Title: Early warnings and missed alarms for abrupt monsoon transitions
Author(s): Z.A. Thomas et al.
MS No.: cp-2015-39
MS Type: Research Article

Editor Decision: Reconsider after major revisions (08 Sep 2015) by Prof. Dr. Martin Claussen
Comments to the Author:
Dear authors,

The referees agree that your paper has substantially improved. Referee 1 and 3 request only minor revisions, while referee 2 is still not convinced by your presentation. As far as I can judge, the latter criticism does not point at major flaws. Nonetheless some of your presentation does not seem to be very clear. Since this is a matter of concise formulation, I am convinced that you will be able to properly deal with it. Hence I encourage you to submit a re-revision which will be reviewed by referee 2.

Best regards

Martin Claussen

Dear Martin

Many thanks for the referee comments. We were very pleased to hear that our manuscript has substantially improved. We have carefully looked at all the comments and have revised and clarified our manuscript accordingly. We thank all three reviewers for their helpful suggestions. We hope you will find further improvement in our responses and revised manuscript.

Best wishes

Zoë Thomas (on behalf of all co-authors)

Suggestions for revision or reasons for rejection (will be published if the paper is accepted for final publication)

2nd Review of "Early warnings and missed alarms for abrupt monsoon transitions" by Z. A. Thomas, F. Kwasniok, C. A. Boulton, P. M. Cox, R. T. Jones, T. M. Lenton, and C. S. M. Turney.

The revised version of the manuscript I find much improved and a lot more convincing. I especially like the revised section two with the separate subsection on assessing significance.

Nonetheless, I still have a few – by now relatively minor – points:

- The discussion of significance of the increases in ACF and VAR for the earlier transitions is much improved, but it still isn't clear immediately why the EWS for all of them are rejected. This would become clearer, if the lines marking the Kendall tau values for the various periods in Fig. 5 were annotated. This way it would become clear, which Kendall tau value is achieved for which transition (though he reader CAN, of course, get this information from Fig. 4), thus making understanding this point more intuitive.
A detailed description of how the surrogate time series are obtained can be found in Section 2.3.1, however, we have pointed the reader to this section in the Figure caption, and include a brief explanation of what a high/low Kendall tau means, as also suggested by Reviewer #3 (lines 248-249). We thank the reviewer for the suggestion of annotating the bars in Figure 5 to show the periods to which they correspond; we have implemented this, which makes the interpretation much clearer.

- The discussion of Fig. 9 is still exceedingly brief. Yes, of course it cannot be expected that such a simple model cannot capture the full dynamics of the system, but this is not discussed at all when the figure is discussed (page 18, lines 432 to page 19, line 455). This way the reader is left wondering what conclusions to draw – the simple one being that the potential model is plain wrong. Therefore the figure needs to be better discussed in order to lend credibility to the use of the potential model.
We have extended the discussion of both the potential model (see lines 297-305, 406-421) and Figure 9 (519-522), including some remarks on the limitations of the potential model:
"*Palaeoclimatic records reflect a multitude of complex processes and any model as simple as equation (1) cannot be expected to be more than a skeleton model used to pinpoint and contrast*

basic dynamical mechanisms" (lines 338-342).

- Line 31: The term "monsoon termination" is highly interesting. Is that standard usage? What is the definition?

The term 'monsoon termination' is used relatively widely within palaeo-monsoon literature e.g. Cheng et al. 2006, *Geology* and Kelly et al. 2006, *Palaeo3*. It simply refers to the timing of the glacial terminations with respect to the monsoon records, rather than the atmospheric CO_2 record.

- Line 44-46: Future monsoon shifts having societal impacts similar to past monsoon shifts would imply that the vulnerability of society has not changed. There are good reasons for doubting this.

This is a fair point in that the vulnerability of society clearly has changed. We have reworded this to remove this potential confusion: "*Though the vulnerability of society has clearly changed, future abrupt monsoon shifts, whether caused by orbital or anthropogenic forcing, are likely to have major devastating societal impacts (Donges et al., 2015).*" (lines 49-63).

Suggestions for revision or reasons for rejection (will be published if the paper is accepted for final publication)

Review of revised manuscript “Early warnings and missed alarms for abrupt monsoon transitions” by Thomas et al.

Main points of criticism on the first version of this ms concentrated on a lack of critical attitude, lack of explanation on methods, and presentation. All reviewers found the subject matter and analysis interesting. While this revision certainly has improved, I still feel it falls somewhat short of standards for a publication in Climate of the Past. Nevertheless, I still believe the authors should be capable of submitting a version that meets these standards.

Specific comments:
I am not always convinced by the presentation and (lack of) flow of the narrative. At present methodological details are explained before or after the results/figures they apply to. This gives the ms the appearance of a series of disconnected or separate paragraphs. Top some extent this may be a matter of taste but there are several places where this becomes problematic.
We are sorry that the reviewer still finds some inconsistencies with our narrative. We have carefully reviewed this again and hope that our changes are satisfactory.

1. Figure 1. What are we seeing here? Delta-O18. But what does it mean? Temperature? Precipitation? There is some discussion on Delta-18 2 pages after introducing Fig. 1, but this is insufficient. If the data represent precipitation, the question is what precip? Annual mean? Summer mean? Extreme values? To know this exactly or as good as possible is important as the authors later on mode these timeseries, a.o. with a model based on a Langevin equation. One cannot judge the validity of the model if one does not know what “x” in this model means.
Related to the point above, we feel that the discussion on speleothem δ^{18}O is in the most appropriate place without disrupting the introduction of the manuscript. We do understand the reviewers point though, and we have therefore added a brief explanation of what the speleothem δ^{18}O refers to earlier in the manuscript when Figure 1 is introduced, and then point to the Section that addresses this in more detail (lines 44-45). Speleothem δ^{18}O from Chinese caves is interpreted to be a precipitation proxy, with more negative δ^{18}O values corresponding to a weaker monsoon and less negative δ^{18}O values corresponding to a weaker monsoon. We thank the reviewer for highlighting this, and have also added an annotation to illustrate this more clearly in Figure 1, which we believe further increases the clarity.

2. The authors defend the Langevin-model by saying it is just a simple skeleton model. This does not mean that assumptions underlying this model should not be discussed and motivated. One assumption is white noise. If we know what x or x-dot means we can discuss how well this assumption is. If eta reflects some precipitation measure it can be valuated from actuo-observations and actuo (climate model) runs. Same for the linear relation between insolation and x-dot. There is a lot written about the relation between hydrological cycle and radiative forcing.
We think it is canonical to start with white noise and a linear forcing in order to keep the model simple and the number of parameters to a minimum. It is beyond the scope of the present study to rigorously test these assumptions with data. Specifically, this model is used to pinpoint and contrast basic dynamical mechanisms, rather than exactly replicating the detailed dynamics of the monsoon. We have compared our model against a simpler model without insolation forcing and against a more complicated model where all four parameters of the potential depend on time. Based on the likelihood function and both the Akaike and the Bayesian information criterion, we are able to refute the other models. More detail on this is now given in the revised manuscript (lines 406-421).

3. In particular, it seems that the amplitude of the noise is chosen by the model or seen as an arbitrary tuning parameter varied in the discussion. The amplitude of the noise determines whether one finds early warning signals or not. Again, the amplitude should and could be constrained by actuo-obs and modeling time series. See also Fig. 11 and subsequent discussion.
The noise level is robustly estimated directly from the speleothem data, *“determined from the dynamical likelihood function based on the time evolution of the system (Kwasniok, 2015)”* (lines 323-325), together with the other model parameters (also lines 310-311 further clarified). The uncertainty in all parameters, including the noise level, is very small, making our model estimation

robust. The noise level is then subsequently varied in order to study early warning signals in a hypothetical scenario with different noise level (see lines 363-365 and 372-373).

4. The authors introduce Type-I and Type_II errors without explaining what they mean. These terms may be common in a small mathematical-statistical expert-group, but this does not extend to the general Climate of the Past readership.
We have included a brief definition of these terms to ensure clarity: *"Although efforts have been taken to reduce the chances of type I (incorrect rejection of a true null hypothesis, otherwise known as a 'false positive') and type II (failure to reject a false null hypothesis, or 'false negative') errors…"* (lines 136-144).

5. One wonders why both 90% and 95% percentiles are used, seemingly at random, for rejecting hypotheses.
The 90% and 95% significance levels are commonly used as benchmarks for statistical significance. However, we should be consistent with which significance levels we use in Figure 5, so we have amended the plot to show the 90% level on all four plots. There is currently no consensus with regards the suitable significance level that should be used (as stated in lines 252-257). Most tipping point literature identifies an increasing trend using the Kendall tau statistic and measures the robustness using a similar null model, where p values of <0.1 are considered 'robust' e.g. Dakos et al. 2008, Boulton and Lenton 2015, *PNAS*. We have thus chosen p values of <0.1 as the benchmark for significance for our study (see lines 260-262).

6. In Fig. 5 the authors could explain more how the surrogate time series are obtained, what it means if the Kendall low or high for specific subsections of the timeseries and which bar in panels a and b corresponds to which period.
A detailed description of how the surrogate time series are obtained can be found in Section 2.3.1, however, we have pointed the reader to this section in the Figure caption, and include a short section explain what a high/low Kendall tau means (lines 248-249). We have colour-coded the bars in Figure 5 to show the periods to which they correspond, which we agree makes interpretation much clearer.

7. The lack of EWS in other subsections of the timeseries than 150-129 ka BP is attributed to a lack of resolution. The possibility of stochastic resonance or noise-induced transitions is not discussed at all. The authors simply "jump" to a conclusion, or even worse, say "we speculate" without addressing other options or motivating their speculation.
We do briefly discuss the possibility of noise-induced switches and stochastic resonance (lines 109-113, 297-305), and conclude that in our potential model, the two stable states are not available at the same time for long enough for noise-induced transitions to play a significant role. We have, however, included a paragraph in the discussion section to further explain why do no not consider these alternate scenarios to be likely (lines 614-623).

8. Figure 10 shows the potential well flattening over a normal transition cycle and a transition cycle at the termination. The distinction between these two is nowhere explained or illustrated. Which cycles do we see? In what respect are they different? Which time period? Please point to the original data!
The two transition cycles in Figure 10 are the termination (150-128.5 kyr) and the period 198-175 kyr, as shown in Figure 10a. We are not quite sure what original data the reviewer is referring to here; this data is the same Sanbao cave $\delta^{18}O$ data as used in the potential model. We have amended the figure caption to make this clear. Figure 10 is intended to illustrate that the potential well is flatter during the transition cycle at the termination in comparison to one of the termination cycles from the glacial period. This distinction helps to explain why early warning signals in the form of increasing autocorrelation and variance are found immediately preceding the termination, but not for the other monsoon transitions (see lines 562-564).

Suggestions for revision or reasons for rejection (will be published if the paper is accepted for final publication)

In my opinion, the authors have managed to come up with a much clearer and more transparent manuscript. It is now clear to me what the authors do and why: The fundamental question is whether one can distinguish from the speleothem record if the abrupt monsoon switches are associated with bifurcations or with switches between permanent alternative states. The authors point to this question and show that their potential model is in line with the bifurcation hypothesis. In principle, I think that this result just merits a publication because I see no killing argument against it. However, it still remains unclear to me to what extent the author's results are any evidence for the bifurcation hypothesis in contrast to a sophisticated speculation. I hope that further research will tackle this question more thoroughly, and that the authors still improve their manuscript, by addressing some of the following points.

The authors state that their potential model should "supplement the analysis of the speleothem records and help interpret the results". I rather think that this model is at the heart of the analysis and that the message of the paper rests on this model. It is thus important to argue why it is an appropriate model, and why alternative explanations (e.g. nonlinear response to forcing, or stochastic resonance) are less plausible, ideally by using statistical tests to refute some hypothesis. The fact that the authors come up with a model that describes the abrupt changes as bifurcations does not prove that the model is more likely to be true than any other model. Although the way the authors derive the model is now transparent, it is not very transparent to me how sensitive the results are to different choices during the model derivation. The fact that a simpler approach fails due to a negative leading coefficient indicates that the model is not robust. I still wonder how robust the results are to the choices during the model derivation. For example, why is the solar forcing a linear term added to the potential U? Why not say that the four parameters of U all depend on time?

We have compared our model against a simpler model without insolation forcing and against a more complicated model where all four parameters of the potential depend on time. Based on the likelihood function and both the Akaike and the Bayesian information criterion, we are able to refute the other models. More detail on this is now given in the revised manuscript (lines 406-421).

The authors do not find “early warnings” though they would be expected if their bifurcation hypothesis was true, and argue that the time series are too short and the noise level is too large for a detection. Is there any further line of evidence to substantiate this claim? How robust is the noise level estimate?

The noise level is robustly estimated directly from the speleothem data, *“determined from the dynamical likelihood function based on the time evolution of the system (Kwasniok, 2015)”* (lines 323-325), together with the other model parameters (also lines 310-311 further clarified). The estimation of all model parameters, including the noise level, is robust; the parameter uncertainties are very small. Based on the assumption that the monsoon transitions are characterized by a bifurcation (which is supported by both our model, and previous studies e.g. Schewe et al. 2012), Figure 11 shows that with a reduced noise level and higher resolution in the potential model simulations, early warning signals are detected. We have, however, added to the initial discussion of false positives of early warning signals (lines 136-144), as well as a further point: “*To guard against type I errors, we determine for this study that ‘statistically significant’ early warning indicators occur with increases in both autocorrelation and variance with* p*-values* > 0.1*. We have chosen this benchmark in line with previous studies using a similar null model that have described results with* $p<0.1$ *as ‘robust’ (Dakos et al., 2008; Boulton & Lenton, 2015)* (lines 257-262, also lines 440-442).

I think it is sensible in this context to check the dependence of “early warnings” on noise level and resolution, using the potential model, as the authors do. However, it is not clear to me whether the results confirm the claim that most transitions are below detectability, while termination II is above detectability. At which length of the record would the signal become significant? I think this is something else than examining the resolution because of the autocorrelation in the time series (see my point on characteristic timescale below).

Figure 11 is intended to illustrate the effects of the noise level and resolution on the potential, and shows that much lower Kendall tau values are measured with an increasing sample step (lower resolution), and a higher noise level. Given that our potential model (and other studies of the EASM) indicates that the monsoon system has bifurcation points between the strong and weak states, a possible explanation is that the resolution of the speleothem data is below detectability, since Figure 11 clearly illustrates the detrimental effect of a lower resolution on Kendall tau values, particularly for autocorrelation (lines 626-628). Indeed, Figure 5 shows that higher Kendall tau values are detected for variance in the monsoon transitions prior to 150 ka BP. Since the monsoon transition at the termination does display early warning signals, we suggest that this may be because the background state of the climate system is different to that of the other monsoon transitions, and may well present a longer timescale of internal variability, which allows the detection of early warning signals.

By the way, just from looking at the data, the time series from Hulu cave does not occur bimodal to me, and the shifts are less abrupt / less permanent. The authors often refer to “the speleothem data”, but I have the impression it is only the Sanbao record they use for their potential model, while they still analyse early warnings in the Hulu record. This seems to be contradictory.

The Hulu cave speleothem record is markedly shorter than the Sanbao cave speleothem record. Indeed the Hulu cave data duplicates only the last 30 kyr of the 100 kyr long Sanbao cave record, where the bimodal character is also less visually strong. The reviewer is correct that we use only the Sanbao cave data to create the potential model; we have made this more explicit.

Further (minor) remarks

Another problem that I think remains in the revised manuscript is the lack of a physical mechanism to explain the relaxation time of the system. The authors correctly point out in line 102 that “Detecting the phenomenon of critical slowing down relies on a timescale separation, whereby the timescale forcing the system is much slower than the timescale of the system’s internal dynamics, which is in turn much longer than the frequency of data sampling the system (Held and Kleinen, 2004).” However, I missed an explanation why this timescale separation applies to the East Asian monsoon (why should monsoon respond much slower to forcing than the resolution of the record, i.e. ~100 years?). Also, this seems to be at odds to the often cited Zickfeld/Levermann/Schewe model which seems to have a much faster timescale given the rapid processes in the atmosphere. I guess it must be the model’s parameters determined by the ocean that somehow adjust slowly to the change in insolation?
We apologise for the confusion here. We interpret the timescale of the forcing to be on an orbital scale – that is, driven by the 23 ka precession cycle. Importantly, the monsoon transitions span hundreds of years (several data points), this meets the criterion that the frequency of our sampling is higher than the timescale of the transition of the system (lines 130-133). This therefore suggests that it is the slow ocean dynamics, rather than faster atmospheric dynamics that may be governing shifts in the ITCZ. This is supported by Deplazes et al. (2013) *Nature Geoscience*, who show that the marine records of monsoon transitions occur over centuries rather than decades. Similarly, the strong correlation in the last glacial cycle between Dansgaard-Oeschger events (linked to changes in ocean circulation) and abrupt monsoon shifts, suggests that it is the slow ocean dynamics that ultimately govern monsoon shifts.

line 97: “While it has been theoretically established that autocorrelation and variance should both increase together (Ditlevsen and Johnsen, 2010; Thompson and Sieber, 2011), there are some factors which can negate this, discussed in detail in Dakos et al. (2012b, 2014).”
I still don’t see clearly why this is noted here. What does it tell about the author’s results? Would they expect an increasing variance in case of the monsoon, and why (not)? As autocorrelation and variance do increase together before termination II, where is the problem?
We have amended this line to remove confusion (lines 120-125).

The test for trends in Kendall’s Tau seem to be done via surrogate time series, which I think is a good idea. But it seems that the surrogate time series have no autocorrelation because it is destroyed by the shuffling. The true data is autocorrelated and thus trends are less robust. Wouldn’t the trend significance then be overestimated? The authors refer to Dakos et al. (2008), and the approach seems to correspond to their H0_1 - one could instead use their Null-hypothesis 2 and/or 3, which take autocorrelation into account.
Importantly, a timeseries with an autocorrelation that remains around 0 and one that remains around 0.5 will have no effect on the value of the Kendall tau, since the tau value is calculated relatively. Thus, the fact that the autocorrelation is destroyed by the shuffling does not change the null model distribution (see lines 247-249). Furthermore, Table S2 of Dakos et al. 2008 shows the p values from each test under each null model, and in all but one of the original time series records, testing with null model 1 (random shuffling) gives the highest p values, meaning that in 7 out of the 8 cases it actually slightly underestimates the significance of the trend. The results are also mixed for their simulated records, suggesting that there is no real preference to which null model is chosen in this case. Figure S3 in Dakos et al. (2008) further shows that there are negligible differences from the null model distributions.

I have the impression the term “tipping point analysis” has been made up by the authors and is very vague. One could instead refer to particular steps in the statistical analysis by using established conventions. Moreover, “noise-induced transition” is not the right term for a random shift of the system into a different attractor basin. As far as I know the term does not refer to one particular event in a stationary time series but to the sudden change of a system’s long-term statistics when the noise level is changed. For example, see books and articles by Berglund, Gentz, Horsthemke and Lefever on this topic.
We use the term ‘tipping point analysis’ to refer to both the pre-processing and the measuring of the trends in autocorrelation and variance over a sliding window. By using ‘tipping point analysis’ as one of our sub-section headings, we feel that the explanation as to what this involves is clear.
We refer to noise-induced transitions in terms of the recent Ashwin et al. (2012) *Phil Trans A*

paper, which refers to noise-induced tipping as ‘stochastic perturbations…which drive long-term climate variations’. We have included this reference and definition in our paper when we refer to noise-induced transitions (lines 109-113). There are several examples in the literature where noise-induced tipping is described in this way, e.g. Lenton (2011) *Nature Climate Change* describes noise-induced transitions as “short-term internal variability [which]…causes a large, nonlinear change in the system state without any change in forcing control”, and Ditlevsen and Johnson (2010) *GRL*, analyse the Dansgaard-Oeschger events and determine that these are “induced by stochastic fluctuations”.

I still think that some figures are not required, for example
Fig. 1: c, d;
Fig. 6 and 7: c, d.
We have removed panels 1c, 6c, 6d, 7c, 7d. However, we would like to keep panel 1d since we emphasize the fact that the data spans an entire glacial cycle, and finishes with Glacial Termination II, of which panel 1d (now 1c) provides good visual evidence.

Fig. 10: I suggest to use individual potential plots, or arrows between potentials and time periods in the record, or write the letter directly next to the line in the plot.
We have amended to add the letter directly next to the line in the plot.

The caption of Fig. 11 is incomprehensible to me.
We have reworded to increase clarity (lines 597-607).

Early warnings and missed alarms for abrupt monsoon transitions

Abstract

Palaeo-records from China demonstrate that the East Asian Summer Monsoon (EASM) is dominated by abrupt and large magnitude monsoon shifts on millennial timescales, switching between periods of high and weak monsoon rains. It has been hypothesised that over these timescales, the EASM exhibits two stable states with bifurcation-type tipping points between them. Here we test this hypothesis by looking for early warning signals of past bifurcations in speleothem $\delta^{18}O$ records from Sanbao Cave and Hulu Cave, China, spanning the penultimate glacial cycle. We find that although there are increases in both autocorrelation and variance preceding some of the monsoon transitions during this period, it is only immediately prior to the abrupt monsoon shift at the penultimate deglaciation (Termination II) that statistically significant increases are detected. To supplement our data analysis, we produce and analyse multiple model simulations that we derive from these

data. We find hysteresis behaviour in our model simulations with transitions directly forced by solar insolation. However, signals of critical slowing down, which occur on the approach to a bifurcation, are only detectable in the model simulations when the change in system stability is sufficiently slow to be detected by the sampling resolution of the dataset. This raises the possibility that the early warning 'alarms' were missed in the speleothem data over the period 224-150 kyr and it was only at the monsoon termination that the change in the system stability was sufficiently slow to detect early warning signals.

Keywords: Speleothem, monsoon, bifurcation, early warning signals, tipping point

1.1 Introduction

The Asian Summer Monsoon directly influences over 60% of the world's population (Wu et al., 2012) and yet the drivers of past and future variability remain highly uncertain (Levermann et al., 2009; Zickfeld et al., 2005). Evidence from radiometrically-dated East Asian speleothem records of past monsoon behaviour (Yuan et al., 2004) suggests that on millennial timescales, the EASM is driven by a 23 kyr precession cycle (Kutzbach, 1981; Wang et al., 2008), but also influenced by feedbacks in sea surface temperatures and changing boundary conditions including Northern Hemisphere ice volume (An, 2000; Sun et al., 2015). The abrupt nature of the monsoon behaviour (interpreted as a precipitation proxy from δ^{18}O values from Chinese speleothem records; see Section 1.4) in comparison to the sinusoidal insolation forcing strongly implies that this response is non-linear (Figure 1); whilst Northern Hemisphere Summer Insolation (NHSI) follows a quasi-sinusoidal cycle, the δ^{18}O profile in speleothems exhibits a step function, suggesting the presence of threshold behaviour in the monsoon system (Schewe et al., 2012). Though the vulnerability of society has clearly changed, future abrupt monsoon shifts, whether caused by orbital or

Deleted: The demise of Chinese dynasties have been linked to monsoon shifts over more recent millennia (Zhang et al., 2008), suggesting that any future changes, whether caused by solar or anthropogenic forcing, could have similarly devastating societal impacts. The abrupt nature of the monsoon behaviour

anthropogenic forcing, are likely to have major devastating societal impacts (Donges et al., 2015).

Figure 1: (a) Northern Hemisphere Summer Insolation (NHSI) at June 30°N (Berger & Loutre, 1991) (grey), δ^{18}O speleothem data from Sanbao Cave (Wang et al., 2008) (dark blue), (b) δ^{18}O speleothem data from Hulu Cave (Wang et al., 2001); speleothem MSH (red), MSP (blue) and MSX (yellow), (c) δ^{18}O per mille benthic carbonate (Lisiecki & Raymo, 2005) (proxy for global ice volume) (purple).

A minimum conceptual model of the East Asian Summer Monsoon developed by Zickfeld et al. (2005), stripped down by Levermann et al. (2009) and updated by Schewe et al. (2012), shows a non-linear solution structure with thresholds for switching a monsoon system between ‘on’ or ‘off’ states that can be defined in terms of atmospheric humidity – in particular, atmospheric specific humidity over the adjacent ocean (Schewe et al., 2012). Critically, if specific humidity levels pass below a certain threshold, for instance, as a result of reduced sea surface temperatures, insufficient latent heat is produced in the atmospheric column and the monsoon fails. This moisture-advection feedback allows for the existence of two stable states, separated by a saddle-node bifurcation (Zickfeld et al., 2005) (although interestingly, the conceptual models of Levermann et al. (2009) and Schewe et al. (2012) are characterised by a single bifurcation point for switching ‘off’ the monsoon and an arbitrary threshold to switch it back ‘on’). Crucially, the presence of a critical threshold at the transition between the strong and weak regimes of the EASM means that early warning

Zoe Thomas 16/10/2015 15:38

Deleted: in comparison to the sinusoidal insolation forcing strongly implies that this response is non-linear (Figure 1); whilst Northern Hemisphere Summer Insolation (NHSI) follows a quasi-sinusoidal cycle, the δ^{18}O profile in speleothems exhibits a step function, suggesting the presence of threshold behaviour in the monsoon system (Schewe et al., 2012).

Deleted: CO_2 (ppmv) from the Antarctic Vostok ice core (Petit et al., 1999) (black), (d) signals related to ‘critical slowing down’ (Dakos et al., 2008; Lenton et al., 2012) could be detectable in suitable proxy records.

The aim of this study was twofold: (1) to test whether shifts in the EASM during the penultimate glacial cycle (Marine Isotope Stage 6) are consistent with bifurcational tipping points, and (2) if so, is it possible to detect associated early warning signals. To achieve this, we analyse two δ^{18}O speleothem records from China, and construct a simple model that we derive directly from this data to test whether we can detect early warning signals of these transitions.

1.2 Detecting early warning signals

We perform ‘tipping point analysis’ on both the δ^{18}O speleothem records and on multiple simulations derived from our model. This analysis aims to find early warning signs of impending tipping points that are characterised by a bifurcation (rather than a noise-induced tipping, induced by stochastic fluctuations with no change in forcing control, or rate-dependent tipping, where a system fails to track a continuously changing quasi-static attractor e.g. (Ashwin et al., 2012)). These tipping points can be mathematically detected by looking at the pattern of fluctuations in the short-term trends of a time-series before the transition takes place. A phenomenon called ‘critical slowing down’ occurs on the approach to a tipping point, whereby the system takes longer to recover from small perturbations (Kleinen et al., 2003; Held & Kleinen, 2004; Dakos et al., 2008). This longer recovery rate causes the intrinsic rates of change in the system to decrease, which is detected as a short-term increase in the autocorrelation or ‘memory’ of the time-series (Ives, 1995), often accompanied by an increasing trend in variance (Lenton et al., 2012). It has been theoretically established that autocorrelation and variance should both increase together

(Ditlevsen & Johnsen, 2010; Thompson & Sieber, 2011). Importantly, it is the increasing trend, rather than the absolute values of the autocorrelation and variance that indicate critical slowing down. Detecting the phenomenon of critical slowing down relies on a timescale separation, whereby the timescale forcing the system is much slower than the timescale of the system's internal dynamics, which is in turn much longer than the frequency of data sampling the system (Held & Kleinen, 2004). Importantly, the monsoon transitions span hundreds of years (corresponding to several data points), meeting the criterion that the frequency of sampling is higher than the timescale of the transition of the system.

Zoe Thomas 12/10/2015 16:51
Deleted: , there are some factors which can negate this, discussed in detail in Dakos et al. (2012b; 2014).

1.3 Missed alarms

Although efforts have been taken to reduce the chances of type I (incorrect rejection of a true null hypothesis, otherwise known as a 'false positive') and type II (failure to reject a false null hypothesis, or 'false negative') errors by correct pre-processing of data e.g. (Lenton, 2011), totally eradicating the chances of false positive and false negative results remains a challenge (Scheffer, 2010; Lenton et al., 2012; Dakos et al., 2014). Type II errors or 'missed alarms', as discussed in Lenton (2011), may occur when internal noise levels are such that the system is 'tipped' into a different state prior to reaching the bifurcation point, precluding the detection of early warning signals. Type I errors are potentially easier to guard against by employing strict protocols by which to reject a null hypothesis.

1.4 Using speleothem δ^{18}O data as a proxy of past monsoon strength

Highly-resolved (~10^2 years) and precisely dated speleothem records of past monsoonal variability are well placed to test for early warning signals. The use of speleothem-based proxies to reconstruct patterns of palaeo-monsoon changes has increased rapidly over recent decades with the development of efficient sampling and dating techniques. However, there is currently some debate surrounding the climatic interpretation of Chinese speleothem δ^{18}O records (An et al., 2015), which can be influenced by competing factors that affect isotope fractionation. The oxygen isotopic composition of speleothem calcite is widely used to reconstruct palaeohydrological variations due to the premise that speleothem calcite δ^{18}O records the stable isotopic content of precipitation, which has been shown to be inversely correlated with precipitation amount (Dansgaard, 1964; Lee & Swann, 2010), a relationship known as the 'amount effect'. Although the δ^{18}O of speleothem calcite in China has traditionally been used as a proxy for the 'amount effect' (Cheng et al., 2006; Wang et al., 2008; Cheng et al., 2009; Wang et al., 2009), this has been challenged by other palaeo-wetness proxies, notably Maher (2008), who argues that speleothems may be influenced by changes in rainfall source rather than amount. The influence of the Indian Monsoon has also been proposed as an alternative cause for abrupt monsoon variations in China (Liu et al., 2006; Pausata et al., 2011), though this has since been disputed (Wang & Chen, 2012; Liu et al., 2014). Importantly, however, robust replications of the same δ^{18}O trends in speleothem records across the wider region suggest they principally represent changes in the delivery of precipitation δ^{18}O associated with the EASM (Cheng et al., 2009; Cheng et al., 2012; Li et al., 2013; Duan et al., 2014; Liu et al., 2014; Baker et al., 2015).

Specific data requirements are necessary to search for early warning signs of tipping points in climate systems; not only does the data have to represent a measure of climate, it also must be of a sufficient length and resolution to enable the detection of critical slowing down. In addition, since time series analysis methods require interpolation to equidistant data points, a relative constant density of data points is important, so that the interpolation does not skew the data. The speleothem δ^{18}O records that we have selected fulfil these criteria, as described in more detail in section 2.1.

2. Methods

2.1 Data selection

We used the Chinese speleothem sequences from Sanbao Cave (31°40’N, 110°26’E) (Wang et al., 2008), and Hulu Cave (32°30’N, 119°10’E) (Wang et al., 2001) to search for early warning signals. Sanbao Cave (speleothem SB11) and Hulu Cave (speleothem MSP) have two of the highest resolution chronologies in the time period of interest, with a relatively constant density of data points, providing some of the best records of Quaternary-scale monsoonal variation. Speleothem $\delta^{18}O$ records offer considerable advantages for investigating past changes in the EASM: their long duration (10^3-10^4 years), high-resolution (~100 years) and precise and absolute-dated chronologies (typically 1 kyr at 1σ), make them ideal for time series analysis. Speleothem SB11 has one of the longest, continuous $\delta^{18}O$ records in China, and is the only series spanning an entire glacial cycle without using a spliced record (Wang et al. 2008). Speleothem MSP has a comparable resolution and density to SB11, though is significantly shorter. Crucially, the cave systems lie within two regionally distinct areas (Figure 2), indicating that parallel changes in $\delta^{18}O$ cannot be explained by local effects.

Figure 2 Map showing the location of Sanbao and Hulu caves.

2.2 Searching for bimodality

A visual inspection of a histogram of the speleothem δ^{18}O data was initially undertaken to determine whether the data are likely to be bimodal. We then applied a Dip-test of unimodality (Hartigan & Hartigan, 1985) to test whether our data is bimodal. To investigate further the dynamical origin of the modality of our data we applied non-stationary potential analysis (Kwasniok, 2013; Kwasniok, 2015). A non-stationary potential model (discussed in more detail in section 2.4) was fitted, modulated by the solar forcing (NHSI June 30°N), covering the possibility of directly forced transitions as well as noise-induced transitions with or without stochastic resonance.

2.3 Tipping point analysis

A search for early warning signals of a bifurcation at each monsoon transition was carried out between 224-128 kyr of the Sanbao Cave and Hulu Cave speleothem records. Stable periods of the Sanbao Cave δ^{18}O record (e.g. excluding the abrupt transitions) were initially identified visually and confirmed by subsequent analysis using a climate regime shift detection method described by Rodionov (2004). Data pre-processing involved removal of long term trends using a Gaussian kernel smoothing filter and interpolation to ensure that the data is equidistant (a necessary assumption for time-series analysis), before the trends in autocorrelation and variance (using the R functions *acf()* and *var()* respectively) are measured over a sliding window of half the data length (Lenton et al., 2012). The density of data points over time do not change significantly in either record and thus the observed trends in autocorrelation are not an artefact of the data interpolation. The smoothing bandwidth was chosen such that long-term trends were removed without overfitting the data. A sensitivity analysis was undertaken by varying the size of the smoothing bandwidth and sliding window to ensure the results were robust over a range of parameter choices. The

nonparametric Kendall's tau rank correlation coefficient was applied (Kendall, 1948; Dakos et al., 2008) to test for statistical dependence for a sequence of measurements against time, varying between +1 and -1, describing the sign and strength of any trends in autocorrelation and variance.

2.3.1 Assessing significance

The results were tested against surrogate time series to ascertain the significance level of the results found, based on the null hypothesis that the data are generated by a stationary Gaussian linear stochastic process. This method for assessing significance of the results is based on Dakos et al. (2012a). The surrogate time series were generated by randomising the original data over 1000 permutations, which is sufficient to adequately estimate the probability distribution of the null model, and destroys the memory while retaining the amplitude distribution of the original time series. The autocorrelation and variance for the original and each of the surrogate time series was computed, and the statistical significance obtained for the original data by comparing against the frequency distribution of the trend statistic (Kendall tau values of autocorrelation and variance) from the surrogate data. Importantly, the Kendall tau values are calculated relatively, thus when the autocorrelation is destroyed by randomisation, the null model distribution does not change. Higher Kendall tau values indicate a stronger increasing trend. The 90th and 95th percentiles provided the 90% and 95% rejection thresholds (or p-values of 0.1 and 0.05) respectively. According to the fluctuation-dissipation theorem (Ditlevsen & Johnsen, 2010), both autocorrelation and variance should increase together on the approach to a bifurcation. Previous tipping point literature has often used a visual increasing trend of autocorrelation and variance as indicators of critical slowing down. Although using surrogate data allows a quantitative assessment of the significance of the results, there is no consensus on what significance

Zoe Thomas 16/10/2015 15:57

Deleted: ;

level is necessary to the declare the presence of precursors of critical slowing down. To guard against type I errors, we determine for this study that ‘statistically significant’ early warning indicators occur with increases in both autocorrelation and variance with p-values < 0.1. We have chosen this benchmark in line with previous studies using a similar null model that have described results with p<0.1 as ‘robust’ (Dakos et al., 2008; Boulton & Lenton, 2015).

2.4 Non-stationary potential analysis

To supplement the analysis of the speleothem records and help interpret the results, a simple stochastic model derived directly from the Sanabo cave $\delta^{18}O$ data was constructed. Non-stationary potential analysis (Kwasniok, 2013; Kwasniok, 2015) is a method for deriving from time series data a simple dynamical model which is modulated by external factors, here solar insolation. The technique allows extraction of basic dynamical mechanisms and to distinguish between competing dynamical explanations.

Zoe Thomas 14/9/2015 15:26

The dynamics of the monsoon system are conceptually described as motion in a time-dependent one-dimensional potential landscape; the influence of unresolved spatial and temporal scales is accounted for by stochastic noise. The governing equation is a one-dimensional non-stationary effective Langevin equation:

$$\dot{x} = -V'(x;t) + \sigma\eta \qquad (1)$$

η is a white Gaussian noise process with zero mean and unit variance, and σ is the amplitude of the stochastic forcing. The potential landscape is time-dependent, modulated by the solar insolation:

$$V(x;t) = U(x) + \gamma I(t)x \qquad (2)$$

The time-independent part of the potential is modelled by a fourth-order polynomial, allowing for possible bi-stability (Kwasniok & Lohmann, 2009):

$$U(x) = \sum_{i=1}^{4} a_i x^i \tag{3}$$

$I(t)$ is the insolation forcing and γ is a coupling parameter. The modulation of the potential is only in the linear term, that is, the time-independent potential system is subject to the scaled insolation forcing $\gamma I(t)$. The model variable x is identified with the speleothem record. The insolation is represented as a superposition of three main frequencies as

$$I(t) = \alpha_0 + \sum_{i=1}^{3} \left[\alpha_i \cos(2\pi t/T_i) + \beta_i \sin(2\pi t/T_i)\right] \tag{4}$$

with time t measured in kyr. The expansion coefficients α_i and β_i are determined by least-squares regression on the insolation time series over the time interval of the speleothem record. The periods T_i are found by a search over a grid with mesh size 0.5kyr. They are, in order of decreasing contribution $\alpha_i^2 + \beta_i^2$, $T_1 = 23$kyr, $T_2 = 19.5$kyr and $T_3 = 42$kyr. This yields an excellent approximation of the insolation time series over the time interval under consideration here.

The potential model covers and allows to us distinguish between two possible scenarios: (i) In the bifurcation scenario, the monsoon transitions are directly forced by the insolation, where two states are stable in turn, one at a time. This corresponds to a fairly large value of γ. (ii) Alternatively, two stable states could be available at all times with noise-induced switching between them. This is realised with $\gamma = 0$, giving a stationary potential. The height of the potential barrier separating the two states could be modulated by the insolation, possibly giving rise to a stochastic resonance which would explain the high degree of coherence between the solar forcing and the monsoon transitions. The latter variant would correspond to a small but non-zero value of γ.

The shape of the potential, as well as the noise level, are estimated directly from the speleothem data according to the maximum likelihood principle. We take a two-step approach, combining non-stationary probability density modelling (Kwasniok, 2013) and dynamical modeling (Kwasniok, 2015). The shape of the potential is estimated from the probability density of the data. The quasi-stationary probability density of the potential model is

$$p(x;t) = Z^{-1}(t)\exp[-2V(x;t)/\sigma^2] \tag{5}$$

with a time-dependent normalisation constant $Z(t)$. The coefficients a_i and the coupling constant γ are estimated by maximising the likelihood function

$$L(x_1,\ldots,x_N) = \prod_{i=1}^{N} p(x_n;t_n) \tag{6}$$

as described in Kwasniok (2013). The size of the data set is $N=1288$. This leaves the noise level undetermined as a scaling of the potential with a constant c and a simultaneous scaling of the noise variance with c keeps the quasi-stationary probability density unchanged. We set $\sigma = 1$ for the (preliminary) estimation of a_i and γ. The noise level is now determined from the dynamical likelihood function based on the time evolution of the system (Kwasniok, 2015). The Langevin equation is discretised according to the Euler-Maruyama scheme:

$$x_{n+1} = x_n - \delta t_n V'(x_n;t_n) + \sqrt{\delta t_n}\sigma\eta_n \tag{7}$$

The sampling interval of the data is $\delta t_n = t_{n+1} - t_n$. The log-likelihood function of the data is

$$l(x_1,\ldots,x_N|x_0) = -\frac{N}{2}\log 2\pi - N\log\sigma - \frac{1}{2}\sum_{n=0}^{N-1}\left(\log\delta t_n + \frac{[x_{n+1} - x_n + \delta t_n V'(x_n;t_n)]^2}{\delta t_n\sigma^2}\right) \tag{8}$$

The scaling constant c is searched on a grid with mesh size 0.01 and the log-likelihood maximised, giving the final estimates of all parameters. Both estimation procedures are applied directly to the unevenly sampled data without any prior interpolation. We remark that the more natural and simpler approach of estimating all parameters simultaneously from the dynamical likelihood (Kwasniok, 2015) here yields a negative leading-order coefficient a_4 and thus the model cannot be integrated over a longer time period without the trajectory escaping to infinity. This possibly points at limitations in the degree of validity of the one-dimensional potential model. Palaeoclimatic records reflect a multitude of complex processes and any model as simple as equation (1) cannot be expected to be more than a skeleton model used to pinpoint and contrast basic dynamical mechanisms. The described estimation method guarantees a positive leading-order coefficient a_4 and therefore a globally stable model.

It has been suggested that the EASM system responds specifically to 21st July insolation at 65°N with a “near-zero phase lag” (Ruddiman, 2006). However, given that EASM development is affected by both remote and local insolation forcing (Liu et al., 2006), we use an insolation latitude local to the Sanbao Cave record, consistent with earlier studies from this and other speleothem sequences (Wang et al., 2001). Since the monthly maximum insolation shifts in time with respect to the precession parameter, the 30°N June insolation was used, though we acknowledge that the insolation changes of 65°N 21 July as used by Wang et al. (2008) are similar with regard to the timing of maxima and minima. Crucially, immediately prior to Termination II, the Chinese speleothem data (including Sanbao Cave) record a ‘Weak Monsoon Interval’ between 135.5 and 129 kyr (Cheng et al., 2009), suggesting a lag of approximately 6.5 kyrs following Northern Hemisphere summer insolation (Figure 1).

Having derived a model from the data, 100 realisations were analysed to test whether early warning signals could be detected in the model output, using the methods set out in section 2.3. We initially chose the sampling resolution of the model outputs to be comparable to the speleothem data (10^2 years). Subsequently, the model was manipulated by changing both the noise level and the sampling resolution in order to explore the effect of these on the early warning signals in a hypothetical scenario. To enable a straightforward comparison of the rate of forcing and the sampling resolution we linearized the solar insolation using the minimum and maximum values of the solar insolation over the time span of the model (224-128 kyr). This approach was preferred rather than using a sinusoidal forcing since early warning signals are known to work most effectively when there is a constant increase in the forcing. To detrend the time series data, we ran the model without any external noise forcing to obtain the equilibrium solution to the system, which we then subtracted from the time series, which did include noise. In addition, we manipulated the noise level of the model by altering the amplitude of the stochastic forcing (σ in Equation 1). The time step in the series was reduced so that 6000 time points were available prior to the bifurcation and to ensure no data from beyond the tipping point was included in the analysis. Sampling the same time series at different resolutions allowed us to explore the effect of this on the early warning signals. When comparing early warning signals for differing sample steps and noise levels, the same iteration of the model was used to enable a direct comparison.

Zoe Thomas 12/10/2015 13:56
Deleted: Sampling the same time series at different resolutions and noise levels allows us to explore the effect of these on the early warning signals. Accordingly, the model was manipulated by changing both the noise level and sampling resolution

that observe bimodality in tropical monsoon systems (Zickfeld et al., 2005; Schewe et al., 2012). We also apply a Dip-test of unimodality (Hartigan & Hartigan, 1985) and find that our null hypothesis of unimodality is rejected (D=0.018, p=0.0063) and thus our data is at least bimodal. To investigate further the dynamical origin of this bimodality we applied non-stationary potential analysis (Kwasniok, 2013; Kwasniok, 2015). This showed a bi-stable structure to the EASM with hysteresis (Figure 3b, c), suggesting that abrupt monsoon transitions may involve underlying bifurcations. The monsoon transitions appear to be predominantly directly forced by the insolation. There is a phase in the middle of the transition cycle between the extrema of the insolation where two stable states are available at the same time but this phase is too short for noise-induced switches to play a significant role.

We are able to clearly refute from the speleothem data the scenario of noise-induced switching between two simultaneously available states in favour of the bifurcation scenario. When fitting a model without solar insolation forcing (that is, $\gamma = 0$) we obtain a stationary potential with two deep wells and noise-driven switching between them. However, the pdf-based log-likelihood of equation (6) is $l = -2149.1$ versus $l = -1943.2$ for the model with insolation forcing and the dynamical log-likelihood of equation (8) is $l = -353.6$ versus $l = -346.6$. This provides very strong evidence for the bifurcation scenario; based on both likelihood functions, both the Akaike and the Bayesian information criterion clearly prefer the model with solar insolation forcing. The value of γ is fairly large and the stationary part of the potential is not strongly bistable, as evidence by the shape of the potential given in Figure 3, ruling out the stochastic resonance scenario. The uncertainty in all parameters, including the noise level, is very small, making our model estimation robust. We tried more complicated models where also the higher-order terms in the potential are modulated by the insolation rather than just the linear term or where the solar insolation enters nonlinearly into the model; the gain in likelihood is found to be rather minor compared to the gain achieved when adding the modulation in the linear term of the potential.

Figure 3 (a) Histogram showing the probability density of the speleothem data aggregated over 224-128 kyr, (b) Bifurcation diagram obtained from potential model analysis, showing bi-stability and hysteresis. Solid black lines indicate stable states, dotted line unstable states, and dashed vertical lines the jumps between the two stable branches. Coloured vertical lines correspond to the insolation values for which the potential curve is shown in panel c; (c) Shows how the shape of the potential well changes over one transition cycle (198-175 kyr) (green long dash = 535 W/m^2, purple short dash = 531 W/m^2, blue solid = 490 W/m^2, red dotted = 449 W/m^2) (for more details see Figure 10).

3.2 Tipping point analysis

We applied tipping point analysis on the Sanbao Cave δ^{18}O record on each section of data prior to a monsoon transition. Although autocorrelation and variance do increase prior to some of the abrupt monsoon transitions (Figure 4), these increases are not consistent through the entire record. Surrogate datasets used to test for significance of our results showed that p-values associated with these increases are only <0.1 for both autocorrelation and variance (Figure 5) in one instance. Although a visual increasing trend has been used in previous literature as an indicator of critical slowing down, we choose more selective criteria to guard against the possibility of false positives.

The only section of data prior to a monsoon transition that sees p-values of <0.1 for the increases in both autocorrelation and variance is for the data spanning the period 150 to 129 kyr in the Sanbao Cave record, before Monsoon Termination II (Figure 6). We find that the Kendall tau value for autocorrelation has a significance level of $p < 0.05$ and for variance a significance level of $p < 0.1$ (Figure 5a and 5b). These proportional positive trends in both autocorrelation and variance are consistent with critical slowing down on the approach to a bifurcation (Ditlevsen & Johnsen, 2010).

To test whether the signal is present in other EASM records, we undertook the same analysis on a second speleothem sequence of comparable age (Figure 7). We find that speleothem MSP from Hulu Cave (32°30’N, 119°10’E) (Wang et al., 2001) displays a comparable increase in autocorrelation and variance to speleothem SB11 from Sanbao Cave, though these do display slightly lower p-values (Figure 5c and 5d).

Furthermore, a sensitivity analysis was performed (results shown for data preceding the monsoon termination in both speleothem SB11 and MSP, Figure 8) to ensure that the results are robust over a range of parameters by running repeats of the analysis with a range of smoothing bandwidths used to detrend the original data (5-15% of the time series length)

and sliding window sizes in which indicators are estimated (25-75% of the time series length). The colour contours show how the Kendall tau values change when using different parameter choices; for the autocorrelation at Sanbao Cave the Kendall tau values are over 0.8 for the vast majority of smoothing bandwidth and sliding window sizes (Figure 8a), indicating a robust analysis.

Deleted: analysis

To help interpret these results we applied our potential model. In the model we find transitions occur under direct solar insolation forcing when reaching the end of the stable branches, explaining the high degree of synchronicity between the transitions and solar forcing. The initial 100 realisations produced from our potential model appear broadly to follow the path of June insolation at 30°N with a small phase lag (Figure 9). The model simulations also follow the speleothem palaeodata for all but the monsoon transition at 129 ka BP near Termination II, where the model simulations show no extended lag with respect to the insolation. Again it has to be kept in mind that the potential model as a skeleton model can only be expected to qualitatively reproduce the main features of the data. Actually observing the speleothem record as a realisation of the model will always be highly unlikely with any model as simple as the present one.

Figure 9 Probability range of 100 model simulations, with the June 30°N NHSI (in red), and the palaeodata from SB11 (in green).

No consistent early warning signals were found in the initial 100 model simulations during the period 224-128 kyr. In order to detect critical slowing down on the approach to a bifurcation, the data must capture the gradual flattening of the potential well. We suggest that early warning signals were not detected due to a relatively fast rate of forcing compared to the sampling of the system; this comparatively poor sampling prevents the gradual flattening of the potential well from being recorded in the data; a feature common to many palaeoclimate datasets. Figure 10 illustrates the different flattening of the potential well over a transition cycle during the glacial period and over the transition cycle at the termination. There is more visible flattening in the potential at the termination, as seen in panel (c), which is thought to be due to the reduced amplitude of the solar forcing at the termination. The distinction between these two transitions cycles helps to explain why early warning signals in the form of increasing autocorrelation and variance are found immediately preceding the termination, but not for the other monsoon transitions.

To test the effect on the early warning signals of the sampling resolution of the model, we compared a range of different sampling time steps in the model (see section 2.4) measuring the Kendall tau values of autocorrelation and variance over each realisation of the model (one realisation displayed in Figure 11), which demonstrates the effects of increasing the sampling time step in the model. We found that whereas an increasing sampling time step produces a steady decrease in the Kendall tau values for autocorrelation (Figure 11b), Kendall tau values remain fairly constant for variance (Figure 11c), suggesting that the latter is not affected by time step changes. This supports the contention by Dakos et al. (2012b) that ‘high resolution sampling has no effect on the estimate of variance’. In addition, we manipulated the noise level and found that decreasing the noise level by a factor of 2 was necessary to identify consistent early warning signals. This is illustrated in Figure 11a, where the grey line represents the noise level as determined by the model, which does not follow a step transition, and cannot be adequately detrended by the equation derived from the model. However, once the noise level is sufficiently reduced, early warning signals (displayed here as high Kendall tau values for autocorrelation and variance) can be detected.

Figure 11 a) Example of single realisation of the approach to a bifurcation from our potential model, which has been generated using 4 different noise levels (original noise = grey, 0.5 noise = black, 0.2 noise = blue, 0.1 noise = green). Tipping point analysis was applied on each realisation, where the red line depicts the detrending line and the grey dashed vertical line is the cut-off point where data is analysed up to; distribution of Kendall

4. Discussion

It is important to note here that although the detection of early warning signals in time series data has been widely used for the detection of bifurcations in a range of systems (Dakos et al., 2008), there are instances when critical slowing down cannot be detected/recorded prior to a bifurcation. First is the assumption that the abrupt monsoon shifts are characterised by a bifurcation, rather than noise-induced tipping or stochastic resonance. The bifurcation hypothesis is supported by previous studies (Zickfeld et al., 2005; Levermann et al., 2009; Schewe et al., 2012) as well as our potential model, which selects a bifurcation as the most likely scenario (whilst considering noise-induced tipping and stochastic resonance). In a noise-induced tipping or stochastic resonance scenario, no early warning signals would be expected since there would be no gradual change in the stability of the system (Lenton, 2011). Even within the bifurcation scenario, it is possible that early warning signals may not be detected due to external dynamics of the system, such as a high level of stochastic noise, or when there is an insufficient sampling resolution. The results illustrated in Figure 11 confirm that early warning signals may not be detected for bifurcations if the rate of forcing is too fast compared to the sampling rate, such that the flattening of the potential is poorly recorded in time series; Figure 11c clearly illustrates the detrimental effect of a lower resolution on Kendall tau values, particularly for autocorrelation. 'Missed alarms' may therefore be common in palaeodata where there is an insufficient sampling resolution to detect the flattening of the potential; a high sampling resolution is thus recommended to help avoid this issue. There is more flattening visible in

the potential for the monsoon transition at 129 ka BP (Termination II), which is due to the reduced amplitude of the orbital forcing at the termination, but it is unclear whether this is sufficient to explain the early warning signal detected in the palaeodata. We suggest that additional forcing mechanisms may be driving the termination e.g. (Caley et al., 2011) which cannot be captured by the potential model (as evidenced by the trajectory of the data falling outside the probability range of the potential model (Figure 9)).

Zoe Thomas 16/10/2015 16:17
Deleted: solar

One possible reason for the detection of a critical slowing down immediately prior to the termination (129 ka BP) is a change in the background state of the climate system. Termination II is preceded by a Weak Monsoon Interval (WMI) in the EASM at 135.5-129 kyr (Cheng et al., 2009), characterised by the presence of a longer lag between the change in insolation and the monsoon transition. The WMI is thought to be linked to migrations in the Inter-tropical Convergence Zone (ITCZ) (Yancheva et al., 2007). Changes in the latitudinal temperature gradient (Rind, 1998) or planetary wave patterns (Wunsch, 2006) driven by continental ice volume (Cheng et al., 2009) and/or sea ice extent (Broccoli et al., 2006) have been suggested to play a role in causing this shift in the ITCZ. For instance, the cold anomaly associated with Heinrich event 11 (at 135 ka BP) has been invoked as a possible cause of the WMI, cooling the North Atlantic and shifting the Polar Front and Siberian High southwards, forcing an equatorward migration of westerly airflow across Asia (Broecker et al., 1985; Cheng et al., 2009; Cai et al., 2015). Such a scenario would have maintained a low thermal gradient between the land and sea, causing the Weak Monsoon Interval and potentially suppressing a simple insolation response. The implication is that during the earlier monsoon transitions in Stage 6, continental ice volume and/or sea-ice extent was less extensive than during the WMI, allowing the solar insolation response to dominate.

5. Conclusions

We analysed two speleothem $\delta^{18}O$ records from China over the penultimate glacial cycle as proxies for the past strength of the EASM to test whether we could detect early warning signals of the transitions between the strong and weak regimes. After determining that the data was bimodal, we derived a non-stationary potential model directly from this data featuring a fold bifurcation structure. We found evidence of critical slowing down before the abrupt monsoon shift at Termination II (129 ka BP) in the speleothem $\delta^{18}O$ data. However, we do not find consistent early warning signals of a bifurcation for the abrupt monsoon shifts in the period between 224-150 kyr, which we term 'missed alarms'. Exploration of sampling resolution from our model suggests that the absence of robust critical slowing down signals in the palaeodata is due to a combination of rapid forcing and the insufficient sampling resolution, preventing the detection of the steady flattening of the potential that occurs before a bifurcation. We also find that there is a noise threshold at which early warning signals can no longer be detected. We suggest that the early warning signal detected at Termination II in the palaeodata is likely due to the longer lag during the Weak Monsoon Interval, linked to cooling in the North Atlantic. This allows a steadier flattening of the potential associated with the stability of the EASM and thus enables the detection of critical slowing down. Our results have important implications for identifying early warning signals in other natural archives, including the importance of sampling resolution and the background state of the climate system (full glacial versus termination). In addition, it is advantageous to use archives which record multiple transitions, rather than a single shift, such as the speleothem records reported here; the detection of an early warning signal during one transition compared to previous events in the same record
