Abstract. Diatoms play a major role in carbon and silicon cycles, and thus diatom-bearing sediments represent an archive of past climatic and environmental settings. In shallow-marine and freshwater environments, the accumulation of diatom frustules forms a sedimentary rock called diatomite. While most global-scale studies of diatom-bearing sediments focus on deep-sea sites, shallow-marine and freshwater diatomites are studied mainly at a regional level. To address this problem, we present a global-scale compilation of diatomite occurrences spanning the Palaeogene (~ 66 to ~ 23 Ma). This period was characterized by initial extreme warmth, followed by prolonged cooling, disrupted by short-term climatic events called hyperthermals and by a number of palaeoceanographic and palaeogeographic changes. The aim of this compilation is to determine the response of diatom production to Palaeogene environmental fluctuations by examining the influence of climate, tectonic activity, and ocean circulation on diatomite deposition. Although climatic factors appear to have had an indirect impact, our study suggests that palaeogeographic and palaeoceanographic changes were key drivers of diatomite deposition during the Palaeogene, particularly from the Early Eocene Climatic Optimum (~ 53 to ~ 49 Ma) onwards. In fact, our compilation suggests the absence of diatomite deposition in epicontinental seas between ~46 and ~ 44 Ma, whereas diatomites did not begin

to accumulate in open-ocean environments until ~ 43.5 Ma. Moreover, we observe that regional climate and volcano-tectonic activity have had an impact on the deposition of freshwater diatomites.

1 Introduction

Diatoms are currently the main primary producers and exporters of organic carbon and silica in the oceans (Barron et al., 2015; Renaudie, 2016). These unicellular microalgae are photosynthetic, which enables atmospheric CO₂ to be transferred to the oceans, resulting in the fixation of organic carbon and the release of O₂ (Guidry et al., 2007; Penman et al., 2020). Diatoms absorb dissolved silica (H₄SiO₄) available in ocean surface waters to develop hydrated silica exoskeletons, called frustules (Kooistra et al., 2007), which are then either dissolved or deposited on the ocean floor and buried in sediments (Yool and Tyrrell, 2003; Guidry et al., 2007; Katz et al., 2024). These processes occur in shallow- and deep-marine settings, as well as in freshwater environments on continents. Sediments containing diatoms, therefore, constitute archives of past geological and environmental processes. The ability of certain assemblages of diatom taxa to adapt to different climatic and environmental

conditions provides information about the environments in which they developed (Kooistra et al., 2007). Consequently, diatoms are a well-suited proxy for palaeoenvironmental and palaeoceanographic reconstructions. However, our understanding of diatom responses to past palaeoceanographic events is mostly shaped by data from the deep ocean. Numerous pelagic diatom records from the global ocean have been generated based on sediments recovered by deep-sea drilling campaigns (e.g. the Deep Sea Drilling Project (DSDP), the Ocean Drilling Program (ODP), and the International Ocean Discovery Program (IODP)), whereas studies of onshore sites are generally conducted at local or regional scales (e.g. McLean and Barron, 1988; Dunbar et al., 1990; Strelnikova, 1992; Radionova et al., 1999, 2003; Kvaček, 2002), and few studies link sites from different regions (Barron et al., 2015; Witkowski et al., 2020). One possible explanation may be found in the scarcity of active fossil marine diatom workers (Witkowski, 2018). Another may be found in the vulnerability of diatoms to diagenetic processes (Knoll et al., 2007), resulting in discontinuities in the record that increase with sediment age.

Although the presence of diatoms since the Cretaceous is well documented, the date of their first appearance in the Mesozoic remains uncertain (Brylka et al., 2023), and their importance in the Palaeogene is not completely understood. The Palaeogene (~ 66 to ~ 23 Ma) is divided into three epochs, beginning with a particularly warm climate during the Palaeocene to early Eocene and slowly cooling towards the Oligocene (Zachos et al., 2001; Cramwinckel et al., 2018; Westerhold et al., 2020). Multiple short-term climate disturbances, often of extreme magnitude, occurred during the early Palaeogene. These so-called hyperthermal events were characterized by a rapid (1000–100 000-year) increase in temperature, lasting from 100 000 to 2 million years, coupled with a rise in atmospheric CO₂, leading to a negative carbon isotope excursion (CIE) and ocean acidification (Foster et al., 2017). During the hyperthermal events, the modification of the carbon cycle – and, subsequently, the silicon cycle – through the intensification of continental weathering, promoted by warm temperatures and elevated atmospheric CO₂ (Berner et al., 1983; Penman et al., 2019), likely led to the increased availability of dissolved silica in the oceans for silica-secreting biota. Diatoms would, therefore, have been more likely to form extensive blooms during these hyperthermal events, but Van Cappellen et al. (2002) suggest that, over short periods corresponding to the residence time of silica in the oceans, the input of aluminium from silicate weathering may have offset the effects of increased [H₄SiO₄] on marine biosiliceous production by reducing the efficiency of silica recycling in the oceans. However, the quantity of living diatoms in the oceans (Leblanc et al., 2012) is such that the Si/C ratio in the biogenic pool (Brzezinski, 1985) should be about 10 times higher than the silica flux brought to the oceans by rivers (Tréguer et al., 1995). Thus, there is a hysteresis in the system due to the storage and recycling of silica

in the biogenic pool, which could last up to 10 times longer than the residence time calculated by simply dividing the fluxes by the concentrations. Furthermore, the inclusion of radiolarians and fossil diatoms in the calculation could actually indicate a longer residence time since these radiolarians and fossil diatoms can potentially increase the total biogenic pool. This hypothesis suggests that after the end of an hyperthermal event, there would still be time to use the additional silica.

The aim of the present work is to verify the response of diatom production to changes in the Palaeogene climate using diatomite records from freshwater and shallow-marine environments. The frequency of diatom-bearing sediments in individual stratigraphic intervals is expected to reveal the response of diatom production to climate change.

To this end, we present a compilation of published Palaeogene shallow-marine and freshwater diatomite occurrences, gathering records on a global scale, with age control relying mainly on diatom biostratigraphy. Based on these data, and using reconstructed sea levels and carbon and oxygen stable-isotope records, we examine the co-occurrence of peaks in diatomite frequency between the Palaeocene–Eocene Thermal Maximum (PETM; ~ 56 Ma) and the Early Eocene Climatic Optimum (EECO; ~ 53 to ~ 49 Ma). We also provide new insights into (1) the role of diatoms in palaeoceanographic and climatic fluctuations and (2) the depositional drivers of diatomite in shallow-marine and freshwater environments during the Palaeogene. Moreover, the compilation and analysis of these data have enabled the detection of a previously unknown gap in the deposition of shallow-marine diatomite between ~ 46 and ~ 44 Ma, which does not correspond to any climatic event documented thus far.

2 Materials and methods

2.1 Lithology

Diatoms develop in aquatic environments under the control of physico-chemical factors such as light and nutrient availability (Battarbee et al., 2001), affecting the type of sediment formed by the accumulation of diatom frustules.

This study is based on a compilation of geographic and stratigraphic diatomite occurrences, including altered diatomite. According to the nomenclature established by Zahajská et al. (2020), diatomite is a consolidated sediment with a high porosity (> 70 %) containing ≥ 50 % diatoms by weight of the sediment. This definition includes diatomites whose matrix is diluted by other types of sediment, such as clay or sand (hence the names “sandy diatomite” and “clayey diatomite”), which are also considered in the compilation.

Diagenetic processes have a major impact on diatomite, e.g. transforming opal-A through an increase in temperature and pressure with growing burial depth, and can lead to the formation of sedimentary rocks such as chert or porcelanite (Zahajská et al., 2020). Therefore, freshwater and shallow-

marine sedimentary rocks containing diatoms – and those specifically recognized in the literature as originating from diatomite – are included in the dataset.

Diatomaceous sediments and sedimentary rocks are not included in this compilation due to the level of uncertainty associated with the characterization of these sediments in the literature.

2.2 Geographic distribution

The compilation, based on a literature survey involving different types of publications (e.g. geological reports and articles on taxonomy and biostratigraphy), covers 106 diatomite occurrences from the Palaeogene (Fig. 1). The dataset is divided into 12 geographic regions: Transuralia–western Siberia, Kazakhstan, the Dnieper–Donets Basin, the middle Volga basin, Kamchatka, western Europe, northern Europe, eastern Europe, North Africa, North America, South America, and Oceania.

Site selection is based on the availability and accuracy of the following parameters: age, geographic coordinates, and lithology. No restrictions are applied to the locations of the sites in order to create a global-scale compilation. However, sites without a precise location are rejected to avoid losing track of the characteristics of their depositional environments. It should be noted that the number of sites for each region is strongly related to the available literature (i.e. the large number of well-documented occurrences on the Eurasian Plate). Despite careful research, other diatomite occurrences may not be represented due to a lack of available information or due to linguistic issues. As the literature survey relies heavily on online searches, papers not indexed in English, French, Spanish, German, Polish, or Russian (the languages that the authors use) could potentially escape our attention. Furthermore, there appears to be an imbalance in the study of diatomites between the Northern and Southern hemispheres, with a greater concentration of research found in the Northern Hemisphere. However, statistical treatment of the compilation shows that there is, in fact, a higher concentration of diatomites in the Northern Hemisphere.

In this study, we consider only freshwater and shallow-marine diatomites. Shallow-marine environments, as opposed to the deep sea, include marine areas up to 200 m in water depth, such as the continental shelf or the upper part of the continental slope in some cases. We intend to cover deep-sea diatom-bearing sediments in a separate compilation, which will allow us to compare diatom accumulation in shallow- and deep-marine environments in a future paper.

A differentiation between depositional environments is also made to enable a better understanding and interpretation of the results. Three depositional environments are distinguished in the compilation: epicontinental seas (abbreviated as ESs), open-ocean settings (OOSs), and freshwater. Epicontinental seas are flooded continental areas, such as continental shelves or larger inland parts flooded by rising sea

levels, whereas open-ocean settings refer to the deposition of diatoms on the continental slope. Although still part of the continental crust, the continental slope is subject to open-ocean conditions, which differ from the conditions of epicontinental seas in terms of ocean circulation. Finally, the freshwater environment brings together lacustrine records in this compilation. While the separation of freshwater and shallow-marine records is an obvious choice due to the differences between these depositional systems, a distinction between diatomites formed in ESs and those formed in OOSs is also necessary. This is done in order to follow the effects of ocean circulation on diatomite deposition.

2.3 Chronology

The age range in this study extends from 66 to 23 Ma, covering the Palaeocene, Eocene, and Oligocene epochs.

In most cases of freshwater diatomites, a published radiometric age measured using adjacent volcanic layers allows for precise dating of lake filling. However, most of the occurrences in this compilation were not precisely dated and required biostratigraphic studies to establish their ages. The correlation between diatomites from the Eurasian Plate and those from other sites can sometimes be a source of biostratigraphic uncertainty due to differences in taxonomic assemblages or a lack of calcareous microfossils that would enable direct correlation. The biostratigraphic ages in this study are based on the direct correlation of diatoms with dinocyst zones and other microplanktonic groups, calibrated with nanofossil zonations and palaeogeomagnetic timescales (Gradstein et al., 2004, 2012), and are compared with diatom assemblages present in the sediments (Scherer et al., 2007).

All ages in this compilation are binned into intervals with a 1 Myr resolution and are given on the Gradstein et al. (2012) timescale. Chronostratigraphic terms used throughout this paper are also consistent with those in Gradstein et al. (2012).

2.4 Statistical treatment

The tabulated number of diatomite occurrences is categorized by depositional setting in Fig. 2 and by basins/geographical clusters in Fig. 3.

In order to assess the error margin induced by stratigraphic uncertainty, we attempted to measure a confidence interval on the observed temporal patterns (see Fig. 2) using a bootstrapping approach (Efron, 1992). For shallow-marine sites, in each trial, half of the sites randomly picked have upper and lower age interval limits that are modified by a randomly selected error from a normal distribution, with a standard deviation corresponding to half the length of the biozone to which the age of the sites has been assigned (with calcareous nanofossils zones for epicontinental seas and calcareous nanofossils, radiolarian zones, or magnetochrons for open-ocean settings). For freshwater sites, the standard deviation corresponds to the error margin of the radiometric estimated age.

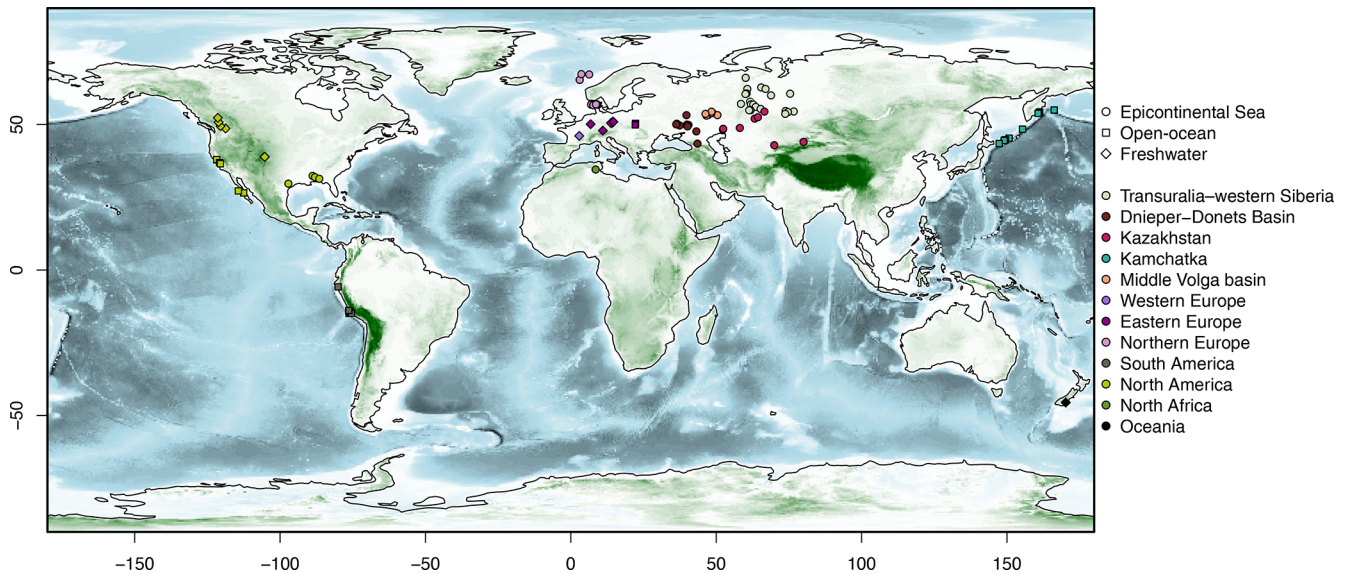

Figure 1. Map showing all the sites compiled in this study, with the colours corresponding to the 12 basins/regions and the shapes corresponding to the types of environments – epicontinental seas, open-ocean settings, and freshwater environments (see the legend). The bathymetry is from Earth TOPOgraphy (ETOPO) 2022 (NOAA NCEI, 2022).

The resulting tabulations are computed over 10 000 trials of this kind, and the mean 95th percentile is kept as the 95 % confidence interval.

The distribution of diatomites is projected with GPlates (Müller et al., 2018) onto the palaeobathymetric maps of Straume et al. (2024) using the Torsvik et al. (2019) rotation model for each 1 Myr time bin (see the Supplement). Four maps are presented here for relevant time intervals: 30 and 35 Ma, shown in Fig. 4, and 44 and 56 Ma, shown in Fig. 5. From these palaeobathymetric maps, the total area represented by the flooded continental platform is computed for each 1 Myr time interval (Fig. 2c) – simplifying the area where the palaeobathymetry is between 0 and 1000 m – in order to test whether the observed temporal pattern in shallow-marine diatomite occurrences is primarily an artefact of fluctuations in the available depositional area. Similarly, the temporal distribution of diatomites is compared with variations in sea level (Miller et al., 2020; Fig. 2d). In both cases, these correlations, or the lack thereof, are tested using a detrended linear regression analysis (Wooldridge, 1999). As the temporal resolution of the sea level curve is higher than that of the diatomite occurrences, the diatomite records are compared not only with the mean sea level corresponding to each 1 Myr time interval but also with the minimum and maximum sea levels during these intervals. In addition, the significance of the points of inflection in the diatomite occurrences discussed in this study is checked with the Chow test (Chow, 1960).

3 Results and interpretations

The compilation of Palaeogene diatomite occurrences is presented in Fig. 2e, where deposits from ESSs, OOSs, and freshwater environments are plotted as separate curves. Freshwater diatomites do not seem to show any trend throughout the Palaeogene, whereas ES diatomite occurrences peak in the late Palaeocene and display high abundance throughout the early Eocene. An abrupt drop in the number of ES occurrences is observed between ~ 46 and ~ 44 Ma, and no OOS occurrences are observed prior to ~ 43.5 Ma.

3.1 Diatom production during the PETM and EECO

Hyperthermal events trigger a negative climatic feedback. Following the significant release of carbon into the atmosphere, the intensification of the hydrological cycle, elevated temperatures, and greenhouse gas concentrations lead to an acceleration of silicate weathering on land, consuming atmospheric CO_2 and subsequently cooling the climate (Walker et al., 1981; Berner et al., 1983; Penman et al., 2019). Accelerated silicate weathering is postulated to cause a drastic increase in the input of dissolved silica (H_4SiO_4) into rivers and, hence, an increased availability of $[\text{H}_4\text{SiO}_4]$ in the oceans during hyperthermal events (e.g. PETM; Penman, 2016). Yet, the response of diatoms to Palaeogene hyperthermal events is not completely understood. Penman (2016) proposes that elevated $[\text{H}_4\text{SiO}_4]$ in the oceans during hyperthermals may have enhanced marine biosiliceous production, thus impacting organic carbon sequestration.

(2020). **(b)** $p\text{CO}_2$ estimates from Foster et al. (2017), with the mean in black and the 95 % confidence interval in grey. **(c)** The estimated area of the continental platform based on the Straume et al. (2024) palaeotopography (see Sect. 2.4). **(d)** Sea level estimates from Miller et al. (2020). **(e)** Tabulated occurrences of diatomites categorized by environment type, with the 95 % confidence interval based on bootstrapped stratigraphic ages (see Sect. 2.4 for explanations). EOT: Eocene–Oligocene transition. MECO: Middle Eocene Climatic Optimum. ELPE: Early Late Palaeocene Event. LDE: Latest Danian Event.

Figure 3. Tabulated diatomite occurrences categorized by basin/region. Only diatomites formed in epicontinental seas and open-ocean settings are shown.

Our data (Fig. 2e) show an abrupt increase in the number of ES diatomite occurrences at the end of the Palaeocene, around the Palaeocene–Eocene Thermal Maximum (PETM; ~ 56 Ma), which is recognized as the most rapid and intense hyperthermal event of the Palaeogene (Penman, 2016). The ES curve then decreases slowly towards the middle Lutetian (~ 44.5 Ma), with two peaks occurring during the Early Eocene Climatic Optimum (EECO; ~ 53 to ~ 49 Ma), the warmest period of the Cenozoic (Anagnostou et al., 2016). The Middle Eocene Climatic Optimum (MECO; ~ 40.5 to ~ 40 Ma) is also marked by a slightly higher number of ES diatomite occurrences, followed by an abrupt drop during the Eocene–Oligocene transition (EOT; ~ 33.9 Ma), which represents a shift from the greenhouse climate of the Eocene to the icehouse climate of the Oligocene (Hutchinson et al., 2001). These results suggest a causal link between hyperthermal events and the deposition of diatomite under ES conditions. The resolution of the dataset is too coarse to determine whether peaks in diatomite deposition are associated with any specific hyperthermal events, especially those occurring during the EECO, when hyperthermals were particularly numerous. Notably, however, the ES diatomite record shows stepwise increases in the number of occurrences that could be associated with the Latest Danian Event (LDE; ~ 62.2 Ma) and the Early Late Palaeocene Event (ELPE; ~ 58.6 Ma).

The area of the continental platform (Fig. 2c) – which represents the surface area of the continental shelf flooded during the Palaeogene – expands during the Palaeocene, consistent with reconstructed $p\text{CO}_2$ levels (Fig. 2b). These results, together with the reduction in sea level (Fig. 2d) during the LDE and ELPE, may explain the trends in diatomite occurrences during these hyperthermals as the result of a reduced availability of flooded continental-platform surfaces (fewer and smaller epicontinental seas) and a weaker negative feedback than during the Eocene hyperthermal events. Nevertheless, detrended regression analysis indicates that the area of the continental platform ($R^2 = 0.1612$; $p = 0.004$), sea level ($R^2 = 0.0426$ and $p = 0.098$ for mean sea level, $R^2 = 0.0004$ and $p = 0.319$ for minimum sea level, and $R^2 = 0.024$ and $p = 0.159$ for maximum sea level), and ES diatomite occurrences are not directly correlated throughout the record, particularly between ~ 46 and ~ 44 Ma, implying that the number of ES diatomite occurrences is not purely an artefact of the space available for deposition. Similar results can be observed during the Oligocene, when $\delta^{18}\text{O}$ (Fig. 2a), $p\text{CO}_2$, the area of the continental platform, and sea level all decrease after the EOT, as does the number of ES diatomite deposits.

On the contrary, during periods of high temperature (as suggested by $\delta^{18}\text{O}$) and high $p\text{CO}_2$, ES diatomite deposition

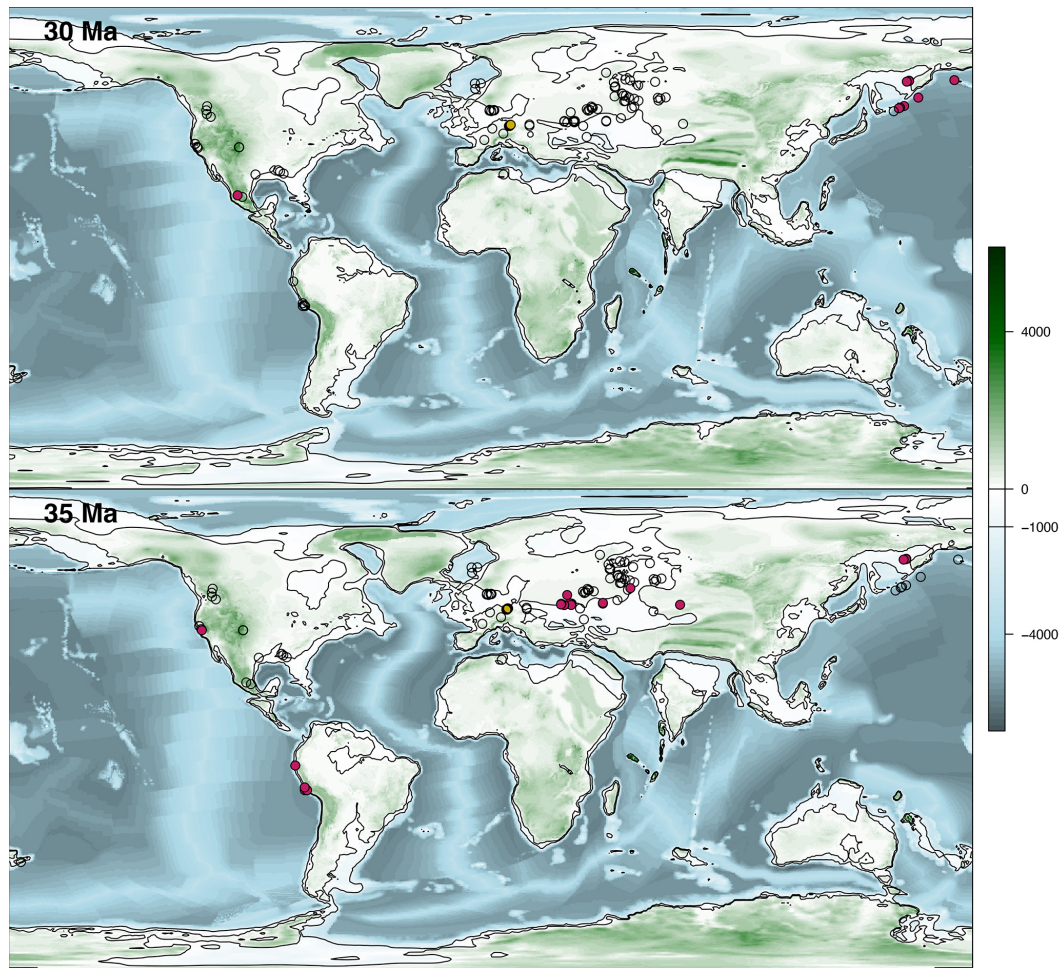

Figure 4. Palaeogeographic and palaeobathymetric maps representing all sites at 30 and 35 Ma. The unfilled circles represent sites that did not contain diatoms at these times, while the magenta circles represent shallow-marine diatoms, and the yellow circles represent freshwater diatoms. The palaeobathymetry is from Straume et al. (2024).

appears to rise, corroborating the link between warm temperatures, high greenhouse gas levels, and enhanced marine production via the increased availability of H_4SiO_4 .

No occurrences of OOS diatomite are found in the compilation before ~ 43.5 Ma, when the number of occurrences starts to increase towards the MECO (Fig. 2e). Three peaks are then present at ~ 37.5 – 35.5 , ~ 31.5 , and ~ 27.5 – 24.5 Ma. These four depositional events in the OOS diatomites seem to coincide with episodes of sea level rise (Fig. 2d). Furthermore, the presence of peaks between hyperthermal events is consistent with the upwelling-related origin of several OOS deposits. Indeed, upwelling is reduced during hyperthermal events due to changes in temperature gradients (Griffith et al., 2021).

Finally, the freshwater diatomites in Fig. 2e do not illustrate any specific response to climate proxies, unlike the ES and OOS deposits. Therefore, several questions arise: why do ES diatomites seem to respond to some hyperthermal events (the PETM and EECO), and why is there a break

in the record between ~ 46 and ~ 44 Ma? Why do the OOS diatomites in our compilation only start to accumulate from ~ 43.5 Ma? And lastly, what drives the deposition of freshwater diatomites?

3.2 Early–middle Eocene diatomites from epicontinental seas

The diatomite record in epicontinental seas implies a response of diatomite accumulation to long-term climate fluctuations. However, a drop in the number of occurrences, unrelated to any known climatic or palaeoceanographic event, is present between ~ 46 and ~ 44 Ma. Nevertheless, from the PETM onwards, the record of ES diatomite occurrences – punctuated by two peaks spanning the EECO – shows a decrease towards the middle Lutetian. As shown in Fig. 3, diatomite occurrences from Transurallia and western Siberia peak at ~ 53.5 Ma, while an increase is observed for Kazakhstan and the middle Volga basin, coinciding with the on-

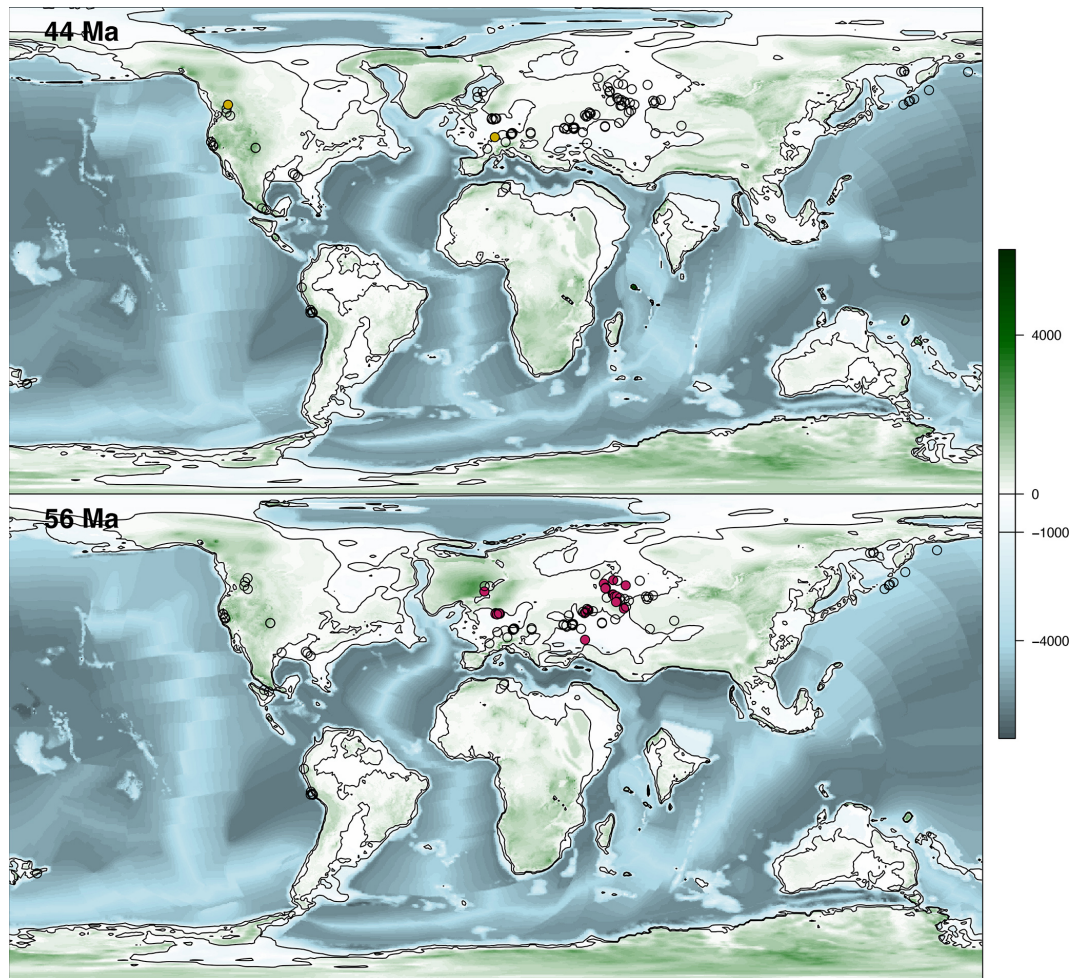

Figure 5. Palaeogeographic and palaeobathymetric maps representing all sites at 44 and 56 Ma. See Fig. 4 for the legends.

set of the EECO. Consequently, we suggest that the inflection point delimiting the start of the disappearance of diatomites is placed at the beginning of the EECO ($F = 33.6$ and $p = 5.22 \times 10^{-7}$ for the Chow test). The end of the event seems easier to place, with the abrupt resumption of diatomite accumulation occurring at ~ 43 Ma.

3.2.1 Climatic impact

A comparison between ES deposits and climate proxies from the end of the EECO (~ 49 Ma) to ~ 44 Ma suggests a correlation between the records (Fig. 2). During the EECO, the short decline between the two peaks in the ES diatomites corresponds to a rapid drop in $p\text{CO}_2$ and temperature, followed by an increase. After the second peak during the EECO, the number of ES diatomites, along with $p\text{CO}_2$ and temperature, decreases slowly in a stepwise fashion until a drop corresponding to the disappearance of the diatomites is reached. From ~ 44.5 Ma, ES diatomite occurrences and $p\text{CO}_2$ begin to increase again, while temperatures reach a peak. These

results are consistent with the scenario described by Penman (2016) and highlight the indirect correlation between climate and diatom productivity. Indeed, the ES diatomite record may illustrate long-term cooling caused by terrestrial silicate weathering from the Eocene onwards (Walker et al., 1981; Wallmann, 2001; Torfstein et al., 2010). However, this scenario is not sufficient for explaining the cessation of diatomite deposition during the middle Eocene.

3.2.2 Tectonic drivers

Global palaeogeography changed markedly throughout the Palaeogene (Figs. 4 and 5; see the Supplement). Key events include the opening of the Tasman and Drake passages in the Southern Ocean (Barron et al., 2015; Vahlenkamp et al., 2018); the collision of the Indian Plate with the Asian continent (Dupont-Nivet et al., 2010); the closure of the Arctic Basin connection with the Volga regions, Transuralia, and western Siberia (Radionova et al., 2003; Smirnov and Konstantinov, 2017); and the contraction of the Tethys Ocean

(Straume et al., 2024). An examination of the lithology of the deposits present in the compilation provides a better understanding of the events that led to the gradual disappearance of diatomites and the abrupt resumption of diatom accumulation.

A notable feature of the Earth's continents during the Late Cretaceous to early Palaeogene is the dominance of relatively flat landforms (Froelich and Misra, 2014; Tsekhovskiy, 2015). At the Cretaceous–Palaeogene boundary, peneplain weathering crusts are associated with destructive tectogenesis in Eurasia (Nikonova and Khudyakov, 1982; Nikonova, 1987; Milanovskii, 1995; Tsekhovskiy, 2015), which potentially provides a substantial amount of dissolved silica to regions undergoing continental or marine sedimentation (Akhmetiev et al., 2012; Smirnov and Konstantinov, 2017; Amon, 2018). Rising concentrations of dissolved silica in river waters lead to a corresponding stimulation of siliceous biota in river–marine mixing zones. On the Eurasian Plate (Transuralia, western Siberia, Kazakhstan, the Dnieper–Donets Basin, and the middle Volga basin), seven levels of biosiliceous sedimentation (diatomite depositional events) have been identified (Jousé, 1978; Strelnikova, 1992; Radionova et al., 1999, 2003; Aleksandrova et al., 2011; Olshtynska, 2013; Olshtynska and Tsoy, 2018; Oreshkina and Aleksandrova, 2017; Oreshkina et al., 2021). The tectonic structure, orography, and landform characteristics of the western Siberian epicontinental basin should be identified as key factors influencing diatomite deposition in this region. The expansion of marine areas in western Siberia during the Palaeocene allowed for extensive meridional communication between the central Asian regions and the Arctic–North Sea region, followed by rapid closure and the decline of the basin. At the Palaeocene–Eocene boundary, the North Atlantic Igneous Province (NAIP) produced intense volcanic activity (Storey et al., 2007), corresponding to a peak in diatomite deposition in northern Europe (Fig. 3). The large silica influx produced by the NAIP might be interpreted as a causal mechanism for diatomite deposition in northern Europe and as a possible influence on diatomite deposition in western Siberia (Smirnov et al., 2020). The depth of the basin along the Ural Mountains, combined with the minimal detrital influx during the Palaeocene and abundant nutrients in the area, led to the formation of a considerably thick photosynthetic zone and enabled diatoms to bloom. However, in the interval from ~ 46 to ~ 44 Ma, changes in sedimentation are observed in the marginal regions of Transuralia, western Siberia, and Kazakhstan. The Russkaya Polyana layers (Akhmetiev et al., 2010) represent a marker of the transition from biosiliceous to terrigenous sedimentation, which inhibits the formation of diatomite (Smirnov and Konstantinov, 2017; Amon, 2018). They also represent the termination of communication between the western Siberian Seaway and the Arctic Basin, reorganizing inter-basin circulation. Since the Eocene, the surface area of marine epicontinental basins has decreased (Fig. 2c), as has the area of distribution

(Figs. 4–5 and the Supplement) and the thickness of the diatomites in their marginal parts. For example, the similarity of diatom assemblages found in the middle Volga basin with those found in western Siberia may indicate that there was a connection between the basins during the Palaeocene. The high marine biosiliceous production gives way to a continental environment during the Eocene due to tectonic reorganization, which closed the inter-basin connections (Radionova et al., 1999). In contrast to the middle Volga basin, the drastic change in palaeogeography in the Dnieper–Donets Basin during the Lutetian (Radionova et al., 1999) allowed for a shift in diatomite accumulation from Transuralia–western Siberia to the Dnieper–Donets Basin (Fig. 3).

The palaeogeographic reorganization of the area during the Palaeogene also affected the southern Tethys margin, including the Gafsa basin. Kocsis et al. (2014b) suggest that the connection with the Tethys Ocean might have increased biosiliceous production via nutrient inputs from upwelling and that Palaeocene–Eocene lithologies in the Gafsa basin are the result of palaeogeographic reorganizations and sea level changes (Fig. 2d).

In North America, the Gulf of Mexico is bordered by the US Gulf Coastal Plain, which hosts Eocene ES diatomites (Fig. 1). During the Cenozoic, this region was affected by several events of transgressive flooding (Galloway et al., 2000), leading to the deposition of diatomites. In the Gulf of Mexico, diatomites and volcanic-ash layers originate from volcanism and uplift in central Mexico and the southwestern United States, causing the flooding of the western basin of the Gulf of Mexico between the late Eocene and early Oligocene (Davis et al., 2016). According to Weaver and Wise (1974), US Gulf Coastal Plain diatomites might be the result of an enhanced nutrient supply to the region in conjunction with favourable ocean currents. Witkowski et al. (2021) highlight the impact of the North Atlantic circulation system on the North American coast and phytoplankton production. Nevertheless, it is interesting to note that an elevated bioSiO_2 flux recorded on Blake Nose (North Atlantic) corresponds to the period between ~ 46 and ~ 42 Ma (Witkowski et al., 2021), which coincides with the period without diatomite occurrences in our compilation (Fig. 3). Comparison of the Blake Nose results with our results suggests a contrasting pattern between the pelagic realms and the nearshore realms. In our compilation, tectonic activity and ocean circulation play a major role in shallow-marine diatomite deposition, which is expected to differ in deep-sea environments. The distribution and deposition of deep-sea diatom-bearing sediments will be examined in a future article and compared with the results of this study.

3.3 Diatomite deposition in open-ocean settings

3.3.1 Lithology

According to our study (Fig. 2e), the accumulation of diatom frustules giving rise to diatomite is estimated to have begun at ~ 43.5 Ma on the west coast of North and South America, in Kamchatka, and in the Polish Outer Carpathians.

If we examine the stratigraphy of sites in western South America just before 43.5 Ma, it appears that the middle Eocene deposits were eroded in several locations. Diatomites formed on the Peruvian coast due to Eocene to Mio-Pliocene subsidence of the region, initiated by subduction and erosion of the area (Malinverno et al., 2021; Di Celma et al., 2022). Thus, a major hiatus extends from the Upper Cretaceous to the middle Eocene, caused by magmatic and metamorphic activities in the arc, as well as by erosion in the region (Dunbar et al., 1990). Malinverno et al. (2021) indicate that the diatom blooms were related to seasonally limited upwelling and suggest that their origin may be linked to the Antarctic Circumpolar Current and the initiation of a proto-Humboldt Current. Furthermore, DeVries et al. (2021) (Appendix B) report that *Rhizosolenia oligocaenica* Schrader (1976) and other Antarctic diatoms are present in the Otuma Formation (Peruvian coastline), dating to the early Oligocene, as well as in the lower Oligocene part of Bering Island (one of the Komandorski Islands, located at the westernmost end of the Aleutians) and in Kamchatka (Gladenkov, 2008, 2019). The Kuril–Kamchatka island arc, including the submarine Vityaz Ridge on the island slope, contains Oligocene diatomites deposited on a Palaeogene volcanogenic–sedimentary complex (i.e. conglomerates, sandstones, and ignimbrites). During the Oligocene, tuffaceous diatomites and effusive volcanics were formed under subaerial conditions and at shallow depths (Lelikov and Emelyanova, 2011). In Kronotsky Bay, adjacent to the Kuril–Kamchatka Trench, Gladenkov (2008) identified Oligocene tuffaceous diatomites correlating with the *Rocella gelida* Zone. Tsoy (2002) indicates that assemblages from the *Rocella gelida* Zone on the island slope of the Kuril–Kamchatka Trench may have formed in deeper water compared to assemblages from the *Rhizosolenia oligocaenica* Zone, due to the deepening of the basin during the Oligocene. In addition, Eocene diatom assemblages similar to those found on the west coast of North America were discovered along volcanic and sedimentary deposits in the Ol'ga and Zhupanovsky canyons of Kronotsky Bay (Tsoy, 2003).

Regarding the west coast of North America, Milam and Ingle (1982) suggest that Palaeogene diatomites in California are indicative of upper and middle bathyal environments with minimal oxygen layers, probably coincident with a period of sea level rise or a tectonic event. According to Barron et al. (1984), the presence of *Fenneria brachiata* (Brightwell) Witkowski (2018) in the Kellogg Shale could represent the conditions of cold-water deposition, similar to those of the California Current system. Further south, diatomites from

Baja California Sur reflect intense upwelling that occurred during the Eocene and possibly tectonic movement (McLean and Barron, 1988).

Finally, in the Polish Outer Carpathians, diatomites accumulated during the Oligocene in depressions located on the basin slope (Kotlarczyk and Kaczmarzka, 1987). According to Van Couvering et al. (1981), the Palaeocene–Eocene deposits in the Carpathians are typical of those in the deep sea, with distal turbidites containing ichnofossils underlying the diatomaceous sediments. Oligocene diatom assemblages suggest basin subsidence, but no palaeoclimatic interpretation is provided (Kotlarczyk and Kaczmarzka, 1987).

The OOS records suggest that the absence of diatomite occurrences prior to ~ 43.5 Ma is related to tectonic factors. It is impossible to state with certainty that no OOS diatomite accumulated before ~ 43.5 Ma, due to lack of published information. However, the OOS sites considered in this study seem to have reached optimal conditions for diatom deposition via tectonic movements, and the presence of Antarctic diatom assemblages in temperate regions of South America may indicate that ocean circulation played a major role in the accumulation of OOS diatomites during the Palaeogene.

3.3.2 Impact of the ocean circulation

The classic view (Haq, 1981; Keller, 1983; Barron, 1987; Miller, 1992; Huber and Sloan, 2001) of the pre-Oligocene ocean is that it was strongly stratified and sluggish relative to the modern ocean. Such a configuration would limit the recycling and rejuvenation of nutrients critical to phytoplankton blooms. Under such conditions, terrestrially sourced nutrients would be more readily available than upwelled ones, as evidenced by the preference for nearshore environments in the early Eocene (Fig. 2e). As global cooling set in following the EECO, this stratification began to disintegrate, with increased deep water formation at high latitudes (Lunt et al., 2017; Zhang et al., 2020). The combined effect of destratification and increased latitudinal gradients allowed for the establishment of more upwelling zones.

With intensified winds, a shift occurred from the early to the late Eocene: upwelling cells moved mainly from low latitudes (Slansky, 1980; Barousseau and Giresse, 1987; Lu et al., 1995; Charisi and Schmitz, 2010; Johnson et al., 2000; Soudry et al., 2006; Prian, 2014; Kocsis et al., 2014a; Meilijson et al., 2023) to middle latitudes (Slansky, 1980; Barousseau and Giresse, 1987; Johnson et al., 2000; Prian, 2014; Kocsis et al., 2014a; Wade et al., 2020) and high latitudes (Marty et al., 1988; Diester-Haass and Zahn, 2001; Diekmann et al., 2004). This increase in upwelling activity would have allowed for more nutrient rejuvenation further from the shore and an increase in OOS diatomite accumulation towards the end of the Eocene (Fig. 2e).

3.4 Freshwater diatomite

A total of 21 palaeolakes from New Zealand, North America, and Europe contain Palaeogene diatomites (Figs. 4 and 5). According to the geology of the sites, all these lakes are associated with tectonic and/or volcanic formations (i.e. lakes in active grabens and maar lakes).

The freshwater diatomites of the České středohoří in northern Bohemia date from the late Eocene to the late Pliocene. Lacustrine sedimentation began with the rifting of the Palaeogene peneplain, initiated by volcanic activity in the region (Prokop, 2003). During the early to middle Eocene, the southern Canadian Cordillera (North America) was affected by the creation of grabens and half-grabens, as well as by the activity of a volcanic arc that produced volcanic fill in the basins. Diatom blooms developed between eruptive episodes, leading to the formation of the diatomite occurrences recorded in this study (Mustoe, 2005, 2011, 2015), such as those observed in Florissant (Colorado), where diatomites formed in a lake interpreted as resulting from the damming of fluvial drainage by a volcanic formation (Benson, 2011). Four maar lakes are also present in the compilation: the Eckfeld Maar and Rott in Germany, Menat in France, and Foulden Maar in New Zealand.

Although Benson et al. (2012) argue that diatom diversity in these lakes was impacted by changes in global climate (i.e. hyperthermals), this does not seem to have affected the number of diatomite occurrences gathered in this study (Fig. 2e). Seasonality, however, played an important role for these diatomites, as did volcano-tectonic activity. In fact, Mustoe (2005) points out that freshwater diatom deposits are often linked to volcanism, due to the large silica input provided by the weathering of volcanic glass. The Giraffe Pipe maar lake from the early Eocene is a good example, with its uniquely preserved diatom-bearing sediments illustrating biodiversity shifts in response to changes in the environment and climate (Siver and Lott, 2023).

4 Conclusions

The number of shallow-marine diatomite occurrences appears to be indirectly correlated with Palaeogene climate change, but the resolution of the data does not allow for the establishment of a precise link between diatomite deposition and individual hyperthermal events. Palaeogeographic reorganization and ocean circulation are identified as the main drivers of changes in diatomite deposition during the Palaeogene and explain the absence of diatomite occurrences in our compilation between ~ 46 and ~ 44 Ma. In addition, comparison of this study with published results from Blake Nose (North Atlantic) suggests differences in the deposition of diatom-bearing sediments between shallow- and deep-marine environments, which will be discussed in a future article.

Although freshwater diatomites do not respond to climatic and palaeogeographic fluctuations on the same spatio-temporal scale as that on which shallow-marine diatomites respond, our study highlights that seasonality and volcano-tectonic activity have a major impact on lacustrine diatoms.

Data availability. The diatomite compilation can be found on Zenodo (Figus et al., 2024) and in the Supplement. Palaeogeographic maps showing all diatomites in each 1 Myr time bin can also be found in the Supplement.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/cp-20-2629-2024-supplement>.

Author contributions. JW designed the study. CF, AYG, TVO, and JW prepared the compilation. CF, AYG, and TVO carried out the biostratigraphic dating. CF and JR processed the data. All co-authors participated in the interpretation of the data. CF prepared the paper, with contributions from all co-authors.

Competing interests. The contact author has declared that none of the authors has any competing interests.
