Abstract. The West Antarctic Ice Sheet Divide (WAIS Divide, WD) ice core is a newly drilled, high-accumulation deep ice core that provides Antarctic climate records of  $_{25}$ the past  $\sim 68$  ka at unprecedented temporal resolution. The

- <sup>5</sup> upper 2850 m (back to 31.2 ka BP) have been dated using annual-layer counting. Here we present a chronology for the deep part of the core (67.8–31.2 ka BP), which is based on stratigraphic matching to annual-layer-counted Greenland ice cores using globally well-mixed atmospheric methane.
- We calculate the WD gas age-ice age difference ( $\Delta$ age) using a combination of firn densification modeling, ice flow modeling, and a dataset of  $\delta^{15}$ N-N<sub>2</sub>, a proxy for past firn column <sup>30</sup> thickness. The largest  $\Delta$ age at WD occurs during the last glacial maximum, and is  $525 \pm 120$  years. Internally consis-
- tent solutions can be found only when assuming little-to-no influence of impurity content on densification rates, contrary to a recently proposed hypothesis. We synchronize the WD chronology to a linearly scaled version of the layer-counted Greenland Ice Core Chronology (GICC05), which brings the
- <sup>20</sup> age of Dansgaard-Oeschger (DO) events into agreement with the U/Th absolutely dated Hulu Cave speleothem record. The small  $\Delta$ age at WD provides valuable opportunities to inves-<sup>40</sup>

tigate the timing of atmospheric greenhouse gas variations relative to Antarctic climate, as well as the interhemispheric phasing of the "bipolar seesaw".

#### 1 Introduction

Deep ice cores from the polar regions provide highresolution climate records of past atmospheric composition, aerosol loading and polar temperatures (e.g. NGRIP community members, 2004; EPICA Community Members, 2006; Wolff et al., 2006; Ahn and Brook, 2008). Furthermore, the coring itself gives access to the ice sheet interior and bed, allowing investigation of glaciologically important processes such as ice deformation (Gundestrup et al., 1993), folding (NEEM community members, 2013), crystal fabric evolution (Gow et al., 1997) and geothermal heat flow (Dahl-Jensen et al., 1998). Having a reliable ice core chronology (i.e., an age-depth relationship) is paramount for the interpretation of the climate records and comparison to marine and terrestrial paleoclimate archives. The West Antarctic Ice Sheet Divide (WAIS Divide, WD) ice core (79.48° S, 112.11° W, 1766 m above sea level, -30 °C present day mean annual temperature) was drilled

- <sup>45</sup> and recovered to 3404 m depth (WAIS Divide Project Mem-<sup>100</sup> bers, 2013). Drilling was stopped 50 m above the estimated bedrock depth to prevent contamination of the basal hydrology. Due to high accumulation rates of 22 cm ice a<sup>-1</sup> at present and ~ 10 cm ice a<sup>-1</sup> during the last glacial maximum
- (LGM), the WD core delivers climate records of unprece-105 dented temporal resolution (Steig et al., 2013; Sigl et al., 2013) as well as gas records that are only minimally affected by diffusive smoothing in the firn column (Mischler et al., 2009; Mitchell et al., 2011, 2013; Marcott et al., 2014). The
- combination of high accumulation rates and basal melting at <sup>110</sup> the WD site results in ice near the bed that is relatively young ( $\sim 68$  ka) compared to cores drilled in central East Antarctica.

In WD, annual layers can be identified reliably for the upper 2850 m of the core, reaching back to 31.2 ka BP (thou-115 sands of years before present, with present defined as 1950 C.E.). Below 2850 m depth an alternative dating strategy is needed. Several methods have been employed previously at

- other deep ice core sites. First, orbital tuning via  $\delta O_2/N_2$  has been applied successfully to several Antarctic cores (Bender, 2002; Kawamura et al., 2007). However, an age span of only ~ 3 precessional cycles in WD, in combination with the low 120 signal-to-noise ratio of  $\delta O_2/N_2$  data, makes this technique unsuitable for WD. The uncertainty in the orbital tuning is
- <sup>70</sup> about one fourth of a precessional cycle ( $\sim 5$  ka), making it a relatively low-resolution dating tool. Second, in Greenland, ice flow modeling has been used to extend layer-counted chronologies (e.g., Johnsen et al., 2001; Wolff et al., 2010). This method requires assumptions about past accumulation <sup>125</sup>
- <sup>75</sup> rates, ice flow and ice sheet elevation. Particularly for the oldest WD ice, the resulting uncertainty would be substantial. Third, several radiometric techniques have been proposed to date ancient ice. Radiocarbon (<sup>14</sup>C) dating of atmospheric CO<sub>2</sub> trapped in the ice is unsuitable as it suffers from *in situ* <sup>130</sup>
- <sup>80</sup> cosmogenic production in the firn (Lal et al., 1990), and the oldest WD ice dates beyond the reach of <sup>14</sup>C dating. Other absolute (radiometric) dating techniques, such as recoil <sup>234</sup>U dating (Aciego et al., 2011), <sup>81</sup>Kr dating (Buizert et al., 2014) or atmospheric <sup>40</sup>Ar build-up (Bender et al., 2008) currently <sup>135</sup>
- suffer from uncertainties that are too large ( $\geq 20$  ka) to make them applicable at WD.

Instead, at WD we use stratigraphic matching to welldated Greenland ice cores using globally well-mixed atmospheric methane (CH<sub>4</sub>) mixing ratios (Blunier et al., 1998,  $^{140}$ 

- <sup>90</sup> 2007; Blunier and Brook, 2001; Capron et al., 2010; Petrenko et al., 2006). This method is particularly suited to WD because of the small gas age-ice age difference ( $\Delta$ age, Sect. 3) and the high-resolution, high-precision CH<sub>4</sub> record available (Sect. 2.1). The method has three main sources of uncer-145
- tainty: (i) the age uncertainty in the records one synchronizes to, (ii)  $\Delta$ age of the ice core being dated, and (iii) the

interpolation scheme used in between the CH<sub>4</sub> tie-points. We present several improvements over previous work that reduce and quantify these uncertainties: (i) we combine the layercounted Greenland Ice Core Chronology (GICC05) and a recently refined version of the U/Th-dated Hulu speleothem record (Edwards et al., in preparation; Reimer et al., 2013; Southon et al., 2012) to obtain a more accurate estimate of the (absolute) ages of abrupt Dansgaard-Oeschger (DO) events (Sect. 4.4); (ii) we combine firn densification modeling, ice flow modeling, a new WD  $\delta^{15}$ N-N<sub>2</sub> dataset that spans the entire core, and a Monte Carlo sensitivity study to obtain a reliable  $\Delta$ age estimate (Sect. 3); and (iii) we compare four different interpolation schemes to obtain an objective estimate of the interpolation uncertainty (Sect. 4.5).

This work is the second part in a series of two papers describing the WD2014 chronology for the WD core in detail. The first part describes the development of the annual layer count from both multi-parameter chemistry and electrical conductivity measurements (Sigl et al., 2014b). The WD2014 chronology is currently the recommended gas and ice timescale for the WD deep core, and as such it supersedes the previously published WDC06A-7 chronology (WAIS Divide Project Members, 2013).

#### 2 Methods

#### 2.1 Data description

Measurements of water stable isotopes. Water isotopic composition ( $\delta^{18}$ O and  $\delta D = \delta^2 H$ ) was measured at IsoLab, University of Washington. Procedures for the deep section of the core are identical to those used for the upper part of the core reported in WAIS Divide Project Members (2013); Steig et al. (2013). Measurements were made at 0.25 to 0.5 m depth resolution using laser spectroscopy (Picarro L2120-*i* water isotope analyzer), and normalized to VSMOW-SLAP (Vienna Standard Mean Ocean Water – Standard Light Antarctic Precipitation). The precision of the measurements is better than 0.1 and 0.8 % for  $\delta^{18}$ O and  $\delta D$ , respectively.

**Measurements of CH**<sub>4</sub>. Two CH<sub>4</sub> datasets were used for WD. The first is from discrete ice samples, and was measured jointly at Pennsylvania State University (0–68 ka, 0.5–2 m resolution) and at Oregon State University (11.4–24.8 ka, 1– 2 m resolution). Air was extracted from ~ 50 gram ice samples using a melt-refreeze technique, and analyzed on a standard gas chromatograph equipped with a flame-ionization detector. Corrections for solubility, blank size and gravitational enrichment are applied (Mitchell et al., 2011; WAIS Divide Project Members, 2013). The second dataset is a continuous CH<sub>4</sub> record measured by coupling a laser spectrometer to a continuous flow analysis setup (Stowasser et al., 2012; Rhodes et al., 2013), and was measured jointly by Oregon State University and the Desert Research Institute (Rhodes et al., in review). The continuous dataset is used to

245

identify the abrupt DO transitions, as it provides better temporal resolution and analytical precision. Both records are

reported on the NOAA04 scale (Dlugokencky et al., 2005). Analytical precision in the CH<sub>4</sub> data ( $2\sigma$  pooled standard deviation) is around 3.2 ppb and 14 ppb for the discrete data <sup>205</sup> from OSU and PSU, respectively, and 3 to 8 ppb for the continuous CH<sub>4</sub> data, depending on the analyzer used (Rhodes et al., in review); the 14 ppb stated for the PSU discrete data

et al., in review); the 14 ppb stated for the PSU discrete data may be an overestimation, as depth-adjacent (rather than laterally adjacent) samples were used in the analysis.

**Measurements of**  $\delta^{15}$ N. Atmospheric N<sub>2</sub> isotopic composition ( $\delta^{15}$ N) was measured at Scripps Institution of

- <sup>160</sup> Oceanography, University of California. Air was extracted from ~ 12 gram ice samples using a melt-refreeze technique, and collected in stainless steel tubes at liquid-He tempera-<sup>215</sup> ture.  $\delta^{15}$ N was analyzed using conventional dual-inlet Isotope Ratio Mass Spectrometry (IRMS) on a Thermo Finni-
- <sup>165</sup> gan Delta V mass spectrometer. Results are normalized to La Jolla (California, USA) air, and routine analytical corrections are applied (Sowers et al., 1989; Petrenko et al., 2006; <sup>220</sup> Severinghaus et al., 2009). Duplicates were not run for most  $\delta^{15}$ N data in this study, but the pooled standard deviations of
- <sup>170</sup> Holocene WAIS Divide  $\delta^{15}$ N data sets with duplicate analyses are 0.003 % (Orsi, 2013). We conservatively adopt an analytical uncertainty of 0.005 % for this data set to allow <sup>225</sup> for other sources of error.

Measurements of [Ca]. Ca concentrations in the ice were measured at the Ultra Trace Chemistry Laboratory at the Desert Research Institute via continuous flow analysis. Longitudinal samples of ice (approximately 100 cm × 3.3 cm × 230 3.3 cm) were melted continuously on a melter head that divides the melt water into three parallel streams. Elemental

- 180 measurements were made on melt water from the innermost part of the core with ultra-pure nitric acid added to the melt stream immediately after the melter head; potentially contaminated water from the outer part of the ice is discarded. Elemental analysis of the innermost melt water stream is per- 235
- formed in parallel on two inductively coupled plasma mass spectrometers (ICPMS), each measuring a different set of elements; some elements were analyzed on both. The dual ICPMS setup allows for measurement of a broad range of 30 elements and data quality control (McConnell et al., 2002, 240
- <sup>190</sup> 2007). Precision of the Ca measurements in WD glacial ice is estimated to be  $\pm 3\%$ . Continuous Ca and CH<sub>4</sub> measurements are done on the same ice, and are exactly co-registered in depth.

### 2.2 Firn densification model description

- Air exchange with the overlying atmosphere keeps the interstitial air in the porous firn layer younger than the surrounding ice matrix, resulting in an age difference between polar 250 ice and the gas bubbles it contains, commonly referred to as Δage (Schwander and Stauffer, 1984). Here we use a counled for densification and the first diffusion model to coloud.
- 200 pled firn densification heat diffusion model to calculate

 $\Delta$ age back in time (Barnola et al., 1991; Goujon et al., 2003; Schwander et al., 1997; Rasmussen et al., 2013), constrained by measurements of  $\delta^{15}$ N of N<sub>2</sub>, a proxy for past firn column thickness (Sowers et al., 1992). The model is based on a dynamical description of the Herron-Langway model formulated in terms of overburden load (Herron and Langway, 1980), which is solved in a Lagrangian reference frame. This model has been applied previously to the Greenland NEEM, NGRIP and GISP2 cores (Rasmussen et al., 2013; Seierstad et al., 2014; Buizert et al., 2014), where it gives a good agreement to the Goujon densification model (Rasmussen et al., 2013; Goujon et al., 2003). The model allows for the inclusion of softening of firn in response to impurity loading (Horhold et al., 2012), following the mathematical description of Freitag et al. (2013a). The equations governing the model densification rates are given in Appendix A.

The model uses a 2 year time step and 0.5 m depth resolution down to 1000 m, the lower model boundary. A thick model domain is needed because of the long thermal memory of the ice sheet. At WD, downward advection of cold surface ice is strong due to the relatively high accumulation rates, and the geothermal gradient does not penetrate the firm column (Cuffey and Paterson, 2010). We further use a lock-in density that equals the mean close-off density (Martinerie et al., 1994) minus  $17.5 \text{ kg m}^{-3}$  (as in Blunier and Schwander, 2000), and an empirical parameterization of lock-in gas age based on firm air measurements from 10 sites (Buizert et al., 2012, 2013).

We furthermore use the steady state version of the Herron-Langway model (Herron and Langway, 1980) in performing sensitivity studies (Sect. 3.2), and the dynamical Arnaud model (Arnaud et al., 2000; Goujon et al., 2003) to validate our  $\Delta$ age solution.

#### 2.3 Temperature reconstruction and ice flow model

Our temperature reconstruction (Fig. 1a) is based on water  $\delta D$ , a proxy for local vapor condensation temperature, calibrated using a measured borehole temperature profile (following Cuffey et al., 1995; Cuffey and Clow, 1997) and, for the last 31.2 ka, adjusted iteratively to satisfy constraints on firn thickness provided by  $\delta^{15}$ N and by the observed layer thickness  $\lambda(z)$ . Using  $\delta^{18}$ O rather than  $\delta$ D in the temperature reconstruction leads to differences that are negligibly small. This borehole temperature calibration approach is possible at WD because the large ice thickness and relatively high accumulation rates help to preserve a memory of past temperatures in the ice sheet. A coupled 1-D ice flow-heat diffusion model converts surface T(t) into a depth profile for comparison to measured borehole temperatures. The 1-D ice flow model calculates the vertical ice motion, taking into account the surface snow accumulation, the variation of density with depth, and a prescribed history of ice thickness. Vertical motion is calculated by integrating a depth-profile of strain rate and adding a rate of basal melt. As in the model of Dansgaard

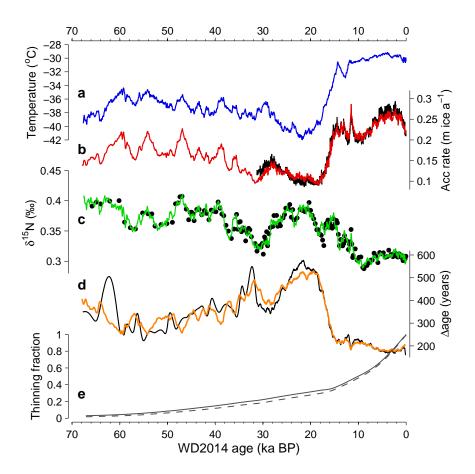

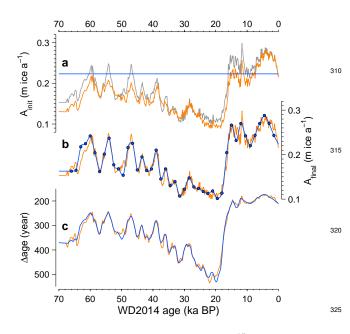

Fig. 1. Modeling  $\Delta$ age for WAIS Divide. (a) Past temperatures reconstructed from water  $\delta D$ , calibrated to the borehole temperature profile. (b) Past accumulation rates as reconstructed by the firn densification inverse model (red), and from the annual layer count (black). (c)  $\delta^{15}N$  data (black dots) with densification model output (green). (d)  $\Delta$ age calculated using the densification model (orange) and using the Parrenin  $\Delta$ depth method (black) with constant 4 m thick convective zone and no correction for thermal  $\delta^{15}N$  fractionation. (e) Modeled thinning function from ice flow model (solid), and a simple Nye strain model for comparison (dashed); the Nye thinning function, which has a uniform strain rate as a function of depth, is given as  $f_{\lambda}(z) = (H - z)/H$  with H the ice sheet thickness (Cuffey and Paterson, 2010, p.616).

and Johnsen (1969), the strain rate maintains a uniform value between the surface and a depth equal to 80% of the ice thickness, and then varies linearly to some value at the base of the 275 ice. This basal value is defined by the "basal stretching parameter"  $f_b$ , the ratio of strain rate at the base to strain rate in the upper 80% of the ice column. The basal ice is melting, so

- part of the ice motion likely occurs as sliding. The along-flow gradient in such sliding is unknown and thus so too is the pa- $_{280}$ rameter  $f_b$ . We overcome this problem by making both the current ice thickness and the basal melt rate free parameters when optimizing models with respect to measured borehole
- temperatures. Because the basal melt rate and the  $f_b$  parameter affect the vertical velocities in similar fashion, the opti-<sup>285</sup> mization constrains a combination of melt rate and  $f_b$  that is tightly constrained by the measured temperatures. Thus we find that varying  $f_b$  through a large range, from 0.1 to 1.5, changes the reconstructed temperature at LGM by less than
- 0.2°C. (Temperatures prior to the LGM are determined rel-290 ative to those at LGM by isotopic variations, so this number

applies further back in time as well.) Effects of the prescribed ice-thickness history are likewise minor; assuming a 150 m thickness increase from LGM to 15 ka changes the reconstructed temperature at LGM by less than 0.2°C compared to a constant thickness. Note that the 1-D flow model used here is simpler than the one used by Cuffey and Clow (1997) in that it does not attempt to calculate changes in the shape of the strain rate profile; the unknown basal sliding motion at the WD site negates the usefulness of such an exercise.

One output of the 1-D flow model is the strain history of ice layers as a function of depth and time. The cumulative strain is represented by the thinning function  $f_{\lambda}(z)$  (Cuffey and Paterson, 2010), the ratio of annual layer thickness at depth in the ice sheet to its original ice-equivalent thickness at the surface when deposited. The modeled thinning function is shown in Fig. 1e (solid line). In the deep part of the ice sheet  $f_{\lambda}(z)$  becomes increasingly uncertain as the unknown basal melt rate and  $f_b$  become the dominant controls. Here we optimize the model by comparing accumu-

**Fig. 2.** Reconstructing A(t) and  $\Delta$ age from  $\delta^{15}$ N: the choice of accumulation template. (a)  $A_{init}(t)$  based on  $\lambda(z)$  from the annual layer count (0-31.2 kaBP) and Clausius-Clapeyron scaling of water stable isotope data (34.2–68 ka) in orange;  $A_{\text{init}} = 0.22 \text{ m a}^{-1}$  in <sub>330</sub> blue; and for comparison the final A(t) solution (Fig. 1b) in grey. For the orange curve we have used the Nye thinning function (1e;, the final ice flow model optimizes the agreement between A(t) obtained from  $\lambda(z)$  and from the inverse firn modeling approach. The WD2014 chronology uses the orange  $A_{init}(t)$  scenario. (b) A(t)found in the inverse firn modeling approach using both  $A_{\text{init}}(t)$  sce-  $^{335}$ narios; color coding as in panel (a). The function  $\xi(t)$  is found as follows. We use control points at 1500 year intervals (blue dots); the algorithm has the freedom to change the value of  $\xi(t)$  at each of these points. In between the control points  $\xi(t)$  is found via linear interpolation. (c) Modeled  $\Delta$ age using both  $A_{init}(t)$  scenarios; color <sub>340</sub> coding as in panel (a).

lation rates derived from  $f_{\lambda}(z)$  with those implied by a firn densification model and the measured  $\delta^{15}$ N of N<sub>2</sub> (Sect. 3.1). While this has little effect on the temperature history reconstruction, it provides an important constraint on calculated basal melt rate, an interesting quantity for ice dynamics studies. Our analysis of basal melt rates and further details of the temperature optimization process and 1-D flow modeling will be provided elsewhere (Cuffey et al., in preparation).

#### 300 **3** The gas age-ice age difference ( $\Delta$ age)

### 3.1 The WD2014 $\Delta$ age reconstruction

The firn densification forward model uses past surface temperature T(t) and accumulation A(t) as model forcings, and provides  $\Delta age(t)$  and  $\delta^{15}N(t)$  as model output.

355

For the past 31.2 ka WD has an annual layer counted 360 chronology; for this period the annual layer thickness  $\lambda(z)$ 

provides a constraint on past accumulation rates via  $\lambda(z) = A(z) \times f_{\lambda}(z)$ . WD accumulation reconstructed from  $\lambda(z)$  is plotted in black in Fig. 1b.

Prior to 31.2 ka we have no such constraint on A(t), and an alternative approach is needed. We use the densification model as an inverse model, where we ask the model to find the A(t) history that minimizes the root mean square deviation between measured and modeled  $\delta^{15}N$ , given the T(t)forcing. The  $\delta^{15}$ N data and model fit are shown in Fig. 1c, the A(t) history that optimizes the  $\delta^{15}$ N fit is shown in Fig. 1b (red), and the modeled  $\Delta$ age is shown in Fig. 1c (orange). The optimal A(t) history is estimated in two steps. First we make an initial estimate  $A_{init}(t)$  for the past accumulation history. Second, we adjust the A(t) forcing by applying a smooth perturbation  $\xi(t)$  such that  $A(t) = [1 + \xi(t)] \times$  $A_{\text{init}}(t)$ ; an automated algorithm is used to find the curve  $\xi(t)$  that optimizes the model fit to the  $\delta^{15}N$  data. For the last 31.2 ka we obtain a good agreement between A obtained from  $\lambda(z)$  and the modeled  $f_{\lambda}(z)$  (Fig. 1b, black) and A obtained from the inverse method (red). The solution we present here is therefore fully internally consistent, i.e., the A and T histories used in the firn densification modeling are the same as those used in the ice-flow modeling, and they provide a good fit to both the  $\delta^{15}$ N data and borehole temperature data. WD does not suffer from the  $\delta^{15}$ N model-data mismatch that is commonly observed for East Antarctic cores during the glacial period (Landais et al., 2006; Capron et al., 2013).

We base our  $A_{\text{init}}$  values on  $\lambda(z)$  for the past 31.2 ka; prior to that we use the common assumption that A follows  $\delta^{18}$ O (i.e., Clausius-Clapeyron scaling); the fit to the  $\delta^{15}$ N data is optimized for  $A = 24.2 \times \exp[0.1263 \times \delta^{18} \text{O}]$ . To test the validity of the Clausius-Clapeyron assumption, we additionally run the scenario  $A_{\text{init}}(t) = 0.22 \,\mathrm{m \, a^{-1}}$  (i.e., constant accumulation at present day level). The A(t) and  $\Delta$ age reconstructed under both Ainit scenarios are similar at multimillennial timescales (Fig. 2). In the layer counted interval (< 31.2 kaBP), A obtained from  $\lambda(z)$  and  $\delta^{18}$ O are significantly coherent at all timescales longer than 3000 years, but not at higher frequencies. This is equivalent to the variability resolved in the  $A_{\text{init}}(t) = 0.22 \,\mathrm{m \, a^{-1}}$  scenario above. We conclude that the WD  $\delta^{15}$ N data support the idea that A follows  $\delta^{18}$ O on multi-millennial timescales. However, there may not be a strong relationship at timescales less than a few thousand years, as is clear from the abrupt A increase around 12 ka seen in  $\lambda(z)$  that is not reflected in  $\delta^{18}$ O (Fig. 1a and b). For consistency between the upper and deeper part of the core we use the  $\Delta$ age values obtained with the inverse densification model for the entire core.

Recently another  $\delta^{15}$ N-based approach has been suggested that uses  $\Delta$ depth, rather than  $\Delta$ age, in reconstructing gas chronologies (Parrenin et al., 2012). This method removes the dependence on T(t), and replaces this by a dependence on the thinning function  $f_{\lambda}(z)$ . Note that this method is very successful in the upper part of an ice core where  $f_{\lambda}(z)$  is well constrained, but not very reliable near the base where 415  $f_{\lambda}(z)$  is highly uncertain. Therefore, the firn densification modeling approach should be considered to be more reli-

able at WD during Marine Isotope Stage (MIS) 2 through 4. Results from the  $\Delta$ depth method are plotted in black in Fig. 1c, and generally show good agreement with the firn 420 modeling approach. A notable exception is the 60-65 ka interval, where the  $\Delta$ depth method overestimates the  $\Delta$ age due to the fact that we have to compress  $\lambda(z)$  strongly in order to 370

fit age constraints derived from DO 18 (Sect. 4.5).

Last, we want to point out that the  $\delta^{15}N$  data support 425 an early warming at WD, as reported recently (WAIS Divide Project Members, 2013). WD  $\delta^{15}$ N starts to decrease

- around 20.5 kaBP, suggesting a thinning of the firn column. 375 The  $\lambda(z)$  (as derived from the layer count) shows that accumulation did not change until 18 kaBP, at which point 430 it started to increase (which would act to increase the firn thickness). The most plausible explanation for the  $\delta^{15}$ N de-
- crease around 20.5 ka BP is therefore an early onset of West-380 Antarctic deglacial warming, in agreement with increasing  $\delta^{18}$ O around that time. The warming enhances the densifica-435 tion rate of polar firn, thereby decreasing its thickness (e.g., Herron and Langway, 1980).

#### $\Delta$ age sensitivity study 3.2 385

Besides A and T there are several model parameters that have the potential to influence the model outcome; these are the convective zone (CZ) thickness (Sowers et al., 1992; Kawamura et al., 2006), surface density ( $\rho_0$ ), and sensitivity to ice

440

- impurity content. In this section we evaluate the sensitivity 445 of the model output to all of these parameters. We performed 1000 model runs in which the model parameters were randomly perturbed. The spread in  $\Delta$ age model results is used to calculate the WD2014 age uncertainty.
- Convective Zone thickness. In the WD2014 model run 450 395 (Sect. 3.1) we use a constant 3.5 m CZ, corresponding to the present day situation (Battle et al., 2011). In the sensitivity study we vary the CZ by one of two methods: (1) We let the CZ be constant in time; its thickness is set by drawing
- from a Gaussian distribution with 3.5 m mean, and 3.5 m  $2\sigma$  455 400 width (i.e., 95 % probability of drawing a value in the 0–7 m range). (2) We let the CZ be a function of accumulation rate (Dreyfus et al., 2010),  $CZ = 3.5 + k \times (A - 0.22)$ ; we draw k from a Gaussian distribution with mean of -10 and a  $2\sigma$
- width of 40 (at an LGM A of  $10 \,\mathrm{cm}\,\mathrm{a}^{-1}$  this gives a CZ of 460 405  $0-10 \,\mathrm{m}$  thickness). In both methods, whenever CZ values are selected that are smaller than 0 m, the CZ thickness is set to 0 m instead. For each of the 1000 model runs in the sensitivity study we randomly selected either of the two methods.
- Surface density. In the WD2014 model run we use past 465 410 surface densities  $(\rho_0)$  as given by the parameterization of Kaspers et al. (2004). In the sensitivity study we add a constant offset to the Kaspers values, the magnitude of which is drawn from a Gaussian distribution of zero mean and a  $2\sigma$

width of  $60 \,\mathrm{kg}\,\mathrm{m}^{-3}$ . This range corresponds to the full range of observed  $\rho_0$  variability in Kaspers et al. (2004).

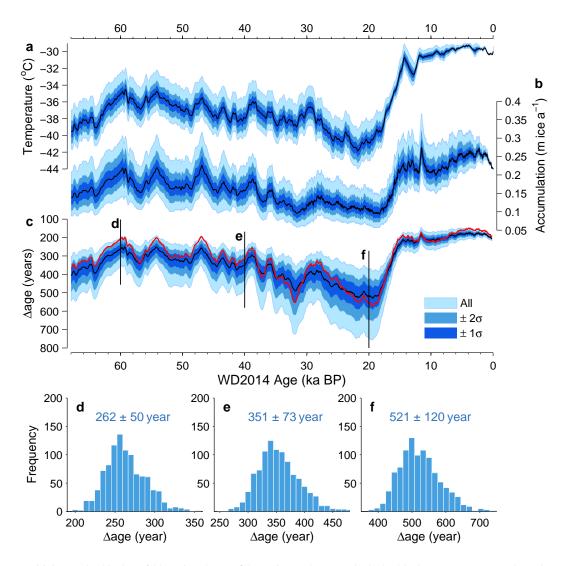

Past temperatures. Model temperature forcing is constrained by  $\delta D$  and measured borehole temperatures. There is, however, a range of solutions allowed by the borehole temperature and ice-flow model; here we use the upper and lower extremes of this range, determined by Monte Carlo analysis using uncertainties of input variables. The scenarios were chosen to provide the maximum T range for the glacial period rather than for the Holocene, because we are interested in the uncertainty in the methane synchronization (68–31.2 kaBP). In the sensitivity study we use T(t) = $T_{\text{optimal}}(t) + \kappa \times \Delta T(t)$ , where  $T_{\text{optimal}}$  is the forcing used in the WD2014 model run (Fig. 1a),  $\Delta T(t)$  is half the difference between the maximum-T and minimum-T scenarios, and  $\kappa$  is drawn from a Gaussian distribution of zero mean and unit  $2\sigma$  width (giving 95 % probability that T(t) is within the extreme range identified from the borehole, Fig. 3a).

 $\delta^{15}$ N uncertainty. We conservatively adopt an analytical uncertainty of 0.005 % for this data set; in addition, the interpretation of  $\delta^{15}$ N in terms of firn thickness is subject to further uncertainty due to irregular firn layering and the stochastic nature of bubble trapping, as was observed for other atmospheric gases such as CH<sub>4</sub> (Etheridge et al., 1992; Rhodes et al., 2013). For each run of the sensitivity study, we therefore perturb each of the individual  $\delta^{15}$ N data points by adding an offset that is drawn from a Gaussian distribution of zero mean and a  $2\sigma$  width of 0.015 %.

Impurity-enhanced densification. Following recent work we include the possibility that increased glacial impurity loading could have enhanced densification rates (Horhold et al., 2012; Freitag et al., 2013a). We use the mathematical formulation of Freitag et al. (2013a), in which the activation energy of the sintering process is a function of the Ca concentration in the firm. The value of  $\beta$ , the sensitivity to Ca, is drawn from a Gaussian distribution with 0.0015 mean and a  $2\sigma$  width of 0.0015. The topic of impurity-enhanced densification is discussed in detail in Sect. 3.3.

The A and  $\Delta$ age scenarios found in the sensitivity study are shown in Fig. 3b and c, respectively. The shaded areas in Fig. 3b and c give the total range of solutions, as well as the  $\pm 2\sigma$  and  $\pm 1\sigma$  confidence intervals. Note that the total range of solutions will depend on the number of model runs (here 1000), but the position of the  $\pm 2\sigma$  and  $\pm 1\sigma$  envelopes does not. To investigate the distribution of values, we include histograms of  $\Delta$ age at 20 ka intervals (Fig. 3d–f). Based on the sensitivity study, we estimate the WD  $\Delta$ age to be  $521\pm120$  years ( $2\sigma$  uncertainty) at the last glacial maximum (LGM,  $\sim 20 \text{ kaBP}$ ). The  $\Delta$ age value of ( $351 \pm 73 \text{ years}$ ) at 40 ka BP gives a representative  $\Delta$ age for MIS 3;  $\Delta$ age at  $60\,\mathrm{ka\,BP}$  is  $262\pm50\,\mathrm{years}.$ 

Additionally, we have repeated our  $\Delta$ age reconstruction using the firn densification physics described by Arnaud et al. (2000), rather than the Herron-Langway description used so

**Fig. 3.**  $\Delta$ age sensitivity study. Shades of blue give the confidence intervals as marked; the black curves represent the values used in the WD2014 chronology; the red curve gives an alternative  $\Delta$ age solution using the Arnaud densification model. (a) Temperature forcing of the densification model. (b) Reconstructed accumulation rates. (c) Reconstructed  $\Delta$ age; note the reversed scale. Histograms of  $\Delta$ age distribution are shown for (d) 60 ka BP, (e) 40 ka BP, and (f) 20 ka BP. Distribution mean with  $2\sigma$  uncertainty bounds are stated.

- <sup>470</sup> far; the Arnaud model provides the physical basis for the 485 commonly used firn densification model of Goujon et al. (2003). More details on the implementation of the Arnaud model are given in Appendix A. Δage found using the Arnaud model is plotted in red in Fig. 3c. Averaged over the
  <sup>475</sup> entire core, Δage found with the Arnaud model is 19 years (about 7%) smaller than Δage from the Herron-Langway
- (about 7%) smaller than  $\triangle$  age from the Herron-Langway model. The Root Mean Square (RMS) difference between<sub>490</sub> both solutions is 35 years, corresponding to 0.63 times the  $2\sigma$ uncertainty found in the sensitivity study. Both solutions are thus found to be in good agreement. The Herron-Langway
- approach is prefered because the internally consistent solution of temperature, accumulation and ice flow associated  $_{495}$ with it is in better agreement with borehole temperature data than the solutions associated with the Arnaud model. Fur-

thermore, the Herron-Langway model is more successful in simulating the magnitude of the  $\delta^{15}$ N response to the accumulation anomaly at 12 ka (not shown), suggesting it has a more realistic sensitivity to accumulation variability.

#### 3.3 Impurity softening of firn?

Recent work suggests a link between densification rates and impurity content (for which  $[Ca^{2+}]$  is used as a proxy) in polar firn (Horhold et al., 2012; Freitag et al., 2013a). Here we measured total [Ca] by ICP-MS, but at WD nearly all Ca is in the form of Ca<sup>2+</sup>. The influence of the impurity sensitivity  $\beta$  (see Eq. (A6) in the Appendix) on  $\Delta$ age at WD is shown in Fig. 4. The sensitivity recommended by Freitag et al. (2013a) from investigating present day firn packs is  $\beta = 1 \times 10^{-2}$ .

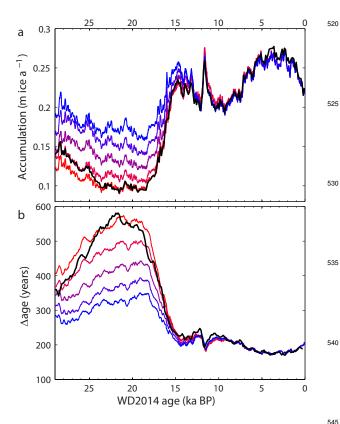

Fig. 4. Impurity enhancement of densification rates at WD. Densification modeling results for (a) accumulation rates, and (b)  $\Delta$ age. We use Ca sensitivities  $\beta = 0$  (red) through  $\beta = 1 \times 10^{-2}$  (blue), in steps of  $2.5 \times 10^{-3}$  (shades of deep purple). Black curves give A and  $\Delta$ age from ice-flow modeling and  $\lambda(z)$ .

We reconstructed A and  $\Delta$ age with the firn densification inverse model using five values of  $\beta$  ranging from  $\beta = 0$  (red) to  $\beta = 1 \times 10^{-2}$  (blue) in steps of  $2.5 \times 10^{-3}$ . Average [Ca] is 500 around  $0.8 \text{ ng g}^{-1}$  in the early Holocene and around  $9 \text{ ng g}^{-1}$ in the LGM, about an order of magnitude change. Following Freitag et al. (2013a) we use the total [Ca], rather than non-sea salt Ca. If densification rates are sensitive to impurity loading (large  $\beta$ , blue curves), this results in increased 505 firn compaction during the LGM. The densification model, which is trying to match the  $\delta^{15}$ N data, will compensate by increasing the A forcing, which in turn results in a decreasing  $\Delta$ age. Hence the model simulations with large  $\beta$  (blue)<sup>560</sup> give a higher A and smaller  $\Delta$ age. 510

For the past 31.2 ka we have an independent A estimate from  $\lambda(z)$ , that we can compare to the solutions from the firm model (Fig. 4, black curve). We also plotted  $\Delta$ age reconstructed via the  $\Delta$ depth method of Parrenin et al. (2012). 565

Remarkably, we find consistent solutions only when using a Ca sensitivity  $\beta \le 2.5 \times 10^{-3}$ , i.e., less than one quarter of the sensitivity suggested by Freitag et al. (2013a). The best fit to the independent LGM (25–20 kaBP) A and  $\Delta$ age estimates is obtained for  $\beta = 0$ . We conclude that WD does not provide any evidence for impurity (or more specifically: Ca) enhancement of densification rates.

An important caveat is that our model uses 10 year average [Ca] values, and therefore cannot resolve effects of interannual layering within the firn. Explicitly modeling the layering would require cm-scale resolution in the dynamical firn model, which is prohibitive from a computational point of view. Furthermore, [Ca] data at the required sub-annual resolution are difficult, if not impossible, to measure for the deepest part of the core where  $\lambda(z)$  is below  $1 \,\mathrm{cm}\,\mathrm{a}^{-1}$ . Increased firn layering and enhanced bulk densification affect the firn thickness in a similar manner; both lead to a shallower lockin depth, and thereby a reduced  $\delta^{15}N$ . Therefore, in order to reconcile our WD results with the impurity-hypothesis of Horhold et al. (2012), one would need to invoke a strong reduction in LGM firn layering relative to the present day to compensate for the impurity-driven increase in bulk densification rates. However, recent work on the EDML core suggests that firn density layering was actually more pronounced during glacial times (Bendel et al., 2013). Including firn layering is therefore likely to only exacerbate the problem.

Work on present day firn has provided support for firn softening by impurity loading (Horhold et al., 2012; Freitag et al., 2013a,b). More work is needed to understand how densification rates are linked to impurity content in a mechanistic, rather than purely empirical way. Perhaps such a microscopic description could provide an explanation why firn densification rates at WD, to first order, do not appear to be affected by order-of-magnitude variations in [Ca] loading. One possible explanation could be that densification rates are controlled by some parameter that co-varies with Ca in modern day firn, yet does not change appreciably over glacial cycles (Fujita et al., 2014).

#### 4 Constructing the WAIS Divide WD2014 chronology

#### 4.1 Annual layer count (0–31.2 ka)

550

A first layer counted chronology for the upper 2800 m of the WD core based on electrical conductivity measurements (ECM), named WDC06A-7, was presented by WAIS Divide Project Members (2013). The WAIS chronology presented in this work, WD2014, uses an updated layer count for the upper 2850 m, based on new data and analyses that have become available since publication of WDC06A-7. These updates are:

- 1. A reassessment of the dating in the upper 577 m (2.4 ka) using high-resolution multi-parameter chemistry data in combination with automated layer detection algorithms (Winstrup et al., 2012);
- 2. A reassessment of the dating between 577–2300 m; (2.4–15.3 ka) using high resolution multi-parameter chemistry data in combination with ECM;

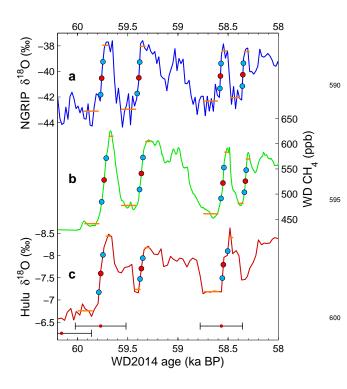

Fig. 5. Determining the midpoint for the abrupt warming phases <sub>605</sub> of (from oldest to youngest) DO 17.2, 17.1, 16.2 and 16.1 in (a) NGRIP  $\delta^{18}$ O (on 1.0063 × GICC05), (b) WD CH<sub>4</sub> (on WD2014) and (c) Hulu  $\delta^{18}$ O with U/Th ages beneath the time series (red dots with error bars). Red dots give the midpoint (50%) of the DO transition, the blue dots give the 25% and 75% marks in the DO transitions. The DO transition at 58.35 ka was not used in Hulu where <sup>610</sup> it is much more gradual than in the other records (possibly because calcite sampling was not perfectly perpendicular to the stalagmite isochrones, or because growth rates were variable in between the U/Th ages).

575

3. A reassessment of the dating between 2300–2800 m; (15.3–29.5 ka) using ECM and dust particle measurements, with the ECM having increasing importance with depth;

615

4. An extension of the annual layer dating between 2800–2850 m; (29.5–31.2 ka) using ECM.

Details on the updated WD layer count and the layer counting methodology are presented in part 1 of the WD2014 papers (Sigl et al., 2014b).

#### 4.2 Methane synchronization (31.2–68 ka)

- For the deep part of the core where an annual layer count is not available we date WD by synchronization to well-dated Northern Hemisphere (NH) climate records of abrupt DO variability using the WD record of globally well-mixed CH<sub>4</sub>.
   <sup>630</sup> This process consists of several steps:
- <sup>585</sup> 1. Determine the midpoint of the abrupt DO transitions in WD CH<sub>4</sub>, NGRIP  $\delta^{18}$ O and Hulu speleothem  $\delta^{18}$ O.

- 2. Assign a gas age to the WD CH<sub>4</sub> tie-points (i.e., the DO transitions).
- 3. Apply the WD  $\triangle$ age (Sect. 3) to find the corresponding ice age at the depth of the CH<sub>4</sub> tie-points.
- 4. Interpolate between the ice age constraints to find the WD depth-age relationship.
- 5. Redo the  $\Delta$ age calculations on the new ice age scale.
- 6. Repeat steps 3–5 iteratively until the depth-age relationship is stable within 1 year. At WD this happened after 3 iterations.

These steps are described in more detail in the following sections.

#### 4.3 Establishing the midpoint in abrupt DO transitions

The procedure for determining the midpoint of the abrupt DO warming transitions is depicted in Fig. 5. For each of the transitions we manually determine pre-event and postevent averages, as indicated by the orange lines. The averaging time is set to 150 and 50 years for stadial and interstadial periods, respectively; this difference in duration is used because (i) several of the interstadials are of short duration, and (ii) Greenland  $\delta^{18}$ O is more variable during stadial climates, requiring longer averaging. For DO 16.1, the duration of the pre-event stadial baseline climate was shorter than 150 years, and the averaging time was reduced to 100 years (Fig. 5).

After determining the pre- and post-event averages, we use linear interpolation of the timeseries to find the time at which the variable of interest had completed 25, 50 and 75 % of the total transition (Fig. 5). We use the 50 % marker (red) as the midpoint of the transition, which is used in the methane synchronization. The 25 % and 75 % markers (blue) are used as the  $\pm 1\sigma$  uncertainty estimate. In rare cases the timeseries contain inversions within the transitions that lead to ambiguity in the timing of the markers; for these events we find the markers using a monotonic spline fit to the data.

The midpoints of abrupt interstadial terminations were determined in the same fashion (WD  $CH_4$  and NGRIP only). Tables 1 and 2 give the results for NH warming, and NH cooling, respectively.

## 4.4 Synchronizing WD to a NGRIP-Hulu hybrid chronology

Abrupt DO variability is expressed clearly in a great number of NH climate records (Voelker, 2002). For the purpose of methane synchronization, our interest is in high-resolution records that express the abrupt DO events very clearly, and are furthermore exceptionally well dated. We here use a combination of two such NH records, namely the Greenland NGRIP  $\delta^{18}$ O record (NGRIP community members, 2004), and a refined version of the Hulu Cave speleothem  $\delta^{18}$ O

Table 1. Overview of CH<sub>4</sub> tie-points for NH warming events.

- <sup>635</sup> record (Edwards et al., in preparation; Reimer et al., 2013; Southon et al., 2012) with improved resolution and additional dating constraints (see Wang et al., 2001, for the original, lower resolution Hulu  $\delta^{18}$ O record). The DO events are <sup>645</sup> resolved most clearly in the NGRIP  $\delta^{18}$ O record, which is
- available at 20 year resolution. We use the GICC05-modelext chronology for this core, which is based on annual layer

counting back to 60 ka BP, and on ice flow modeling for ice older than 60 ka (Rasmussen et al., 2006; Svensson et al., 2006; Wolff et al., 2010). While annual layer counting provides accurate relative ages (e.g., the duration of DO interstadials), it provides relatively inaccurate absolute ages due to the cumulative nature of counting uncertainty (Table 1). The refined Hulu  $\delta^{18}$ O record also shows the abrupt DO

**Fig. 6.** Hulu-NGRIP age offset at the midpoint of the DO  $\delta^{18}$ O transitions. The error bars denote the root sum square of the midpoint determination uncertainty in NGRIP and Hulu  $\delta^{18}$ O (Table 1). The GICC05 ages are placed on the BP 1950 scale, rather than the b2k<sub>700</sub> scale (years prior to 2000 C.E.).

events in high temporal resolution (Fig. 5). The speleothem
chronology is based on U/Th radiometric dating, providing <sup>705</sup> much smaller uncertainty in the absolute ages than GICC05 (Table 1). The reason for selecting this record over other speleothem records is the large number of U/Th dates, the low detrial Th at the site, and the high sampling resolution

of the  $\delta^{18}$ O record (Wang et al., 2001). In the Hulu data, 710 as in other records of DO variability, the interstadial onsets are more pronounced and abrupt than their terminations. We therefore only use the timing of the former as age constraints, as they can be established more reliably. The onset of NH interstadial periods as expressed in Hulu  $\delta^{18}$ O is given in Ta-715 ble 1.

In both the NGRIP and Hulu Cave  $\delta^{18}$ O records we have determined the ages of the midpoints of the DO transitions (Fig. 5; Table 1); a plot of their difference (Hulu age mi-

- nus NGRIP age) is shown in Fig. 6, where the error bars 720 denote the root sum square of the NGRIP and Hulu midpoint determination uncertainty (Sect. 4.3). The Hulu ages are systematically older than the NGRIP ages, and the age difference increases going further back in time. Note that
- the Hulu-NGRIP age difference is smaller than the stated  $_{725}$  GICC05 counting uncertainty (832 to 2573 years), but larger than the Hulu age uncertainty (92 to 366 years). A linear fit through these data, forced to intersect the origin, is given by  $0.0063 \times \text{GICC05}$  age, suggesting that the GICC05 annual
- <sup>675</sup> layer count on average misses 6.3 out of every 1000 layers. <sup>730</sup> Because of this observation we use a linearly scaled version of the GICC05 chronology (GICC05  $\times$  1.0063) as the target chronology for methane synchronization. This approach has several advantages. First, it respects both the superior rela-
- tive ages (i.e., interval durations) of GICC05, as well as the 735 superior absolute ages of the Hulu chronology. Second, it is

very simple to convert between the WD2014 and GICC05 chronologies (CH<sub>4</sub>-synchronized section of the chronology only); one simply needs to divide WD2014 ages by 1.0063 (and add 50 years to convert to the b2k reference date). Third, it still allows for direct synchronization of WD CH<sub>4</sub> to the NGRIP  $\delta^{18}$ O record, providing more tie-points than direct synchronization to the Hulu record would. Note that the GICC05 × 1.0063 target chronology respects the Hulu age constraints in an average sense only; the age of individual events differs between Hulu and our target chronology by up to 180 years.

The exercise of finding the transition midpoints and determining the GICC05-Hulu scaling factor was performed by two of the authors (J.P.S. and C.B.), independently of each other. The scaling factors obtained were 1.0063 and 1.0064, respectively, showing that, to first order, this result is insensitive to (subjective) judgment in identifying the transitions. The difference between the Hulu ages and  $1.0063 \times \text{GICC05}$ ages are all within the stated Hulu  $2\sigma$  dating error (Table 1). Consequently, our chronology is not in violation of any Hulu constraint as it respects the Hulu  $2\sigma$  error at all of the tie points. In deriving the scaling we have assumed that the abrupt DO transitions observed in NGRIP and Hulu are simultaneous, which is not necessarily true. The variations in monsoon intensity represented by Hulu  $\delta^{18}$ O are commonly explained by meridional movement of the inter tropical convergence zone (ITCZ) and tropical rainfall belts (Wang et al., 2001, 2006; Kanner et al., 2012); modeling work suggests such atmospheric readjustments occur on decadal timescales in response to NH high-latitude forcing (Chiang and Bitz, 2005; Broccoli et al., 2006; Cvijanovic and Chiang, 2013). Moreover, CH<sub>4</sub> emission changes are near-synchronous with Greenland  $\delta^{18}$ O variations, which they lag by only a few decades on average (Huber et al., 2006; Baumgartner et al., 2014; Rosen et al., 2014). Since both CH<sub>4</sub> emissions and Hulu  $\delta^{18}$ O are closely linked to tropical hydrology, timing lags between NGRIP and Hulu are also expected to be on decadal time scales. The uncertainty in the NGRIP-Hulu phasing is therefore probably small (decadal) relative to the correction we apply (up to 400 years).

Rather than synchronizing WD CH<sub>4</sub> to Greenland CH<sub>4</sub> records, we have chosen to synchronize directly to NGRIP  $\delta^{18}$ O, which varies in phase with CH<sub>4</sub> (but with a nearly constant time lag). We let the midpoint in the CH<sub>4</sub> transitions lag the midpoint in the NGRIP  $\delta^{18}$ O transition by 25 years, as suggested by studies of Greenland  $\delta^{15}$ N-CH<sub>4</sub> phasing (Huber et al., 2006; Baumgartner et al., 2014; Rasmussen et al., 2013; Kindler et al., 2014; Rosen et al., 2014). The rationale behind this approach is threefold. First, throughout MIS 3 the NGRIP  $\delta^{18}$ O record has both better precision and higher temporal resolution than any available Greenland CH<sub>4</sub> record (Baumgartner et al., 2014; Brook et al., 1996; Blunier et al., 2007). Second, the dating of Greenland gas records depends on the highly variable  $\Delta$ age function, which is not equally well constrained for all DO events (Schwander

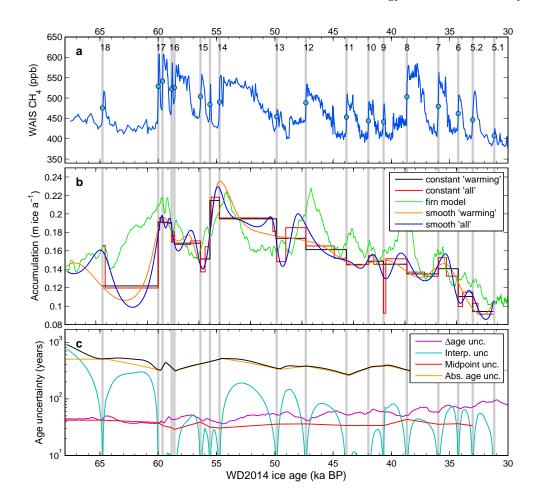

Fig. 7. Interpolating between the CH<sub>4</sub> age constraints. (a) WD discrete CH<sub>4</sub> record with the abrupt stadial-interstadial transitions marked. DO numbering given at the top of the panel. (b) Different annual layer thickness scenarios, converted to an accumulation rate for comparison to the  $\delta^{15}$ N-based firn model reconstructions. The interpolation strategy is to use either constant accumulation rates between tie-points ("constant"), or a smoothly varying  $\lambda(z)$  ("smooth"); the age constraints used are either only the NH warming events ("warming"), or both the NH warming and cooling events ("all"). (c) Estimated  $2\sigma$  uncertainties in the WD2014 chronology due to  $\Delta$ age, choice of interpolation scheme, midpoint detection, and the absolute age constraints used in the synchronization. Total ice age uncertainty is plotted in black.

et al., 1997; Rasmussen et al., 2013). This reliance on Greenland  $\Delta$ age would introduce an additional source of uncertainty. The NGRIP  $\delta^{18}$ O record, on the other hand, is accu-755 rately dated through the GICC05 layer count. Third, Green-

land CH<sub>4</sub> records are more strongly impacted by firn smoothing than the WD CH<sub>4</sub> record, because glacial accumulation is lower in Greenland (Greenland glacial Δage is about 2–3 times as high as WD Δage during that time). In summary, <sup>745</sup> our approach circumvents the uncertainties associated with using Greenland CH<sub>4</sub> as an intermediary. Or to state this an

using Greenland CH<sub>4</sub> as an intermediary. Or to state this another way: the uncertainty in the phasing between CH<sub>4</sub> and Greenland  $\delta^{18}$ O is smaller than the uncertainty in the Greenland  $\Delta$ age.

#### 750 4.5 Interpolation between age constraints

We can assign a gas age to each of the depths where an abrupt WD  $CH_4$  transitions occurs; we do this for DO 4.1 through

DO 18, i.e., the events prior to 31.2 ka BP (the onset of the WD layer count). The gas age we assign is equal to 1.0063 times the GICC05 age for the same event, with 25 years subtracted to account for the slight CH<sub>4</sub> lag behind Greenland  $\delta^{18}$ O. By adding  $\Delta$ age (Sect. 3) to this gas age we assign an ice age. These assigned ages are printed in boldface in Tables 1 and 2.

To obtain a continuous depth-age relationship between these ice age constraints, we have to apply an interpolation strategy. This task amounts to estimating the annual layer thickness  $\lambda(z)$  along the deep part of the core. The simplest approach is to assume a constant accumulation rate in between the age constraints; this is shown in Fig. 7b for the case where we use the age constraints from NH warming events only (black), or the age constraints from both NH warming and cooling events (red). The disadvantage of this approach is that it results in discontinuities in  $\lambda(z)$  (the first derivative

- of the depth-age relationship), which we consider highly unrealistic. A more realistic approach is therefore to assume that  $\lambda(z)$  is continuous and smooth (Fudge et al., 2014); 825 Fig. 7b shows two scenarios in which we use a spline function to estimate  $\lambda(z)$ , where again we have applied age constraints from NH warming events only (orange) or age con-
- straints from both NH warming events only (orange) of age constraints from both NH warming and cooling events (blue). For comparison, past A obtained from the firn densification model (Sect. 3) is plotted in green (Fig. 7b). While the  $\delta^{15}$ N-based A follows the synchronization-based A estimates broadly, the millennial-scale details do not agree. We want to point out that this is not unexpected, since both methods have their imperfections. In particular, any errors in  $_{835}$ the GICC05 age model or in our modeled thinning function  $f_{\lambda}(z)$  will strongly impact the synchronization-based A es-
- timates in Fig. 4.5b. The discrepancy is pronounced between 60–65 ka, where we have to strongly reduce  $\lambda(z)$  in order to fit the age constraint(s) from DO 18, while  $\delta^{15}$ N provides no <sup>840</sup> evidence for very small A during this interval.
- For the WD2014 chronology we have applied the smooth  $\lambda(z)$  interpolation scheme using all age constraints (i.e., both NH warming and cooling events). The midpoint detection uncertainty is comparable for all events, and systematically <sup>845</sup> smaller at the start of interstadial periods than at the terminations (Tables 1 and 2). For short interstadials (e.g., DO
- <sup>795</sup> 9) this leads to a large relative uncertainty in the event duration, and thereby a large uncertainty in the implied accumulation rates (Fig. 7b). We force the interpolation to fit all NH warming constraints perfectly, yet relax this requirement for NH cooling constraints to prevent large swings in  $\lambda(z)$
- for the short duration events. The WD2014 chronology fits the NH warming and NH cooling age constraints with a 0 850 and 16 year root mean square offset, respectively. Because the duration of (inter-)stadial periods is well constrained in the layer-counted GICC05 chronology, using both the NH
   warming and NH cooling tie-points results in a more robust
- chronology. The duration of (inter-)stadial periods is 0.63% <sup>855</sup> longer in WD2014 than in GICC05, which is well within the stated GICC05 counting error of 5.4% (31.2–60 ka interval).

#### 4.6 Age uncertainty

The age uncertainty we assign to the deep part (> 2850 m) of the WD2014 chronology has four components.

The first source of uncertainty is the  $\Delta$ age calculation; we use the  $2\sigma$  uncertainty obtained in the  $\Delta$ age sensitivity study (Sect. 3.2). The second source of uncertainty is the <sup>865</sup> choice of interpolation scheme used to obtain a continuous chronology; here we use the standard deviation between the 4 different interpolation schemes of Fig. 7b) as an uncertainty estimate. The third source of uncertainty is the difficulty in determining the timing of the abrupt events in the <sup>870</sup> timeseries; we use the uncertainty in the midpoint evaluation

(root sum square of WD CH<sub>4</sub> and NGRIP  $\delta^{18}$ O estimates). The last source of uncertainty is the age uncertainty in the hybrid NGRIP-Hulu chronology that we synchronize to. We use the stated Hulu age uncertainty, plus 50 years to account for possible leads or lags in the NGRIP-Hulu  $\delta^{18}$ O phasing, plus the absolute value of the offset between the Hulu ages and the  $1.0063 \times \text{GICC05}$  ages. For DO events where we do not have reliable Hulu age estimates (Table 1), we set the uncertainty to the Hulu age uncertainty of the nearest event, plus the uncertainty in the interval duration specified by the GICC05 layer count. For example, for DO 14 we do not have a reliable Hulu age estimate, and we use the Hulu age uncertainty of DO 16.2 (226 years) plus the uncertainty in the DO 14 to DO 16.2 interval duration on GICC05 (209 years), giving a total of 226 + 209 = 435 years.

The uncertainties  $(2\sigma \text{ values})$  are plotted in Fig. 7c (log scale). We assume these four uncertainties to be independent, and use their root sum square as the total uncertainty estimate on the WD2014 ice age scale (Fig. 7c, black curve). Note that the fourth source of uncertainty is only relevant when considering absolute ages; when evaluating relative ages (e.g., between WD ice and WD gas phase, or between WD and NGRIP) this last contribution does not need to be considered. For the deepest WD ice (3404 m depth) we thus find an age of  $67.7 \pm 0.9$  kaBP.

#### 5 Discussion

860

While the WAIS Divide ice core does not extend as far back in time as deep cores from the East Antarctic plateau, its relatively high temporal resolution (due to the high snow accumulation rate) makes it an ice core of great scientific value. WD accumulation rate during the LGM ( $\sim 10 \,\mathrm{cm}\,\mathrm{a}^{-1}$  ice equivalent) is still higher than the present day accumulation rate at the EPICA (European project for ice coring in Antarctica) Dronning Maud Land core ( $7 \,\mathrm{cm}\,\mathrm{a}^{-1}$ ), which is generally considered a high-accumulation core (EPICA Community Members, 2006). With 68 ka in 3404 m of core, the core average  $\lambda$  is  $5 \,\mathrm{cm}\,\mathrm{a}^{-1}$ ; at the onset of the last deglaciation (18 kaBP)  $\lambda$  is around  $4 \,\mathrm{cm}\,\mathrm{a}^{-1}$ ; near the bed  $\lambda$  is around  $0.4 \,\mathrm{cm}\,\mathrm{a}^{-1}$ . This high temporal resolution provides the opportunity for obtaining very detailed climatic records.

High accumulation rates also result in a small  $\Delta$ age. Figure 8 compares  $\Delta$ age between several Antarctic cores (note the logarithmic scale).  $\Delta$ age at WD is approximately one third of the  $\Delta$ age at EPICA DML (EDML) and Talos Dome (TALDICE), and one tenth of the  $\Delta$ age at EPICA Dome C (EDC), Vostok and Dome Fuji. Because the uncertainty in the  $\Delta$ age (or  $\Delta$ depth) calculation is typically on the order of 20 %, a smaller  $\Delta$ age allows for a more precise inter-hemispheric synchronization with Greenland ice core records using CH<sub>4</sub>. The small WD  $\Delta$ age uncertainty during MIS 3 allows investigation of the phasing of the bipolar seesaw (Stocker and Johnsen, 2003) at sub-centennial precision (WAIS Divide Project Members, in review).

In comparing the shape of the  $\Delta$ age profiles, there are some interesting differences (Fig. 8). It is important to realize that not all the  $\Delta$ age histories shown were derived in the same way; WD and Dome Fuji  $\Delta$ age were derived using densification models, and the other four were derived using the  $\Delta$ depth approach (Parrenin et al., 2012) and a Bayesian inverse method that includes a wide range of age markers

- (Veres et al., 2013). We will therefore focus on comparing the WD and Dome Fuji results.  $\Delta$ age at WD shows more pronounced variability than at Dome Fuji, particularly during MIS 3. The reason is that at Dome Fuji the glacial firn pack is about 4000 years old, and consequently the firn column integrates over 4000 years of climate variability, thereby dampening the  $\Delta$ age response to millennial scale climatic variability. At WD the glacial firn layer is only about 350 years old, and therefore the firn is in near-equilibrium with the millen-
- <sup>890</sup> nial scale climate variations. This difference in response time is also obvious during the deglaciation, where WD  $\Delta$ age transitions from glacial to interglacial values between 18– 14.5 ka BP, while Dome Fuji takes more time (18–10 ka BP). Surprisingly, EDML  $\Delta$ age does not show a strong deglacial  $\Delta$ age response, unlike all the other cores.

The relatively small  $\Delta$ age at WAIS Divide also allows for precise investigation of the relative timing of atmospheric greenhouse gas variations and Antarctic climate (Barnola et al., 1991; Pedro et al., 2012; Caillon et al., 2003; Parrenin et al., 2013; Ahn et al., 2012). Recent works suggest that during the last deglaciation the rise in atmospheric CO<sub>2</sub> lagged

- the onset of pan-Antarctic warming by approximately 0 to 400 years (Pedro et al., 2012; Parrenin et al., 2013). This Antarctic warming around 18 kaBP is presumably driven by the bipolar seesaw, as it coincides with a reduction in
- Atlantic overturning circulation strength as seen in North-Atlantic sediment records (McManus et al., 2004). The WD<sub>930</sub>  $\Delta$ age at 18 ka (gas age) is 515±91 years (2 $\sigma$ ), much smaller than at central East-Antarctic sites such as EPICA Dome C,
- where  $\Delta$ age is approximately  $3850 \pm 900$  years (Veres et al., 2013, with the  $\Delta$ age uncertainty taken to be the difference between the gas age and ice age uncertainties). The preci-935 sion with which one can determine the relative phasing of climatic (i.e.,  $\delta^{18}$ O of ice) and atmospheric signals is set 915 by the uncertainty in  $\Delta$ age (or equivalently, the uncertainty
- in  $\Delta$ depth). High resolution WD records of CO<sub>2</sub> and CH<sub>4</sub> (Marcott et al., 2014) place the onset of the deglacial rise in <sub>940</sub> the atmospheric mixing ratio of these greenhouse gases on the WD2014 chronology at 18,010 and 17,820 years BP, re-
- spectively. However, evaluating the relative phasing of CO<sub>2</sub> and Antarctic climate is complicated by the observation of asynchronous deglacial warming across the Antarctic continent (WAIS Divide Project Members, 2013). Attempts to capture the climate-CO<sub>2</sub> relationship in a single lead-lag
  value may be an oversimplification of deglacial climate dy- 945 namics.

An important next step will be to synchronize the WD chronology with other Antarctic cores via volcanic match-

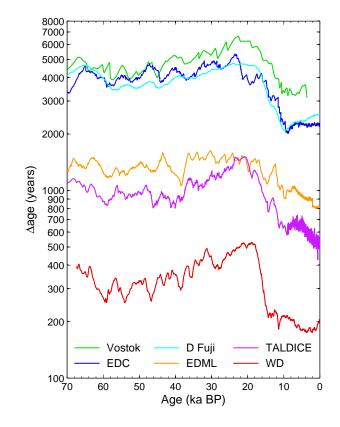

Fig. 8. Comparison of  $\Delta$ age for different Antarctic cores, plotted on the gas-age scale. Dome Fuji  $\Delta$ age from Kawamura et al. (2007); WD from Sect. 3; all others from Bazin et al. (2013); Veres et al. (2013).

ing and other age markers (e.g., Severi et al., 2007; Sigl et al., 2014a). Because of the annual layer count and possibility of tight synchronization to Greenland ice cores, WD could contribute to an improved absolute dating of Antarctic cores, as well as improved cross-dating between cores. Such cross-dating could help inform the WD chronology as well, particularly in the deepest part of the core where the ice is potentially highly strained, as suggested by the interpolation difficulties in the 60–65 ka interval (Fig. 7b). With a synchronized chronology, WD could improve the representation of West Antarctic climate in Antarctic ice core stacks (Pedro et al., 2011; Parrenin et al., 2013), and provide a more refined pan-Antarctic picture of the climate-CO<sub>2</sub> relationship.

#### 6 Summary and conclusions

We have presented a first chronology for the deep (> 2850 m) section of the WAIS Divide ice core, which is based on stratigraphic matching to Greenland ice cores using globally well-mixed methane. We use a dynamical firm densification model constrained by  $\delta^{15} N$  data to calculate past  $\Delta age$ , and find that  $\Delta age$  was smaller than  $525 \pm 120$  years

for all of the core. Using high resolution WD records of at-

<sup>950</sup> mospheric CH<sub>4</sub>, we synchronize WD directly to Greenland NGRIP  $\delta^{18}$ O for the abrupt onset and termination of each of the DO interstadials. To each event we assign an age corre-<sub>1000</sub> sponding to 1.0063 times its GICC05 age, which brings the ages in agreement with the high-resolution U/Th-dated Hulu

speleothem record. The uncertainty in the final chronology is based on the uncertainties in: (i) the ∆age calculations, as evaluated with a sensitivity study, (ii) the interpolation strategy, as evaluated by comparing four different interpolation methods, (iii) determining the timing of events in the differ-1005
ent time series, and (iv) the ages of the hybrid NGRIP-Hulu chronology we are synchronizing to.

Due to the combination of a small  $\Delta$ age and a high-resolution methane record, the WAIS Divide ice core can be synchronized more precisely to Greenland records than any

other Antarctic core to date. This is important when investigating inter-hemispheric climate relationships such as the bipolar seesaw. The small WD  $\Delta$ age furthermore provides valuable opportunities for precise investigation of the relative phasing of atmospheric greenhouse gas variations and Antarctic climate.

#### Appendix A

#### **Densification physics**

The densification rates used in this work are based on the<sup>1020</sup> empirical steady state model by Herron and Langway (1980)

(the H-L model). We use the H-L model with minor modifications that allow it to be run dynamically (i.e., with timevariable T and A), and to include the softening effect of impurities following Freitag et al. (2013a). The H-L model divides the firn column in two stages, separated at the critical density  $\rho_c = 550 \text{ kg m}^{-3}$ , occurring at the critical depth  $z_c$ .

For the upper firm ( $\rho \le \rho_c$ , stage 1), the densification rates are given by:

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = k_1 A \left(\rho_{\rm ice} - \rho\right) \tag{A1}_{_{10}}$$

985 with

$$k_1 = 11 \exp\left(-\frac{E_1}{RT}\right) \tag{A2}$$

where  $E_1 = 10.16 \text{ kJ mol}^{-1}$  is the activation energy for stage 1, and R the universal gas constant. Because both the sinking velocity of deposited layers (w = dz/dt) and the densification rate scale linearly with A, the resulting density-depth profile  $\rho(z)$  in stage 1 becomes independent of A, and sensi-1040 tive to T variations only.

For the deeper firn ( $\rho > \rho_c$ , stage 2), we use Eq. (4c) from Herron and Langway (1980), which was first derived by Sigfús J. Johnsen. This equation gives the densification rate in terms of overburden load, which allows the model to<sub>1045</sub> be run dynamically. The stage 2 densification rates are given by:

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = k_2^2 \frac{(\sigma_z - \sigma_{z_c})(\rho_{\mathrm{ice}} - \rho)}{\ln\left[(\rho_{\mathrm{ice}} - \rho_c)/(\rho_{\mathrm{ice}} - \rho)\right]} \tag{A3}$$

with

1015

$$k_2 = 575 \exp\left(-\frac{E_2}{RT}\right) \tag{A4}$$

where  $E_2 = 21.4 \text{ kJ mol}^{-1}$  is the activation energy for stage 2, and  $\sigma_z$  denotes the firm overburden load at a given depth in Mg m<sup>-2</sup>:

$$\sigma_z = \int_0^z \rho(z') \mathrm{d}z' / 1000 \tag{A5}$$

Note that we divide by 1000 to convert from  $kgm^{-3}$  to  $Mgm^{-3}$ , the units used by Herron and Langway (1980).

We use the mathematical description by Freitag et al. (2013a) to include the hypothesized firn softening effect of impurities. In this approach an increasing Ca concentration, as a proxy for mineral dust content, lowers the activation energy of firn, thereby enhancing densification rates. This is tantamount to stating that dusty firn behaves as if it were "warmer" than its climatological temperature. The H-L activation energies of Eqs. (A2) and (A4) are modified by [Ca] in the following way:

$$E^{\text{Ca}} = E^{\text{HL}} \times \alpha \left[ 1 - \beta \ln \left( \frac{[\text{Ca}]}{[\text{Ca}]_{\text{crit}}} \right) \right]$$
(A6)

where  $E^{\text{Ca}}$  and  $E^{\text{HL}}$  are the Ca-modified and original H-L activation energies, respectively,  $[\text{Ca}]_{\text{crit}} = 0.5 \ \mu\text{g kg}^{-1}$  is the minimum concentration at which impurities affect densification, and  $\alpha$  and  $\beta$  are calibration parameters. Whenever  $[\text{Ca}](z) < [\text{Ca}]_{\text{crit}}$ , we set  $[\text{Ca}](z) = [\text{Ca}]_{\text{crit}}$ .

The parameter  $\beta$  sets the sensitivity to dust loading, and  $\alpha$  is a normalization parameter that is included to account for the fact that the original H-L model was calibrated without the impurity effect. Consequently, if  $\beta > 0$ , one needs to compensate by setting  $\alpha > 1$  to preserve the original H-L calibration. The work by Freitag et al. (2013a) recommends  $\beta = 0.01$  and  $\alpha = 1.025$  (which yields  $E^{\text{Ca}} = E^{\text{HL}}$  at [Ca] = 5.73 µg kg<sup>-1</sup>).

In the experiment presented in Fig. 4 we changed the dust sensitivity  $\beta$ ; it is clear that we need to simultaneously change  $\alpha$  to keep the model well calibrated to present day conditions. To achieve this, we let  $\alpha = 1.007 + \beta \ln(0.8/0.5)$  in the experiment, where we use the fact that the mean late Holocene [Ca] is around  $0.8 \,\mu g \, \text{kg}^{-1}$  at WD. This approach ensures that, to first order, the present day  $E^{\text{Ca}}$  is invariant with  $\beta$ . This means that whatever value we choose for  $\beta$ , we will obtain a good fit to the present day  $\Delta \text{age}$ ,  $\delta^{15}$ N and A values that are are well known from direct observations

(Battle et al., 2011).

To validate the H-L model  $\Delta$ age simulations, we repeated the firn modeling using the densification physics of Arnaud et al. (2000), which is also the basis of the model by Gou-<sup>1100</sup>

jon et al. (2003). Our implementation of the Arnaud model is

1050

1060

based on the description in the latter paper, with one modification at the critical density that we outline here.

In the Arnaud model, densification in the stage 1 follows<sub>1105</sub> the work of Alley (1987), and is given by:

$$\frac{dD}{dt} = \gamma \left(\frac{P}{D^2}\right) \left(1 - \frac{5}{3}D\right) \tag{A7}$$

with D the relative density  $D = \rho/\rho_{ice}$ , P the overburden<sup>1110</sup> pressure, and  $\gamma$  a scaling factor used to make the densification rates continuous across the critical density  $D_c$ . Stage 2 densification is given by:

$$\frac{dD}{dt} = k_A \left( D^2 D_c \right)^{\frac{1}{3}} \left( \frac{a}{\pi} \right)^{\frac{1}{2}} \left( \frac{4\pi P}{3aZD} \right)^3 \tag{A8}$$

with

1065 
$$k_A = 4.182 \times 10^4 \exp\left(-\frac{E_A}{RT}\right) \tag{A9}$$

where *a* is the average contact area between the grains,  $Z_{1120}$  is the coordination number, and  $E_A$  is the activation energy (60 kJ mol<sup>-1</sup>). Arnaud densification rates for stage 3 ( $D \ge 0.9$ ) are describe elsewhere (Goujon et al., 2003; Arnaud et al., 2000).

The difficulty in implementing this model is the following.<sup>1125</sup> The densification rates of Eqs. (A7–A8) exhibit a discontinuity at the critical density  $D = D_c = 0.6$ , that cannot be remedied with the scaling factor  $\gamma$ . On approaching  $D_c$ , densification rates given by Eq. (A7) go to zero (due to the inclusion of the term  $(1 - \frac{5}{3}D)$ , while densification rates given by Eq. (A8) go to infinity because the contact area *a* equals zero at  $D = D_c$ . Clearly neither equation gives a realistic result at  $D = D_c$ . Therefore, in our implementation of the Arnaud

- model we use the H-L densification rates of Eq. (A1) in stage<sup>135</sup> 1, instead of Eq. (A7). We take the onset of stage 2 to be the density at which Eqs. (A1) and (A8) intercept, thus avoiding the singularity in Eq. A8. This approach has the additional
- advantages of removing dependence on ad-hoc scaling factor  $\gamma$ , and introducing realistic temperature dependence for stage 1 densification. Because stage 1 spans just the top 10– 20% of the firn column, the modification has only a minor influence on the overall behavior of the Arnaud model. The
- Goujon model code avoids the singularity in Eq. (A8) by<sub>1145</sub> extending stage 1 to  $D_c + \varepsilon$  (Anaïs Orsi, personal communication, 2014), a procedure not described in Goujon et al. (2003).
