abrupt warming. Similarly, glaciers from Cordillera Darwin ($54\text{--}55^\circ$ S), the southernmost ice field in South America, underwent rapid recession from their LGM moraines located in central and northern Tierra del Fuego prior to 17 500 yr BP and led to ice-free conditions by 16 800 yr BP near the modern ice fronts (Hall et al., 2013). Sea surface temperature records from the SE Pacific (Caniupán et al., 2011) are consistent with these terrestrial records; however, their timing, structure, magnitude and rate of change may be overprinted by the vicinity of former ice margins and shifts in marine reservoir ages (Caniupán et al., 2011; Siani et al., 2013).

In contrast, in the Andean sector of central-western Patagonia ($45\text{--}48^\circ$ S) very few studies have been conducted about the timing of glacial advances near the end of the LGM or the structure and chronology of glacial retreat and climate

changes during T1. Recent chronologies include cosmogenic radionuclides of terminal moraines of the Río Blanco, recessional moraines deposited by the Lago Cochrane ice lobe (LCIL) (Boex et al., 2013; Hein et al., 2010) (Fig. 1) and optically stimulated luminescence dating of glaciolacustrine beds associated with the glacial Lake Cochrane (GLC) (47° S) (Glasser et al., 2016). These studies reported ages between 29 000 and 19 000 yr BP for the final LGM advance and drainage of GLC toward the Pacific between 13 000 and 8000 yr BP caused by the breakup of the northern and southern Patagonian ice fields during the final stages of T1 (Turner et al., 2005). Palynological interpretations from the Lago Shaman ($44^\circ 26'$ S, $71^\circ 11'$ W, 919 m a.s.l.) and Mallín Pollux ($45^\circ 41'$ S, $71^\circ 50'$ W, 640 m a.s.l.) sites (de Porras et al., 2012; Markgraf et al., 2007), located east of the Andes (Fig. 1), indicate the predominance of cold and dry conditions during T1 and reduced southern westerly wind (SWW) influence. The validity and regional applicability of these stratigraphic, chronological and palynological interpretations, however, awaits replication with detailed strati-

graphic and geomorphic data from sensitive sites constrained by precise chronologies.

Paleoclimate simulations (Bromwich et al., 2004, 2005) and stratigraphic studies (Kaufman et al., 2004) in the periphery of the Laurentide Ice Sheet in North America have detected that large ice sheets exerted important impacts on the thermal structure and atmospheric circulation on regional, continental and zonal scales from the LGM to the early Holocene. This aspect has remained largely unexplored in the PIS region and might be a factor of importance for understanding the dynamics of the SWW and climatic and biogeographic heterogeneities through T1 on a regional scale. Progress in this field requires an understanding of the deglacial chronology of the PIS and a suite of sensitive paleoclimate sites across and along the residual ice masses through the last transition from extreme glacial to extreme interglacial conditions.

In this study we report high-resolution pollen and macroscopic charcoal records from sediment cores we collected from Lago Edita (47°8' S, 72°25' W, ~570 m a.s.l.), a medium-sized closed-basin lake (radius ~250 m) located in Valle Chacabuco ~16 km northeast of the Cochrane township, east of the central Patagonian Andes (Fig. 1). The relevant source area for pollen from lakes of this size is about 600–800 m from the lake's edge, according to numerical simulations using patchy vegetation landscapes (Sugita, 1994). Stratigraphic and chronological results from Valle Chacabuco are important for elucidating the timing and rates of deglaciation in this core region of the PIS because this valley is located approximately 90 km upstream from the LGM moraines deposited by LCIL east of Lago Cochrane relative to the modern ice fronts, and its elevation spans the highest levels of GLC during T1. The Lago Edita data allow the assessment of vegetation and fire-regime and climate changes during the last global transition from extreme glacial to extreme interglacial conditions in central-western Patagonia. The aim of this paper is to contribute to (1) the development of a recessional chronology of the LCIL and (2) regressive phases of GLC, (3) document the composition and geographic shifts of the glacial and deglacial vegetation, (4) understand the tempo and mode of vegetation and climate changes during T1 and the early Holocene, (5) constrain the regional climatic influence of the PIS during T1 in terrestrial environments, and (6) improve our understanding of the biogeography of the region, including the identification of possible dispersal routes of tree taxa characteristic of modern evergreen forests in central-western Patagonia during T1.

2 Study area

Central Chilean Patagonia, i.e., the Aysén region (43°45'–47°45' S), includes numerous channels, fjords, islands and archipelagos along the Pacific side, attesting to tectonic subsidence of Cordillera de la Costa and intense glacial erosion

during the Quaternary. The central sector features an intricate relief associated with the Patagonian Andes with summits surpassing 3000 m a.s.l., deep valleys, lakes of glacial origin, and active volcanoes such as Hudson, Macá, Cay, Mentolat and Melimoyu (Stern, 2004). The Andes harbors numerous glaciers and the northern Patagonian ice field (Fig. 1), which acted as the source for multiple outlet glacier lobes that coalesced with glaciers from the southern Patagonian ice field to form the PIS during Quaternary glaciations, that blocked the drainage toward the Pacific, funneling large volumes of glacial meltwater toward the Atlantic (Turner et al., 2005). Farther to the east the landscape transitions into the back-arc extra-Andean plains and plateaus.

Patagonia is ideal for studying the paleoclimate evolution of the southern midlatitudes, including past changes in the SWW, because it is the sole continental landmass that intersects the low and mid-elevation zonal atmospheric flow south of 47° S. Orographic rains associated with storms embedded in the SWW enhance local precipitation caused by the ascent of moisture-laden air masses along the western Andean slopes, giving way to subsidence and acceleration of moisture-deprived winds along the eastern Andean slopes (Garreaud et al., 2013). This process accounts for a steep precipitation gradient across the Andes, illustrated by the annual precipitation measured in the coastal township of Puerto Aysén (2414 mm year⁻¹) and the inland Balmaceda (555 mm year⁻¹) (<http://explorador.cr2.cl/>), localities separated by ~80 km across the west to east axis of the Andes. The town of Cochrane, located ~15 km south of our study site features annual precipitation of 680 mm year⁻¹ and a mean annual temperature of 7.8 °C (Fig. 1).

Weather station and reanalysis data along western Patagonia show positive correlations between zonal wind speed and local precipitation, a relationship that extends to sectors adjacent to the eastern slopes of the Andes (Garreaud et al., 2013; Moreno et al., 2014). Therefore, changes in local precipitation in the Aysén region are good diagnostics for atmospheric circulation changes associated with the frequency and intensity of storms embedded in the SWW over a large portion of the southeast Pacific. This relationship can be applied to paleoclimate records from central Chilean Patagonia for inferring the behavior of the SWW on the basis of past changes in precipitation or hydrologic balance.

The steep precipitation gradient, in conjunction with adiabatic cooling and enhanced continentality toward the east, influences the distribution and composition of the vegetation, inducing altitudinal, latitudinal and longitudinal zonation of plant communities throughout the Patagonian Andes. Physiognomic and floristic studies (Gajardo, 1994; Luebert and Plischoff, 2006; Pisano, 1997; Schmithüsen, 1956) have recognized five units or communities, which we characterize succinctly in the following sentences:

- Magellanic moorland is a unit that occurs in maritime sectors with high precipitation (3000–4000 mm year⁻¹)

and low seasonality) along the islands, fjords and channels. It is dominated by cushion-forming plants such as *Donatia fascicularis*, *Astelia pumila* and *Tetroncium magallanicum*. Also present are the hygrophilous cold-resistant trees *Nothofagus betuloides* and the conifers *Pilgerodendron uviferum*, *Lepidothamnus fonkii* and *Podocarpus nubigena*.

- Evergreen rainforest is present in humid, temperate (1500–3000 mm year⁻¹; < 600 m a.s.l.) sectors of Aysén. This unit is characterized by the trees *Nothofagus nitida*, *N. betuloides*, *Drimys winteri* and *P. nubigena*, along with *P. uviferum* in waterlogged environments.
- Winter deciduous forests are located in cooler and/or drier sectors with higher seasonality (400–1000 mm year⁻¹; 500–1180 m a.s.l.). The dominant tree is *Nothofagus pumilio*, which intermingles with *N. betuloides* at western sites and the Patagonian steppe eastward. In the latter *N. pumilio* forms monospecific stands and presents a species-poor understory. A study of the spatial and temporal variation in *N. pumilio* growth at the tree line along its latitudinal range (35°40′–55° S) in the Chilean Andes (Lara et al., 2005) showed that temperature has a spatially larger control on tree growth than precipitation and that this influence is particularly significant in the temperate Andes (> 40° S). These results suggest that low temperatures are the main limiting factor for the occurrence of woodlands and forests at high elevations in the Andes, considering that precipitation increases with elevation at any given latitude (Lara et al., 2005). The modern tree line near Cochran is dominated by *N. pumilio* and lies between 800 and 1180 m a.s.l.
- Patagonian steppe occurs in substantially drier (< 500 mm year⁻¹) lowland areas with heightened continentality. This unit is dominated by herbs of the families Poaceae (*Festuca*, *Deschampsia*, *Stipa*, *Hordeum*, *Rytidosperma*, *Bromus*, *Elymus*) and Rubiaceae (*Galium*) and shrubs of the families Apiaceae (*Mulinum*), Rosaceae (*Acaena*), Fabaceae (*Adesmia*) and Rhamnaceae (*Discaria*).
- High-Andean desert occurs in the windswept montane environments above the tree line (> 1000 m a.s.l.) under cold conditions, a high-precipitation regime and prolonged snow cover throughout the year. This vegetation unit is represented by herbs of the families Poaceae (*Poa*, *Festuca*), Asteraceae (*Nassauvia*, *Senecio*, *Perezia*), Berberidaceae (*Berberis*), Brassicaceae (*Cardamine*), Santalaceae (*Nanodea*), Rubiaceae (*Oreopolus*) Apiaceae (*Bolax*) and Ericaceae (*Gaultheria*, *Empetrum*), along with *Gunnera magellanica* and *Valeriana*, with occasional patches of *Nothofagus antarctica*.

3 Materials and methods

We collected overlapping sediment cores over the deepest sector of Lago Edita (8 m water depth) from an anchored coring rig equipped with 10 cm diameter aluminum casing tube, using a 5 cm diameter Wright piston corer and a 7.5 cm diameter sediment–water interface piston corer with a transparent plastic chamber. We characterized the stratigraphy through visual descriptions, digital X radiographs to identify stratigraphic structures and loss on ignition to quantify the amount of each organic, carbonate and siliciclastic component in the sediments (Heiri et al., 2001).

The chronology of the record is constrained by accelerator mass spectrometry (AMS) radiocarbon dates on bulk sediment and chronostratigraphic correlation of the H1 tephra from Mount Hudson (Stern et al., 2016). The radiocarbon dates were calibrated to calendar years before present (yr BP) using the CALIB 7.0 program. We developed a Bayesian age model using the Bacon package for R (Blaauw and Christen, 2011) to assign interpolated ages and confidence intervals for each level analyzed.

We processed and analyzed continuous and contiguous sediment samples (2 cm³) for pollen and fossil charcoal. The samples were processed using a standard procedure that includes 10 % KOH, sieving with a 120 µm mesh, 46 % hydrofluoric acid (HF) and acetolysis (Faegri and Iversen, 1989). We counted between 200 and 300 pollen grains produced by trees, shrubs and herbs (terrestrial pollen) for each palynological sample and calculated the percent abundance of each terrestrial taxon relative to this sum. The percentage of aquatic plants was calculated in reference to the total pollen sum (terrestrial plus aquatic pollen) and the percentage of ferns from the total pollen and spores sum. Zonation of the pollen record was aided by a stratigraphically constrained cluster analysis on all terrestrial pollen taxa with ≥ 2 %, after recalculating sums and percentages.

We identified the palynomorphs based on a modern reference collection housed at the laboratory of Quaternary paleoecology of Universidad de Chile, along with published descriptions and keys (Heusser, 1971). In most cases the identification was done at family or genus level, in some cases at the species level (*Podocarpus nubigena*, *Drimys winteri*, *Gunnera magellanica*, *Lycopodium magellanicum*). The palynomorph *Nothofagus dombeyi* type includes the species *N. antarctica*, *N. pumilio*, *N. betuloides* and *N. dombeyi*. The morphotype *Fitzroya/Pilgerodendron* includes the cupressaceous conifers *Fitzroya cupressoides* and *Pilgerodendron uviferum*. We calculated running means of selected pollen taxa using a triangular weighing function of values along seven adjacent levels.

We tallied microscopic (< 120 µm) and macroscopic (> 106 µm) charcoal particles to document regional and local fire events, respectively. Microscopic particles were counted from each pollen slide, while macroscopic charcoal was counted from 2 cm³ sediment samples obtained from 1 cm

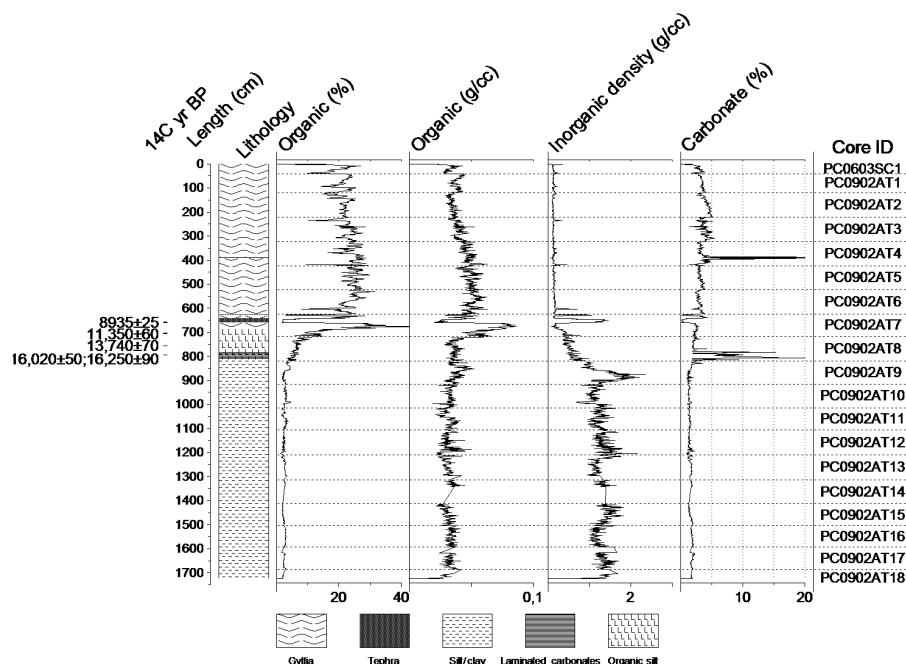

Figure 2. Stratigraphic column, radiocarbon dates and loss-on-ignition data from the Lago Edita record. The labels on the right indicate the identity and stratigraphic span (dashed horizontal lines) of each core segment.

thick and continuous and contiguous sections. The samples were prepared using a standard procedure that involves deflocculation in 10 % KOH and careful sieving through 106 and 212 μm diameter meshes to avoid rupture of individual particles, followed by visual inspection on a Zeiss KL 1500 LCD stereoscope at 10 \times magnification. These results were analyzed by a time series analysis to detect local fire events using the CharAnalysis software (Higuera et al., 2009), interpolating samples at regular time intervals based in the median time resolution of the record. We deconvoluted the CHAR signal into a peaks and background component using a lowess robust-to-outlier smoothing with a 100-year window width. We calculated locally defined thresholds to identify statistically significant charcoal peaks or local fire events (99th percentile of a Gaussian distribution).

4 Results

The sediment stratigraphy (Fig. 2) reveals a basal unit of blue-grey mud between 1726 and 819 cm, horizontally laminated for the most part, in some sectors massive and sandier with small amounts of granule and gravel immersed in a clayey matrix (segment PC0902AT9). These inorganic clays are overlain by organic silt between 819 and 678 cm and organic-rich lake mud (gyttja) in the topmost 678 cm. We found laminated authigenic carbonates between 794–759 and 394–389 cm (range: 5–20 %); for the remainder of the record carbonate values are negligible or null (< 5 %). The record includes two tephra between 630–628 and 661–643 cm,

which exhibit sharp horizontal contacts with the over and underlying mud and, consequently, we interpret them as aerial fallout deposits from explosive events originating from Mount Hudson (H1 tephra) and from Volcán Mentolat (M1 tephra) based on geochemical data (Stern et al., 2016).

The radiocarbon results show an approximately linear increase in age with depth between 19 000 and 9000 yr BP (Fig. 3), which, in conjunction with the sediment stratigraphy, suggests undisturbed in situ pelagic deposition of lake mud and tephra in the Lago Edita basin. This study focuses on the interval between 19 000 and 9000 yr BP (Fig. 2, Table 1) and consists of 155 contiguous palynological and macroscopic charcoal levels with a median time step of 65 years between analyzed samples.

4.1 Pollen stratigraphy

We divided the record in six zones based on conspicuous changes in the pollen stratigraphy and a stratigraphically constrained cluster analysis to facilitate its description and discussion (Fig. 4). The following section describes each pollen zone, indicating the stratigraphic and chronological range, and the mean abundance of major taxa in parentheses.

Zone Edita-1 (795–780 cm; 19 000–18 100 yr BP) is dominated by Poaceae (33 %) and *Empetrum* (32 %). This zone starts with a gradual increase in *Empetrum*, attaining its maximum abundance (~ 53 %) at the end of this zone. Asteraceae subfamily Asteroideae (7 %), *Acaena* (4 %), Caryophyllaceae (3 %) and Cyperaceae (9 %) de-

Figure 3. Age model of the Lago Edita record, with the blue zones representing the probability distribution of the calibrated radiocarbon dates and the grey zone representing the calculated confidence interval of the Bayesian age model.

Table 1. Radiocarbon dates from the Lago Edita core. The radiocarbon dates were calibrated to calendar years before present using the CALIB 7.0 program.

Laboratory code	Core	Material	Length (cm)	¹⁴ C yr BP ± 1σ	Median probability (yr BP)	2σ range (yr BP)

crease, while Poaceae shows fluctuations in its abundance between 2 and 16 % over the entire interval. Other herbs and shrubs such as Ericaceae (3 %), *Phacelia* (~ 2 %), *Valeriana* (1 %), *Gunnera magellanica* (~ 2 %), Apiaceae (< 1 %), and Asteraceae subfamily Cichorioideae (< 1 %) remain relatively steady. The arboreal taxa *N. dombeyi* type (10 %), *Fitzroya/Pilgerodendron* (2 %), *P. nubigena* (< 1 %) and *D. winteri* (< 1 %) are present in low abundance, as well as the ferns *L. magellanicum* (~ 1 %) and *Blechnum* type (5 %) and the green microalgae *Pediastrum* (2 %).

Zone Edita-2 (780–758 cm; 18 100–16 800 yr BP) begins with a decline in *Empetrum* (30 %) and an increase in Poaceae (34 %), followed by its decrease until the end of this zone. *N. dombeyi* type (15 %), Caryophyllaceae (5 %) and Asteraceae subfamily Asteroideae (5 %) show a rising trend in this zone, while other arboreal taxa (*Fitzroya/Pilgerodendron* (3 %), *P. nubigena* (< 1 %) and *D. winteri* (< 1 %) and most of the herbs maintain an abundance similar to that of the previous zone. *L. magellanicum* (2 %)

and *Pediastrum* (4 %) rise slightly, and high variability in Cyperaceae (7 %) is shown.

Zone Edita-3 (758–701 cm; 16 800–13 200 yr BP) is characterized by a sharp rise in Poaceae (45 %) and a declining trend in *Empetrum* (15 %). The conifer *P. nubigena* (2 %) starts a sustained increase, while *N. dombeyi* type (13 %) and *Fitzroya/Pilgerodendron* (3 %) remain relatively invariant. *D. winteri* (< 1 %) and *Misodendrum* (< 1 %), a mistletoe that grows on the *Nothofagus* species, appear in low abundance in an intermittent manner. *Pediastrum* (30 %) shows a rapid increase until 15 600 yr BP, followed by considerable variations in its abundance until the end of this zone (between 19 and 55 %). *L. magellanicum* (3 %) shows a steady increase, while *Blechnum* type (6 %) remains invariant and Cyperaceae (7 %) exhibits large fluctuations superimposed upon a declining trend.

Zone Edita-4 (701–681 cm; 13 200–11 600 yr BP) starts with an increase in *N. dombeyi* type (29 %) and a minor rise in *Misodendrum* (1 %). *P. nubigena* (5 %) starts this zone

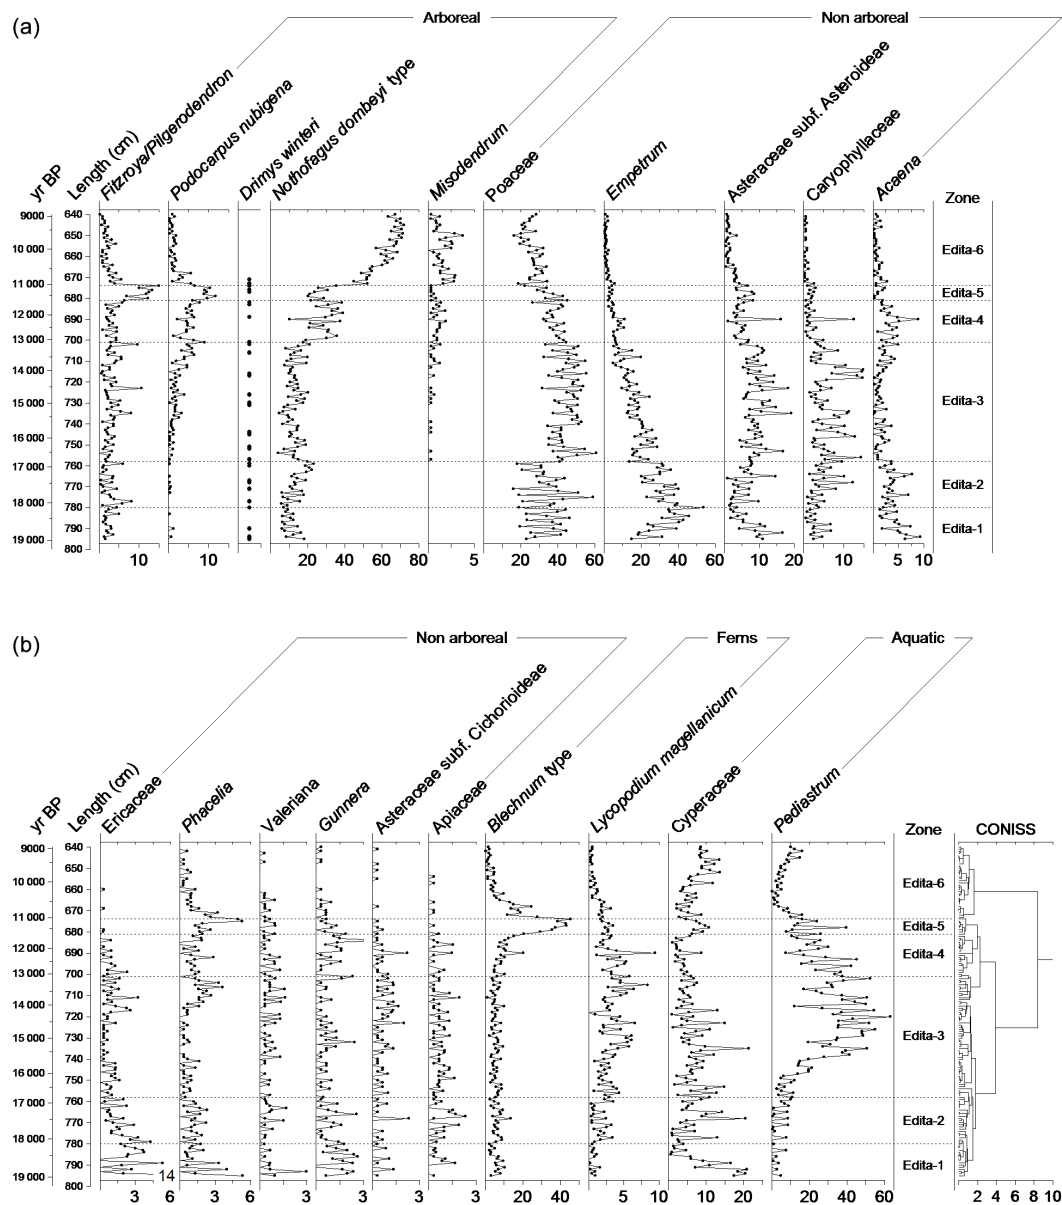

Figure 4. Percentage pollen diagrams from the Lago Edita core. The labels on the right indicate the identity and stratigraphic span (dashed horizontal lines) of each pollen assemblage zone. The black dots indicate the presence of *Drimys winteri* pollen grains, normally < 2 %.

with variability and stabilizes toward the end, concurrent with *Fitzroya/Pilgerodendron* (3 %) and traces of *D. winteri* (< 1 %). *Poaceae* (38 %) shows a steady decrease, while *Empetrum* (6 %) continues with a declining trend that started during the previous zone. *Asteraceae* subfamily *Asteroideae* (5 %) and *Caryophyllaceae* (2 %) decrease, *L. magellanicum* (3 %), *Cyperaceae* (4 %) and *Pediastrum* (24 %) decline gradually with considerable fluctuations, while *Blechnum*-type (11 %) shows modest increases.

Zone Edita-5 (681–674 cm; 11 600–11 100 yr BP) shows marked declines in *N. dombeyi* type (27 %) and *Poaceae* (33 %) in concert with a noticeable increase in the conifers

Fitzroya/Pilgerodendron (12 %) and *P. nubigena* (9 %), which reach their peak abundance in the record. The abundance of herbs and shrubs decreases or remains steady, with the exception of an ephemeral increase in *Phacelia* (3 %). *Blechnum* type (39 %) shows a remarkable increase to its peak abundance in the entire record, while *L. magellanicum* (3 %), *Cyperaceae* (8 %) and *Pediastrum* (17 %) rise slightly.

Zone Edita-6 (674–640 cm; 11 100–8940 yr BP) is characterized by an abrupt increase in *N. dombeyi* type (62 %) and *Misodendrum* (2 %), along with a noticeable decline in *Fitzroya/Pilgerodendron* (2 %) and *P. nubigena* (2 %) at the beginning of this zone. *Poaceae* (26 %) shows a downward

trend over this period, while other herbs and shrubs (*Empetrum*, Ericaceae, Caryophyllaceae, Asteraceae subfamily Asteroideae, *Acaena*, *Phacelia*, *Valeriana*, *Gunnera magellanica*, Apiaceae and Asteraceae subf. Cichorioideae) show their lowest abundance in the record. *Blechnum* type (7 %) drops sharply, followed by a gradual decline in concert with *L. magellanicum* (1 %). Cyperaceae (7 %) and *Pediastrum* (6 %) show initial declines followed by increases toward the end of this zone.

4.2 Charcoal stratigraphy

The record from Lago Edita shows absence of macroscopic charcoal particles between 19 000 and 14 300 yr BP followed by an increase in charcoal accumulation rate (CHAR) that led to a variable plateau between 13 200 and 12 000 yr BP, a 1000-year-long decline, and a sustained increase led to peak abundance at 9700 yr BP. Charcoal values then declined rapidly to intermediate levels by 9000 yr BP. We note a close correspondence between the arboreal pollen abundance (as a percentage) and the CHAR, suggesting that charcoal production was highly dependent upon quantity and spatial continuity of coarse woody fuels in the landscape (Fig. 5).

Time series analysis of the macroscopic charcoal record revealed 11 statistically significant peaks we interpret as local fire events within the Lago Edita watershed (Fig. 5). The temporal structure of these events indicates a sequence of millennial-scale peaks in fire frequency, with maxima at 14 100, 13 100, 12 000, 10 900 and 9600 yr BP. We observe a steady increase in the fire frequency maxima from 14 100 to 10 900 yr BP (Fig. 5).

5 Discussion

5.1 Paleovegetation and paleoclimate

Given the size of Lago Edita (radius ~ 250 m) its pollen record is adequate to reflect local vegetation within 600–800 m from the lake's edge. An extra-local component is also present considering that species of the genus *Nothofagus* also produce large quantities of pollen grains susceptible to long-distance transport (Heusser, 1989). These attributes suggest that the Lago Edita fossil pollen record might be a good sensor of the vegetation located on the western end of Valle Chacabuco and the Lago Cochrane basin. The record (Figs. 4, 6) documents dominance of herbs and shrubs (chiefly Poaceae, *Empetrum* and Asteraceae, accompanied by Caryophyllaceae, *Acaena*, Ericaceae, *Phacelia*, *Valeriana*, and Apiaceae in lower abundance) found above the modern tree line and the Patagonian steppe between 19 000 and 11 000 yr BP, followed by increasing *Nothofagus*. We interpret this as the establishment of scrubland (~ 13 000–11 000 yr BP), woodland (~ 11 000–10 500 yr BP) and forest (~ 10 500–9000 yr BP). Within the interval dominated by non-arboreal taxa, we distinguish an initial phase with abun-

Figure 5. Macroscopic charcoal record from the Lago Edita core and results of CharAnalysis: the blue line is the background component, the red line is the locally defined threshold, triangles are statistically significant charcoal peaks and magnitude is the residual abundance that supersedes the threshold. CHAR is the charcoal accumulation rate.

dant *Empetrum* between 19 000 and 16 800 yr BP, followed by diversification of the herbaceous assemblage and predominance of Poaceae during the interval ~ 16 800–11 000 yr BP (Figs. 4, 6). This change is contemporaneous with a sustained rise in *P. nubigena* and the mistletoe *Misodendrum* coeval with conspicuous increases in *Lycopodium magellanicum* and the green microalgae *Pediastrum*. We em-

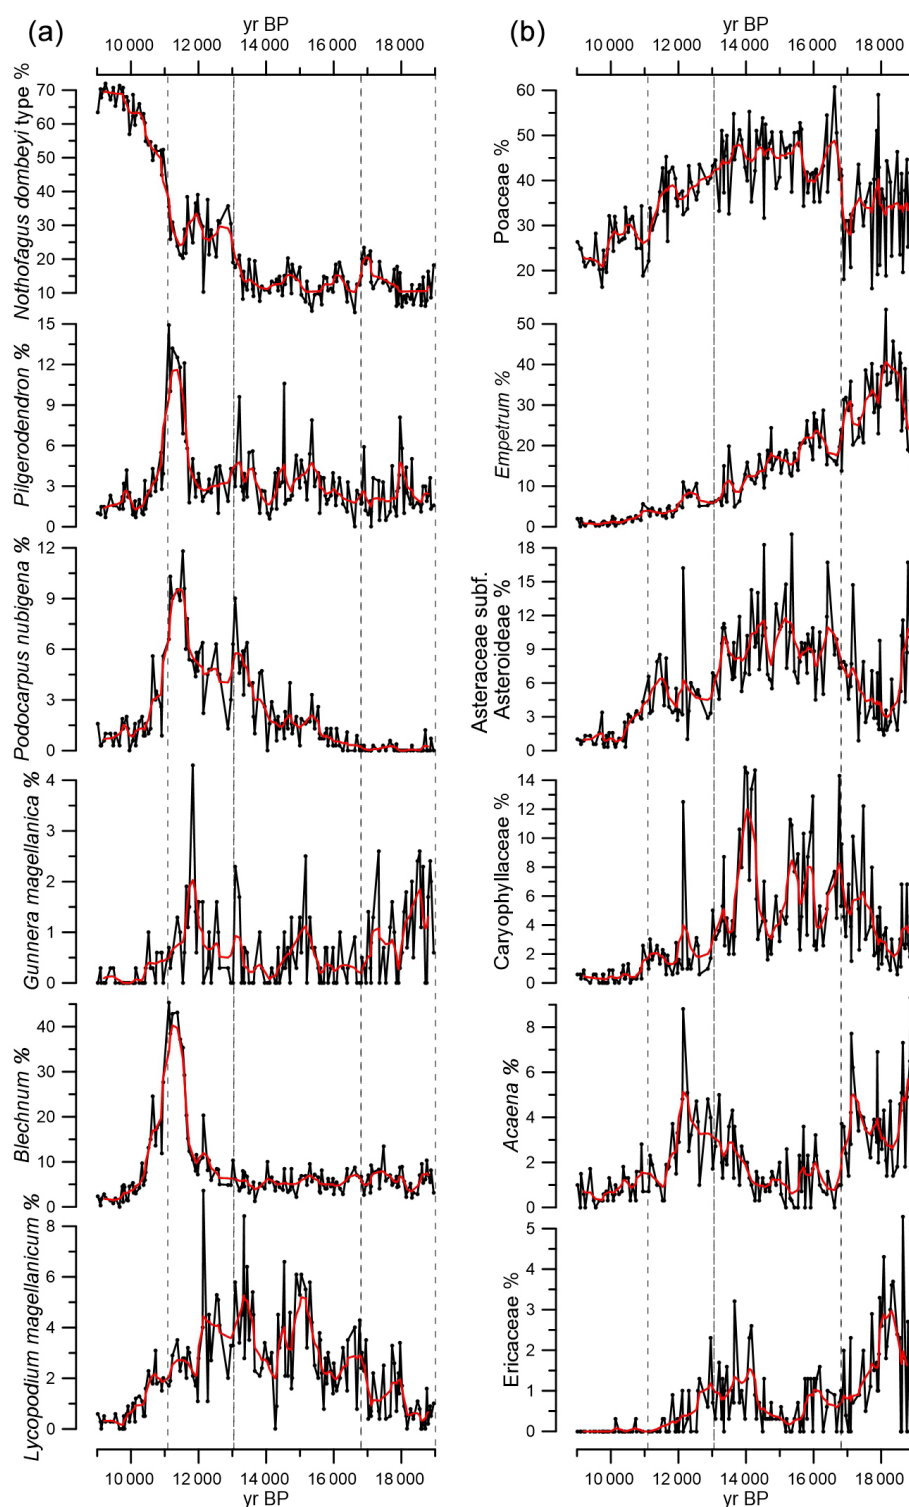

Figure 6. Selected palynomorph abundance of the Lago Edita record shown in the timescale domain. The red lines correspond to weighted running means of seven adjacent samples with a triangular filter. The taxa shown in the left panel are characteristic of humid environments currently found in sectors adjacent to the Pacific coast and/or the Andean tree line in the study area. The taxon *Nothofagus dombeyi* type, which includes multiple species with contrasting climatic tolerances, is also found in (relatively) humid sectors east of the Andes. The herbs and shrubs shown in the right panel are either cosmopolitan or present in the Patagonian steppe and sectors located at or above the Andean tree line in central-western Patagonia.

phasize the continuous presence of the arboreal *Nothofagus* and *Fitzroya/Pilgerodendron* in low but constant abundance (~ 15 and $\sim 3\%$, respectively) between 19 000 and 13 000 yr BP, along with traces ($< 2\%$) of hygrophilous trees (*Podocarpus nubigena*, *Drimys winteri*) and herbs (*Gunnera magellanica*, *Lycopodium magellanicum*) accounting, in sum, for a persistent $\sim 25\%$ of the pre-13 200 yr BP pollen record (Figs. 4, 6). We note that the *Nothofagus* parkland on the western end of Valle Chacabuco and the Lago Cochrane basin must have approached the vicinity of Lago Edita at 16 800 yr BP, judging from the appearance of *Misodendrum* during that time (Figs. 4, 6) under relatively constant mean *Nothofagus* abundances.

The conifer *Podocarpus nubigena* remained in low abundance ($< 2\%$) prior to ~ 14 500 yr BP in the Lago Edita record, increased between 14 500 and 13 000 yr BP, experienced a variable decline between 13 000 and 11 800 yr BP, reached a maximum between 11 800 and 11 200 yr BP, and declined between 11 200 and 10 200 yr BP (Figs. 4, 6). This cold-resistant hygrophilous tree is commonly found in temperate evergreen rainforests along the Pacific coast of central Patagonia and is currently absent from the eastern Andean foothills at the same latitude. Its presence and variations in the Lago Edita record suggest an increase in precipitation relative to the pre-14 500 yr BP conditions, with millennial-scale variations starting at ~ 13 000 yr BP. The variable decline in *P. nubigena* at 13 000 yr BP coincided with an increase in *Nothofagus* that led to a variable plateau of $\sim 30\%$ between 13 000 and 11 200 yr BP, which we will discuss in the following paragraphs.

The mixed palynological assemblage between ~ 19 400 and 11 000 yr BP has no modern analogues in the regional vegetation (Luebert and Plissock, 2006; Mancini, 2002). Possible explanations for its development involve (a) downslope migration of high-Andean vegetation driven by snow line and tree line lowering associated with intense glaciation in the region, coupled with (b) the occurrence of scattered, low-density populations of hygrophilous trees and herbs along the eastern margin of the PIS during the LGM and T1. We rule out the alternative explanation that pollen grains and spores of hygrophilous trees and herbs in Lago Edita represent an advected signal through the Andes from ice-free humid Pacific sectors harboring these species because (i) no empirical basis is currently available for ice-free conditions and the occurrence of cold-resistant hygrophilous taxa along the western Andean slopes or the Pacific coast of central Patagonia during the LGM. In fact, the oldest minimum limiting dates for ice-free conditions in records from the Taitao Peninsula and the Chonos Archipelago yielded ages of $14\,335 \pm 140$ and $13\,560 \pm 125$ ^{14}C yr BP (median age probability, MAP: 17 458 and 16 345 yr BP), respectively (Haberle and Bennett, 2004; Lumley and Switsur, 1993). (ii) The appearance of *Fitzroya/Pilgerodendron* and *Podocarpus nubigena* at ~ 15 000 and ~ 14 000 yr BP, respectively, occurred 4000–5000 years later in coastal Pacific sites relative to the Lago

Edita record (Fig. 7), and (iii) background levels of *Nothofagus* between 15 and 20 % in Lago Edita predate the appearance and expansion of this taxon in coastal Pacific sites and, once realized, its abundance in Lago Edita cannot be attributed to long-distance transport from the western Pacific coast (Fig. 7).

Previous palynological studies from bogs located east of the central Patagonian Andes (de Porras et al., 2012; Markgraf et al., 2007) (Mallín Lago Shaman and Mallín Pollux, Fig. 1) interpreted dry conditions prior to ~ 12 000 yr BP, based on the premise that low abundance of arboreal taxa and predominance of herbs and shrubs were indicative of Patagonian Steppe communities. The glacial-to-interglacial vegetation change in those studies was interpreted as a westward shift of the forest-steppe boundary brought by lower-than-present SWW influence at 44 – 46° S, followed by a rise in temperature and precipitation at the end of the last glaciation. In contrast, the Lago Augusta site (located in Valle Chacabuco ~ 7 km northeast of Lago Edita) (Fig. 1) shows a pollen assemblage prior to 15 600 yr BP dominated by high-Andean herbs and shrubs, along with taxa characteristic of hyper-humid environments along the Pacific coasts of central Patagonia (*Nothofagus*, *Fitzroya/Pilgerodendron*, *Podocarpus nubigena*, *Saxegothea conspicua*, *Drimys winteri*, *Dysopsis glechomoides* and the ferns *Blechnum*, *Hymenophyllaceae* and *Cystopteris*) (Villa-Martínez et al., 2012). It appears then that floristic elements of modern Patagonian forests were present in low abundance and in a discontinuous manner along the eastern flank of the PIS between 44 and 47° S. The data from Lago Edita shown in this paper, along with the results from Lago Augusta, suggest that Valle Chacabuco harbored cryptic refugia (Bennett and Provan, 2008) of rainforest trees and herbs during the interval 19 000–11 000 yr BP. Therefore, the interpretation of lower-than-present precipitation of SWW origin in previous studies (de Porras et al., 2012; Markgraf et al., 2007) is not applicable to the Valle Chacabuco area over this time interval. Plant colonization of Valle Chacabuco must have started from the LGM limits located east of Lago Cochrane and followed the shrinking ice masses to the west once the newly deglaciated sectors were devoid of glaciolacustrine influence through T1.

Declines in and the virtual disappearance of the cold-resistant hygrophilous trees *Fitzroya/Pilgerodendron* and *Podocarpus nubigena* along with the herbs *Gunnera magellanica* and *Lycopodium magellanicum* took place at ~ 11 000 yr BP in the Lago Edita record (Figs. 4, 6) in response to a sudden decline in precipitation relative to the ~ 14 500–11 000 yr BP interval. These changes were contemporaneous with a sustained rise in *Nothofagus*, decreases in all other shrubs and herbs and a major increase in macroscopic charcoal (Fig. 5), signaling an increment in arboreal cover, higher spatial continuity of coarse fuels and forest fires. We interpret this arboreal increase and fire-regime shift as driven by warming, which might have triggered a tree line

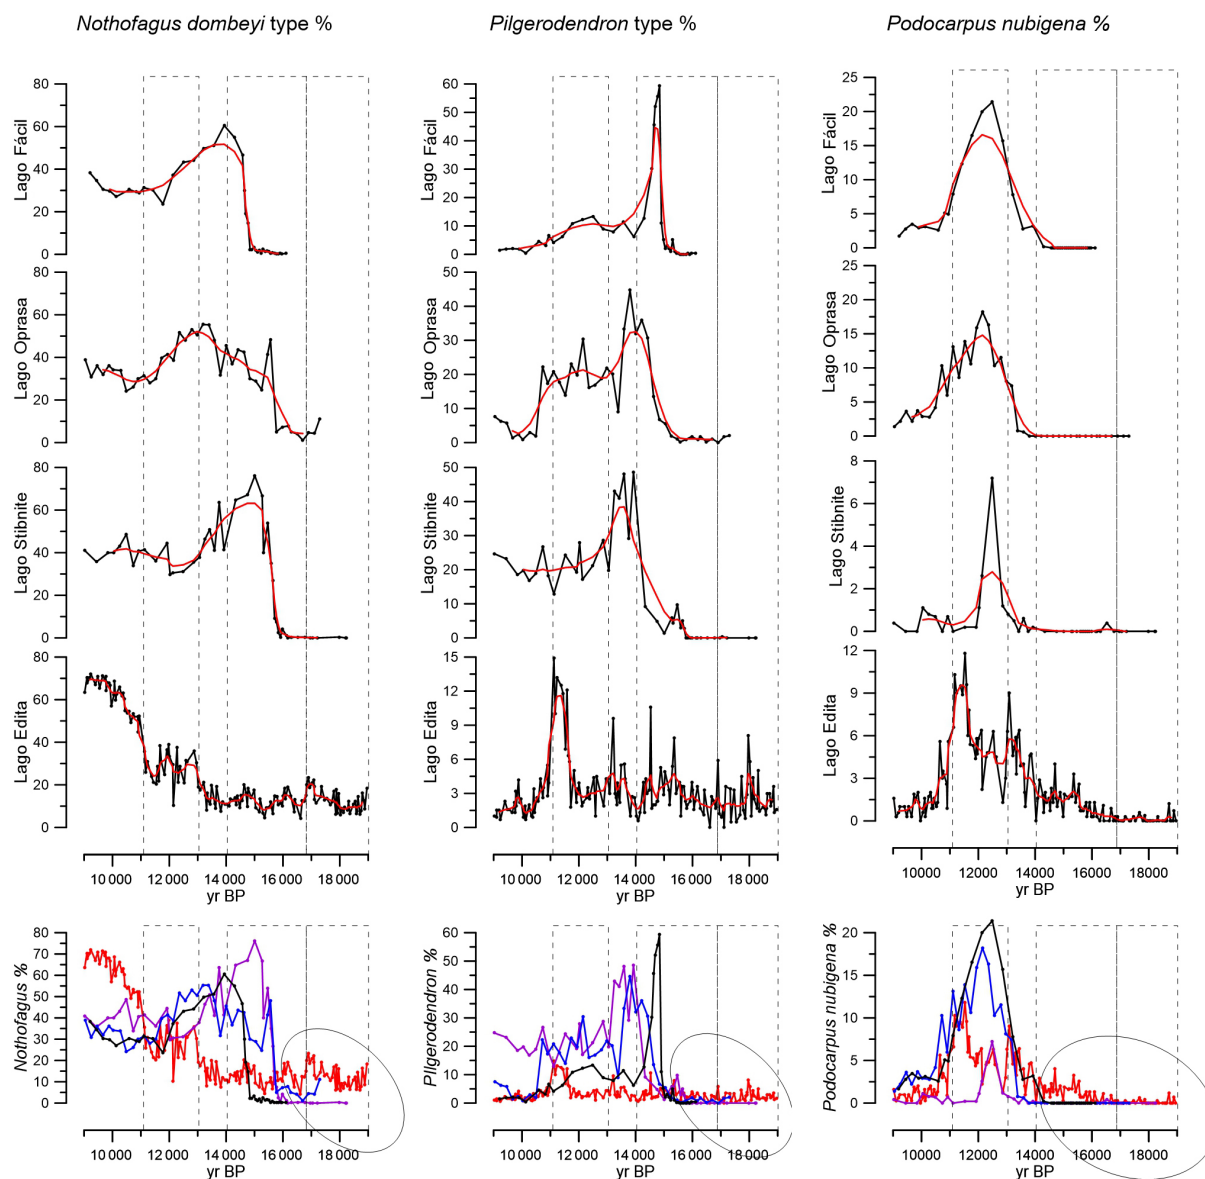

Figure 7. Comparison of selected tree pollen recorded in Lago Fácil, Lago Oprasa, Lago Stibnite (Lumley and Switsur, 1993) and Lago Edita. The red line corresponds to a weighted running mean in each record of seven adjacent samples with a triangular filter. The lower panels show the curves from all sites expressed in a common percent scale (Lago Fácil is the purple line, Lago Oprasa is the blue line, Lago Stibnite is the black line and Lago Edita is the red line).

rise and favored the spread and/or densification of woody species and coarse fuels (Figs. 4, 5, 6). Possible ignition agents for the beginning of fire activity at 14 300 yr BP in the Lago Edita record include the incendiary effects of explosive volcanic activity, lightning strikes and human activity. We rule out volcanic disturbance as a driving factor, considering the lack of contemporary tephra in the stratigraphy of the Lago Edita sediment cores, and we cannot support nor reject other ignition agents considering the current lack of stratigraphic proxies to constrain their likely influence in the Valle Chacabuco area. Finally, *Nothofagus* forests (~ 70 % abun-

dance) were established near Lago Edita between 10 000 and 9000 yr BP.

5.2 Glacial recession in Valle Chacabuco and the Lago Cochrane basin

Stratigraphic and chronological results from Lago Edita are key for deciphering the evolution of Valle Chacabuco and for constraining the timing and rates of deglaciation in this core region of the PIS. Previous studies (Hein et al., 2010) indicate that Valle Chacabuco was overridden by the LCIL during the LGM and deposited the Río Blanco

moraines ~ 90 km downstream from Lago Edita, distal to the eastern end of Lago Cochrane in Argentina (Argentinian name: Pueyrredón). Cosmogenic radionuclide dating of three main moraine limits by Hein et al. (2010) yielded cosmogenic ^{10}Be exposure ages, recently recalculated by Kaplan et al. (2011) at $\sim 21\,100$, $\sim 25\,100$ and $\sim 28\,700$ yr BP. This was followed by glacial recession starting at $19\,600 \pm 800$ yr BP, formation of GLC and stabilization and deposition of the Lago Columna and Lago Posada moraines before $17\,600 \pm 900$ yr BP ~ 55 km upstream from the Río Blanco moraines (Hein et al., 2010; Kaplan et al., 2011) (Fig. 1). Further glacial recession led to the westward expansion and lowering of GLC until the LCIL stabilized and deposited moraines in Lago Esmeralda between $13\,600$ and $12\,800$ yr BP ~ 60 km upstream from the Lago Columna and Lago Posada moraines (Turner et al., 2005). Recession from this position led to sudden drainage of GLC toward the Pacific Ocean via Río Baker, once the continuity between the northern and southern Patagonian ice fields was breached by glacial recession and thinning. These data suggest that Valle Chacabuco may have been ice-free and devoid of glaciolacustrine influence after $\sim 17\,600$ yr BP. More recently, Boex et al. (2013) reported a cosmogenic radionuclide-based reconstruction of vertical profile changes of the LCIL through the LGM and T1 that reveals deposition of (i) the Sierra Colorado lower limit by $28\,980 \pm 1206$ yr BP, which can be traced to the Río Blanco moraines; (ii) the highest summits of the Cerro Oportus and Lago Columna moraines by $18\,966 \pm 1917$ yr BP; and (iii) the María Elena moraine by $17\,088 \pm 1542$ yr BP. According to these data, Valle Chacabuco may have been ice-free after $\sim 17\,000$ yr BP.

Lago Edita is a closed-basin lake located ~ 11 km east of the Cerro Tamango summit along the ridge that defines the southern edge of the Valle Chacabuco watershed (Fig. 1). Lacustrine sedimentation in Lago Edita started when ice-free conditions developed in Valle Chacabuco, as the LCIL snout retreated eastward to a yet unknown position. The Lago Edita cores show 9 m of blue-gray clays with millimeter-scale laminations, interrupted by sporadic intervals of massive pebbly mud appreciable in X radiographs and the LOI_{550} record as increases in the inorganic density data (Fig. 2). We also found exposed glaciolacustrine beds and discontinuous fragments of lake terraces in the vicinity of Lago Edita, attesting for a large lake that flooded Valle Chacabuco in its entirety. Differential GPS measurements of 570 m a.s.l. for the Lago Edita surface and 591 m a.s.l. for a well-preserved terrace fragment located ~ 150 m directly south of Lago Edita provide minimum-elevation constraints for GLC during this stage. The Lago Augusta site (Villa-Martínez et al., 2012), located ~ 7 km northeast of Lago Edita on the Valle Chacabuco floor at 444 m a.s.l. (Fig. 1), shows 8 m of basal glaciolacustrine mud (Fig. 2), lending support to our interpretation.

Glaciolacustrine sedimentation persisted in Lago Edita and Lago Augusta until the surface elevation of GLC dropped below 570 and 444 m a.s.l., respectively, and the

closed-basin lakes developed. The chronology for this event is constrained by statistically identical AMS dates of $16\,250 \pm 90$ and $16\,020 \pm 50$ ^{14}C yr BP (UCIAMS-133418 and CAMS-144454, respectively) (Table 1) from the same level in the basal portion of the organic sediments in the Lago Edita record; this estimate approaches the timing for the cessation of glaciolacustrine influence in Lago Augusta, radiocarbon-dated at $16\,445 \pm 45$ ^{14}C yr BP (CAMS-144600) (Table 1). Because we observe approximately the same age for the transition from glaciolacustrine to organic-rich mud in both stratigraphic layers, we interpret the weighted mean age of those three dates ($16\,254 \pm 63$ ^{14}C yr BP, MAP: 19 426 yr BP, two different laboratories) as a minimum-limiting age for ice-free conditions and nearly synchronous glaciolacustrine regression from elevations 591 and 444 m a.s.l. in Valle Chacabuco. We acknowledge that Villa-Martínez et al. (2012) excluded the age of date CAMS-144600 from the age model of the Lago Augusta palynological record because it was anomalously old in the context of other radiocarbon dates higher up in the core.

Comparison of the radiocarbon-dated stratigraphy from the Lago Edita record with the exposure-age-dated glacial geomorphology from Lago Cochrane (Pueyrredón), Valle Chacabuco and the surrounding mountains reveals the following:

- The geochronology for the innermost (third) belt of Río Blanco moraines ($\sim 21\,100$ yr BP) (Hein et al., 2010; Kaplan et al., 2011), glacial deposits on the highest summits of Cerro Oportus and the Lago Columna moraines ($18\,966 \pm 1917$ yr BP) (Boex et al., 2013) is compatible (within error) with the onset of organic sedimentation in Lago Edita and Lago Augusta at 19 426 yr BP in Valle Chacabuco. If correct, this indicates a ~ 90 km recession of the LCIL from its LGM limit within ~ 1500 years.
- The dates of Hein et al. (2010) for the final LGM limit and Lago Columna and Lago Posada moraines, as well as the chronology of Boex et al. (2013) for the María Elena moraine, should be considered as minimum-limiting ages. This is because cosmogenic radio nuclide ages for these landforms postdate the onset of organic sedimentation in Lago Edita and Lago Augusta, despite being morphostratigraphically distal (older) than Valle Chacabuco.
- As shown in Fig. 1, Lago Edita is located along a saddle that establishes the southern limit of the Río Chacabuco catchment and the northern limit of the Lago Cochrane basin. According to Hein et al. (2010) the drainage divide on the eastern end of the Lago Cochrane (Pueyrredón) basin is located at 475 m a.s.l.; therefore, the presence of this perched glacial lake with a surface elevation of 591 m a.s.l. requires the presence of

ice dams located in the Valle Chacabuco and the Lago Cochrane basin. This suggests that both valleys remained partially ice covered and that enough glacier thinning and recession early during T1 enabled the development of a topographically constrained glacial lake that covered Valle Chacabuco up to the aforementioned saddle.

- The high stand of GLC at 591 m a.s.l. lasted for less than 1500 years during the LGM and was followed by a nearly instantaneous lake-level lowering of at least ~ 150 m at $\sim 19\,400$ yr BP in Valle Chacabuco. The abrupt large-magnitude drainage event of this predecessor lake was recently recognized by Bourgois et al. (2016), but its chronology and hydrographic and climatic implications have not been addressed in the Quaternary literature.

5.3 Biogeographic and paleoclimatic implications

The persistence of scattered, low-density populations of rain-forest trees and herbs east of the Andes during the LGM and T1 (Figs. 4, 6) implies that precipitation delivered by the SWW must have been substantially higher than at present (680 mm year^{-1} measured at the Cochrane meteorological station). Because local precipitation in western Patagonia is positively and significantly correlated with low-level zonal winds (Garreaud et al., 2013; Moreno et al., 2010, 2014), we propose that the SWW influence at 47° S was stronger than present between 19 000 and 11 000 yr BP, in particular between 16 800 and 11 000 yr BP. Subsequent increases in arboreal vegetation, chiefly *Nothofagus*, at $\sim 13\,000$ and $\sim 11\,000$ yr BP led to the establishment of forests near Lago Edita between 10 000 and 9000 yr BP (Figs. 4, 6). We interpret these increases as episodes of tree line rise driven by warming pulses coupled with a decline in SWW strength at 47° S (relative to the $\sim 14\,500$ – $11\,000$ yr BP interval), as suggested by the disappearance of cold-resistant hygrophilous trees and herbs at $\sim 11\,000$ yr BP. We speculate that the warm pulse and decline in SWW influence at $\sim 11\,000$ yr BP might account for the abandonment of early Holocene glacier margins in multiple valleys in central Patagonia (Glasser et al., 2012).

Five salient aspects of the Lago Edita record are relevant for deciphering the pattern and rates of climate change and dispersal routes of the vegetation in Central Patagonia (47° S) during T1:

1. There is an absence of stratigraphically discernable indications of deglacial warming between 19 400 and 13 000 yr BP, in contrast to northwestern Patagonian records (the Canal de la Puntilla–Huelmo record, Fig. 1) (Moreno et al., 2015), which show that 75–80 % of the glacial–interglacial temperature recovery was accomplished between 17 800 and 16 800 yr BP (Fig. 8). The record from Lago Stibnite ($46^\circ 26'\text{ S}$, $74^\circ 25'\text{ W}$),

located in central-western Patagonia upwind from the PIS and Lago Edita (Fig. 1), shows a rapid increase in arboreal pollen from $\sim 2\%$ to $> 80\%$ in less than 1000 years starting at 16 200 yr BP (Fig. 8). We posit that cold glacial conditions lingered along the periphery of the shrinking PIS during T1, affecting adjacent downwind sectors such as Valle Chacabuco. According to Turner et al. (2005) the LCIL stabilized and deposited moraines in Lago Esmeralda, located ~ 10 km upstream along the glacier flow line and ~ 240 m lower in elevation than Lago Edita, between 13 600 and 12 800 yr BP. We propose that the climatic barrier for arboreal expansion vanished in downwind sectors such as Valle Chacabuco once glacial recession from the Lago Esmeralda (Fig. 1) margin breached the continuity of the northern and southern Patagonian ice fields along the Andes. Thus, we propose that regional cooling induced by the PIS along its eastern margin through T1 accounts for the delayed warming in Valle Chacabuco relative to records located in the western and northwestern sectors (Fig. 8).

2. Cold and wet conditions prevailed between 19 400 and 16 800 yr BP, followed by an increase in precipitation at 16 800 yr BP. The latter event is contemporaneous with the onset of a lake-level rise in Lago Lepu  (43  S, central-east Isla Grande de Chilo ) (Fig. 8), which Pesce and Moreno (2014) interpreted as a northward shift of the SWW as it recovered from a prominent southward shift from latitude ~ 41 to 43° S (Fig. 8) following the onset of T1 (Moreno et al., 2015).
3. Significant ice recession (~ 90 km) from the eastern LGM margin of the LCIL was accomplished between $\sim 21\,000$ and 19 400 yr BP, at times when northwestern Patagonian piedmont glacier lobes experienced moderate recession during the Varas interstade (Denton et al., 1999; Moreno et al., 2015) (Fig. 8). In contrast to the LCIL, northwestern Patagonian piedmont glacier lobes re-advanced to their youngest glacial maximum position during a cold episode between 19 300 and 17 800 yr BP that featured stronger SWW influence at 41 – 43° S (Moreno et al., 2015) (Fig. 8). One explanation for this latitudinal difference might be that northward-shifted SWW between 19 300 and 17 800 yr BP fueled glacier growth in northwestern Patagonia while reducing the delivery of moisture to central Patagonia, causing the LCIL to continue the recession it had started during the Varas interstade.
4. A mosaic of cold-resistant and hygrophilous trees and herbs currently found along the humid western slopes of the Andes of central Chilean Patagonia and cold-resistant shrubs and herbs common to high-Andean and Patagonian steppe communities developed along the eastern margin of the PIS during the LGM and T1 (Figs. 4, 6). We posit that glacial withdrawal and

Figure 8. Comparison of the percent sum of arboreal pollen (AP) in records from Lago Edita, Lago Stibnite (Lumley and Switsur, 1993) and the spliced Canal de la Puntilla-Huelmo time series (Moreno et al., 2015), as proxies for local rise in tree line driven by deglacial warming. These data are compared to the delta Deuterium record from the EPICA Dome Concordia (EDC) ice core (Stenni et al., 2010), and hydrologic estimates from northwestern Patagonia. The latter consist of the percent abundance of Magellanic moorland species found in the spliced Canal de la Puntilla-Huelmo record (Moreno et al., 2015), indicative of a hyper-humid regime, and the percent abundance of the littoral macrophyte *Isoetes savatieri* from Lago Lepué (Pesce and Moreno, 2014), indicative of low lake level (LL) during the earliest stages of T1 and the early Holocene (9000–11 000 yr BP). The vertical dashed lines constrain the timing of the early Holocene SWW minimum at 41–43° S (9000–11 000 yr BP) (Fletcher and Moreno, 2011), a low-precipitation phase during the early termination at 41–43° S (16 800–17 800 yr BP) associated with a southward shift of the SWW (Pesce and Moreno, 2014), the final LGM advance of piedmont glacier lobes (17 800–19 300 yr BP) and the final portion of the Varas interstade (19 300–21 000 yr BP) in the Chilean Lake District (Denton et al., 1999; Moreno et al., 2015). The dashed green horizontal lines indicate the mean AP of each pollen record prior to their increases during T1 (Lago Edita: 17 %, Lago Stibnite: 2 %, spliced Canal de la Puntilla-Huelmo: 31 %). The ascending oblique arrow represents a northward shift of the SWW the descending arrow represents a southward shift of the SWW at the beginning of T1.

drainage of GLC through T1 provided a route for the westward dispersal of hygrophilous trees and herbs, contributing to the forestation of the newly deglaciated sectors of central-western Patagonia.

5. The cold-resistant hygrophilous conifer *Podocarpus nubigena* increased between 14 500 and 13 000 yr BP, suggesting an increase in precipitation brought by the SWW to the eastern Andean slopes of central Patagonia. This was followed by a decline, which was contemporaneous with a rise in the regional *Nothofagus*-dominated tree line between 13 000 and 11 200 yr BP. These interpretations imply stronger SWW influence of the SWW at 47° S during the Antarctic Cold Reversal and warming during Younger Dryas time.

We conclude that warm pulses at $\sim 13\,000$ and $\sim 11\,000$ yr BP and a decline in SWW influence at 47° S starting at $\sim 11\,000$ yr BP brought T1 to an end in central-western Patagonia. The earliest of these events overlaps in timing with the culmination of Patagonian (Garcia et al., 2012; Moreno et al., 2009; Strelin et al., 2011; Strelin and Malagnino, 2000) and New Zealand glacier advances (Kaplan et al., 2010; Putnam et al., 2010) during the Antarctic Cold Reversal. Our data suggest that the subsequent warm pulse, which was accompanied by a decline in SWW strength at $\sim 11\,000$ yr BP (Moreno et al., 2010, 2012), was the decisive event that led to the end of T1 in the study area.
