Dear Raphael,

Thank you for reviewing our manuscript a second time. Our paper has improved from these two rounds of constructive comments.

Please see our replies below (reviewer comments italicized):

1. The signal remains quite weak in the observational period, due to the influence of internal variability and the relatively weak eruptions with still uncertain forcing. The authors have pointed out this in the text, with some additional paragraphs in the revised version. I think it is worth mentioning this caveat in the abstract (potentially accompanied by the argument that the LM model analysis is helpful in this regard thanks to the larger number of eruptions available and possibility to quantify the (internal-)noise component).

Agreed. We have modified our abstract to discuss the caveat of the L20 (historic) eruptions yielding inconclusive results.

2. Are the correlation values in Figure 9 correct? From the Figure, I would rather expect significant values in both seasons for temperature and non-significant correlation for DJF-precip. Is it possible that the numbers got mixed up here or did I get something wrong?

The correlation values previously reported were correct, and are slightly altered in the new text due to a more consistent spatial domain averaging (see comment #3 below).

The temperature response is indeed significant in JJA (in the northern South American domain) in response to volcanic forcing, but when this spatially averaged temperature is plotted against the spatially averaged isotopic signal (using 45 volcanic events in the regression), there is a weak and non-significant relation. We argued in the text that precipitation reduction in northern South America is instead the dominant contributor to the isotopic enrichment that we see during this season/location. During DJF, we believe both temperature and precipitation are important in driving the isotopic signal, although the two factors seem to be driving it in opposite directions. In the spatial composite or in a multiple linear regression, the temperature effect "wins" (unlike JJA) if only those two predictors are used. We have added a supplementary Figure S7, reproduced below, to our manuscript and added text in section 3.2.3 to further support this interpretation.
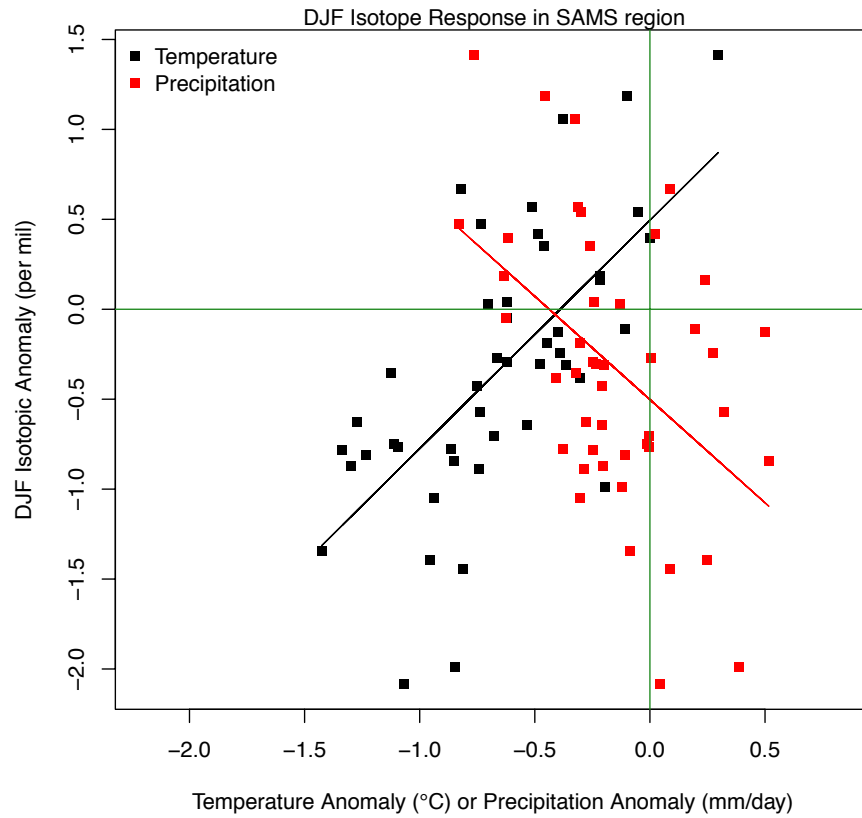

Fig. S7. Regression of spatially-averaged DJF $\delta^{18}O_p$ anomaly vs. temperature (black squares) or
precipitation (red squares). The regression uses all 45 LM volcanic events and averaging is done
over the SAMS domain defined in the text. Black and red lines are the corresponding (least-
squares) regression lines.

*3. I am a bit surprised by the weak signal in Fig. 12 bottom-right panel (isotopic
response in JJA). This was not well visible in the figure in the first submission, so it did
not call my attention. The purple square is hardly outside the range of values from the
control simulation. In Fig. 10 the values seem to be quite large (mostly above 0.3 over
the domain considered), so the value of ca. 0.15 in Fig. 12 appears to be too low. Is this
because the northern part of the selected domain is affected by the negative values
seen over the Atlantic? Would this make it worth moving the northern limit 1-2
degrees south to have a more consistent domain?*

56 *If not, I think it's worth noting in the text that the signal is only marginally larger than*
57 *internal variability for this specific season and variable.*
58
59 Thank you for pointing this out. We agree that our choice of domain was not optimal.
60 We have changed the averaging domain, which now yields a larger JJA isotopic
61 signal (Figure 12, bottom right) that is easier to reconcile with the large signal in the
62 spatial composite (Figure 10). Figures 2 and 9 have been re-plotted and domains
63 redefined throughout the text for consistency.
64

The influence of volcanic eruptions on the climate of tropical South America during the

last millennium in an isotope-enabled GCM

88   **Abstract**

89

90   Currently, little is known on how volcanic eruptions impact large-scale climate

91   phenomena such as South American paleo-ITCZ position and summer monsoon behavior.

92   In this paper, an analysis of observations and model simulations is employed to assess the

93   influence of large volcanic eruptions on the climate of tropical South America. This

94   problem is first considered for historically recent volcanic episodes for which more

95   comprehensive global observations exist, but also where fewer events and the

96   confounding effects of ENSO lead to inconclusive interpretation of the impact of

97   volcanic eruptions at the continental scale. Therefore, we also examine a greater number

98   of reconstructed volcanic events for the period 850 C.E. to present that are incorporated

99   into the NASA GISS ModelE2-R simulation of the Last Millennium.

100   An advantage of this model is its ability to explicitly track water isotopologues

101   throughout the hydrologic cycle and simulating the isotopic imprint following a large

102   eruption. This effectively removes a degree of uncertainty associated with error-prone

103   conversion of isotopic signals into climate variables, and allows for a direct comparison

104   between GISS simulations and paleoclimate proxy records.

105   Our analysis reveals that both precipitation and oxygen isotope variability respond

106   with a distinct seasonal and spatial structure across tropical South America following an

107   eruption. During austral winter, the heavy oxygen isotope in precipitation is enriched,

108   likely due to reduced moisture convergence in the ITCZ domain and reduced rainfall over

109   northern South America. During austral summer, however, precipitation is depleted in

110   heavy isotopes over Amazonia, despite reductions in rainfall, suggesting that the isotopic

120   response is not a simple function of the 'amount effect.' During the South American

121   monsoon season, the amplitude of the temperature response to volcanic forcing is larger

122   than the rather weak and spatially less coherent precipitation signal, complicating the

123   isotopic response to changes in the hydrologic cycle.

142   **1. Introduction**

143

1.1.   Volcanic Forcing on Climate

145

Plinian (large, explosive) volcanic eruptions are a dominant driver of naturally

forced climate variability during the Last Millennium (LM, taken here to be 850 C.E. to

present; e.g., Stothers and Rampino, 1983; Hansen et al., 1992; Crowley et al., 2000;

Robock et al., 2000; Robock, 2003; Goosse et al., 2005; Yoshimori et al., 2005; Emile-

Geay et al., 2008; Cole-Dai, 2010; Timmreck, 2012; Iles et al., 2013; Schurer et al.,

2014). In addition to their importance for 20th century climate, they are the largest

magnitude external forcing during last 1000 years of the pre-industrial period, the most

recent key interval identified by the Paleoclimate Modelling Intercomparison Project

Phase III (PMIP3). As such, these eruptions serve as a natural testbed to assess the skill

of climate models in simulating how climate responds to external perturbations.

Although the most significant climate impacts of eruptions are realized over just a

few years following the eruption, they provide the source of the largest amplitude

perturbations to Earth's energy budget during the LM. For example, the eruption of Mt.

Pinatubo in June 1991, although transitory, exerted a radiative forcing comparable to an

instantaneous halving of atmospheric CO_2 [Hansen et al., 1992; Minnis et al., 1993; see

also Driscoll et al. (2012) for models in the Coupled Model Intercomparison Project

Phase 5 (CMIP5)]; several paleo-eruptions during the LM likely had an even larger

global impact (Figure 1).

The principle climate impact from volcanic eruptions results from the liberation

of sub-surface sulfur-containing gases such as sulfur dioxide, which are injected into the

Allegra N LeGrande 2/19/2016 8:51 AM
Deleted: and hydrogen sulfide

7

167 stratosphere and react with water to form sulfate aerosols (e.g., Harshvardhan and Cess,

168 1976; Coakley and Grams, 1976; Pollack et al., 1976, 1981; Lacis et al., 1992). The most

169 pronounced impact of large tropical eruptions includes a radiatively cooled troposphere

170 and heated stratosphere (e.g., Lacis et al., 1992; Robock and Mao, 1995; Stenchikov et al.,

171 1998). Sulfate aerosols from the Mt. Pinatubo eruption grew from a background effective

172 radius of ~0.2 μm up to ~0.8 μm, strongly scattering incoming solar radiation. For sulfate

173 aerosols in this size range, this shortwave scattering is 5-10x larger than the increase in

174 infrared opacity from the aerosols, and results in a warming stratosphere and cooling of

175 Earth's surface (Turco et al., 1982; Lacis et al., 1992).

176   Studies on the impacts of volcanic eruptions have generally focused on global or

177 Northern Hemisphere metrics (e.g., Lucht et al., 2002; Gillett et al., 2004; Shindell et al.,

178 2004; Oman et al., 2005; Oman et al., 2006; Anchukaitis et al., 2010; Peng et al., 2010;

179 Evan et al., 2012; Zhang et al., 2013; Man et al., 2014), for instance in examining

180 responses to the East Asian monsoon system (EAMS) or the Arctic Oscillation.

181 Comparatively little attention has been given to the Southern Hemisphere, or to South

182 America specifically (although see Joseph and Zeng, 2011, and Wilmes et al., 2012).

183 Some previous work has focused on the Southern Annular Mode in the ERA-40 and

184 NCEP/NCAR reanalysis, in addition to a previous version of NASA Goddard Institute

185 for Space Studies (GISS) Model-E (Robock et al., 2007) and in a subset of CMIP3

186 models (Karpechko et al., 2010) or in CMIP5 (Gillett and Fyfe, 2013).

187   How volcanic forcing is expressed over South America remains an important

188 target question for several reasons. First, recognition of the South American monsoon

189 system (SAMS) as an actual monsoon system is less than two decades old (Zhou and Lau,

8

190   1998), and thus study of SAMS dynamics is still relatively young (section 1.3) and very

191   little work has been done specifically focused on volcanic eruptions. For instance, should

192   we expect to see a reduction in austral summer rainfall (during the monsoon season) as

193   has been reported for the EAMS (Man et al., 2014)? Secondly, the largest volcanic

194   eruptions during the late 20th century (e.g., Mt. Agung, 1963, Indonesia; El Chichón,

195   1982, Mexico; Mt. Pinatubo, 1991, Island of Luzon in the Philippines- hereafter, these

196   three events are referred to as L20 eruptions) occur quasi-simultaneously with an

197   anomalous El Niño-Southern Oscillation (ENSO) state, and in general represent a small

198   sample size in a noisy system. This limits the prospect of robust hypothesis testing and

199   guidance for what impacts ought to be expected following large eruptions at the

200   continental scale. Finally, South America offers promise for a comparatively dense

201   network of high-resolution proxy locations relative to other tropical regions (see below),

202   offering the potential to detect whether South American hydroclimate signals to large

203   eruptions are borne out paleoclimatically.

204   In this study, we explore the post-volcanic response of South American climate

205   operating through the vehicle of unique model simulations (spanning the LM) using the

206   recently developed GISS ModelE2-R (LeGrande et al., 2015, in prep; Schmidt et al.,

207   2014a), which allows for the sampling of a greater number of events than is possible over

208   the instrumental period. Emphasis is placed on temperature and precipitation, but a novel

209   part of this study extends to the response of water isotopologues (e.g., $H_2^{18}O$)

210   [colloquially referred to hereafter as 'isotopes' and expressed as $\delta^{18}O$ in units per mil (‰)

211   vs. Vienna Standard Mean Ocean Water]. The isotopic composition of precipitation

9

212 ($\delta^{18}O_p$) is a key variable that is directly derived from proxy data used in tropical

213 paleoclimate reconstructions.

214   The aim of this paper is to create a potentially falsifiable prediction for the

215 isotopic imprint that a volcanic eruption should tend to produce across the South

216 American continent. The ability to explicitly model the isotopic response allows for a less

217 ambiguous comparison of simulations and paleoclimate records and for hypothesis

218 testing. It is unclear whether or not the current proxy archives are suitable to test such a

219 prediction with high confidence, given dating uncertainties (in both proxies and in the

220 actual timing of eruptions), or the level of noise in proxy data and the real world.

221 Additionally, the prevailing high-resolution archives in South America only feature a few

222 tropical records (Vimeux et al., 2009; Neukom and Gergis, 2012; Vuille et al., 2012).

223 Nonetheless, the growing number of high-resolution records offers hope that testing the

224 modeled response to high-frequency volcanic signals will be an avenue for future

225 research. This can also better inform debate centered on the inverse problem in

226 interpreting isotopic signals (i.e., what do observed changes in proxy data imply about

227 past climate changes?), which remains contentious (section 1.4).

228   The structure of this article is as follows: in the remaining part of section 1, we

229 summarize previous literature on the impact of large volcanic eruptions on paleoclimate,

230 in addition to a discussion of South American climate. Section 2 presents data and

231 methodology, including how volcanic forcing is implemented in ModelE2-R. Section 3

232 discusses our results and we end with conclusions in section 4.

233

234 1.2.   Volcanic forcing during the Last Millennium

235

236   Volcanic forcing has had a very large influence on the climate of the LM

237 (Crowley, 2000; Hegerl et al., 2003; Shindell et al., 2004; Mann et al., 2005; Hegerl et al.,

238 2006; Fischer et al., 2007; D'Arrigo et al., 2009; Timmreck, 2012; Esper et al., 2013;

239 Ludlow et al., 2013; Schurer et al., 2014). Several studies (Miller et al., 2012; Schurer et

240 al., 2014; Atwood et al., 2016; McGregor et al., 2015) collectively provide a compelling

241 case that volcanic forcing may be substantially more important than solar forcing on a

242 hemispheric-to-global scale during the LM, in addition to driving a large portion of the

243 inter-annual to multi-decadal variability in LM simulations (Schmidt et al., 2014b).

244   Two volcanic forcing datasets (Gao et al., 2008; Crowley and Unterman, 2013)

245 relying on ice core reconstructions of volcanism are used as input in the LM ModelE2-R

246 simulations (and are the CMIP5/PMIP3 LM standard), as discussed in Section 2.

247

248 1.3.   Tropical South American Climate

249

250   South America is home to nearly 390 million people. The continent spans a vast

251 meridional extent (from ~10 °N to 55 °S), contains the world's largest rainforest (the

252 Amazon), in addition to one of the driest locations on Earth (the Atacama desert). The

253 continent has diverse orography, spanning the high Andes along the Pacific to Laguna del

254 Carbón in Argentina, the lowest point in the Southern Hemisphere. Because of this, South

255 America hosts a rich diversity of climate zones and biodiversity, all of which may

256 respond in unique ways to external forcing.

257   The most prominent climatic feature of tropical and subtropical South America is

Chris Colose 2/19/2016 5:56 PM
Deleted: 2015, in press

259   the South American monsoon system (Zhou and Lau, 1998; Marengo et al., 2001; Vera et

260   al., 2006; Garreaud et al., 2009; Marengo et al., 2012). Much of South America is in a

261   monsoon regime, with tropical/subtropical rainfall over the continent exhibiting a

262   pronounced seasonal cycle. Unlike other monsoon systems such as that in Asia, low-level

263   easterly winds prevail during the entire year in tropical South America, although the wind

264   anomalies do change direction when the annual mean wind field is removed from winter

265   and summer composites (Zhou and Lau, 1998).

266   During austral winter, the maximum in continental precipitation is largely

267   restricted to north of the equator, in a band-like pattern associated with the oceanic Inter-

268   Tropical Convergence Zone (ITCZ). During austral summer, convection is displaced

269   from northwestern South America, and a band of heavy precipitation covers much of the

270   continent, from the southern Amazon Basin to central Brazil and northern Argentina. A

271   distinctive feature of the SAMS is the South Atlantic Convergence Zone (SACZ), a band

272   of cloudiness and precipitation sourced primarily from the tropical Atlantic that extends

273   diagonally (southeastward) from the Amazon towards southeastern Brazil (Figure 2).

274   The SAMS onset occurs around the end of October and the demise between the

275   end of March and April (e.g., Nogués-Paegle et al., 2002; Vera et al., 2006; Silva and

276   Carvalho, 2007). The dominant mode of intraseasonal precipitation variability over South

277   America during summer exhibits a dipole pattern (Nogués-Paegle and Mo, 1997),

278   seesawing between the SACZ region and Southeastern South America, the latter

279   including the densely populated La Plata basin with local economies strongly dependent

280   on agricultural activities.

281　　　　The SAMS is strongly modulated by ENSO behavior on inter-annual timescales

282　　(Vuille and Werner, 2005; Garreaud et al., 2009). In general, SAMS-affected regions of

283　　tropical South America tend to experience drier than normal conditions during El Niño,

284　　while conditions in subtropical latitudes are anomalously humid, including the

285　　southeastern part of the continent. Surface air temperatures tend to be anomalously warm

286　　in tropical and subtropical South America during El Niño events. These relationships

287　　depend somewhat on the time of year, and during La Niña events, the pattern is

288　　essentially reversed.

289

290　　1.4.　Recent South American Monsoon reconstructions from isotopic proxies

291

292　　　　　SAMS variability spanning most of the Holocene has been diagnosed from

293　　speleothem records in the Peruvian Andes (Kanner et al., 2013) and a review focused on

294　　the last 1,000-2,000 years was given in Bird et al. (2011) and Vuille et al. (2012). In all

295　　cases, a critical piece of information that is required to properly diagnose paleo-SAMS

296　　variability is the ability to translate oxygen isotope variability from natural recorders into

297　　a physical climate signal of interest.

298　　　　　Early work on isotopes in ice core records from the tropical Andes detected a

299　　Little Ice Age (LIA) signal in the oxygen isotope composition of the ice, with results

300　　initially interpreted to reflect variations in local temperature due to their resemblance to

301　　ice core records from Greenland (e.g., Thompson et al., 1995, 1998) and due to their

302　　isotopic enrichment over the past 150 years, in parallel with rising global mean

303　　temperatures (Thompson et al., 2006). A temperature-dependence to oxygen isotope

13

304   variability has been long known and is particularly important in mid-to-high latitudes

305   (Dansgaard, 1964) and is most directly related to the ratio of initial and final water vapor

306   content of a parcel that is transported horizontally, rather than the temperature-

307   dependence of fractionation itself (Hoffman and Heimann, 1997).

308   This interpretation in the tropics has been challenged through a number of

309   observational and modeling efforts (Hardy et al., 2003; Vuille and Werner 2005; Vimeux

310   et al., 2005, 2009; Kanner et al., 2012) which suggest that the isotopic signal is more

311   closely related to the degree of rainout upstream in regions of intense convection (in the

312   case of South America, over the Amazon basin). Additionally, since sea surface

313   temperatures (SST) in the Pacific have a large influence on SAMS intensity on inter-

314   annual timescales in the present, oxygen isotope variability over much of tropical South

315   America is linked to the state of the equatorial Pacific (Bradley et al., 2003; Vuille et al.,

316   2003a,b).

317   In regimes that are highly convective in nature as in tropical South America,

318   empirical evidence shows that the amount of precipitation (the so-called "amount effect",

319   Dansgaard, 1964) rather than the condensation temperature correlates most strongly with

320    $\delta^{18}O_p$ variability, at least on seasonal to inter-annual time scales. In reality, however, the

321   rainout most relevant for the oxygen isotope signal may be at a significant distance from

322   the site where the proxy is derived, potentially complicating the use of local calibrations

323   to climatology as a guide for $\delta^{18}O_p$ interpretations (Schmidt et al., 2007). Isotopic

324   concentrations are explainable as being a function of original concentration, rainout along

325   the moisture transport path, and mixing.

326   The influence of precipitation amount on $\delta^{18}O_p$, in addition to changes in the

14

327 partitioning of precipitation sources, has also been identified on decadal to orbital

328 timescales through speleothem records and lake sediments (Cruz et al., 2005; Van

329 Breukelen et al., 2008; Bird et al., 2011; Kanner et al., 2012). These studies have also

330 highlighted the role of latitudinal displacements of the ITCZ, which is ultimately the

331 main moisture conduit for precipitation over the South American continent. Furthermore,

332 many records collected throughout South America now provide evidence for enriched

333 $\delta^{18}O_p$ values during the Medieval Climate Anomaly, which is indicative of weakened

334 SAMS convection and rainout, followed by depleted $\delta^{18}O_p$ values, suggesting heavier

335 rainfall during the LIA in tropical South America (Bird et al., 2011; Apaestegui et al.,

336 2014) with an opposite response in Northeast Brazil (Novello et al., 2012). This, in turn,

337 has been interpreted in terms of North Atlantic SST anomalies (Vuille et al., 2012; Ledru

338 et al., 2013) and the position of the Atlantic ITCZ.

339   Nonetheless, oxygen isotopes respond in unique ways depending on the climate

340 forcing of interest. Indeed, a unique, quantitative local relationship between an isotope

341 record and any particular climate variable of interest is unlikely to hold for all timescales

342 and prospective forcing agents (Schmidt et al., 2007) thus motivating the use of forward

343 modeling to work in conjunction with proxy-based field data. For the remainder of this

344 paper, we focus specifically on the volcanic forcing response.

345

346 **2.   Methodology**

347

348 2.1.   Data

349

15

350   The primary tool used in this study is the water isotope-enabled GISS ModelE2-

351   R. ModelE2-R is a fully coupled atmosphere-ocean GCM (LeGrande et al., 2015, in prep;

352   Schmidt et al., 2014a) that explicitly tracks stable water isotopes. The version used here

353   is the same as the non-interactive atmospheric composition (NINT) physics version used

354   in the CMIP5 experiments (Miller et al., 2014). The current model features 2° latitude x

355   2.5° longitude horizontal resolution and 40 vertical levels in the atmosphere up to 0.1 hPa,

356   and is coupled to the Russell Ocean that conserves heat, water mass, and salt (Russell et

357   al., 1995) at 1° x 1.25° resolution with 32 vertical levels. ModelE2-R includes

358   stratospheric dynamics and prescribed ozone and aerosol species.

359   Due to uncertainties in past radiative forcing, a suite of LM simulations using

360   ModelE2-R have been run with different combinations of plausible solar, volcanic, and

361   anthropogenic land use histories (Schmidt et al., 2011, 2012) but with identical

362   greenhouse gas and orbital evolution. These simulations span the period 850-2005 C.E.

363   There are two reconstructions of past volcanic activity (Gao et al., 2008; Crowley and

364   Unterman, 2013) that are used in six combinations of the ModelE2-R LM simulations

365   (see the 'past1000' experimental design at http://data.giss.nasa.gov/modelE/ar5/, and

366   below).

367   For the LM, three forcing combinations are available in the GISS ModelE2-R

368   simulations that use the Crowley reconstruction for volcanic perturbations. These include

369   Pongratz et al. (2008) [land]/ Krivova et al. (2007) [solar], Kaplan et al (2010)

370   [land]/Krivova et al. (2007) [solar], and Pongratz et al. (2008) [land]/Steinhilber et al.

371   (2009) [solar] (see Schmidt et al., 2011, 2012). We focus only on results from the

372   Crowley reconstruction prior to 1850 CE due to a mis-scaling of the Gao forcing in the

16

373   model that roughly doubled the appropriate radiative forcing. For the historical period

374   (1850-present), the volcanic forcing history is based on Sato et al. (1993) and is

375   equivalent among the different (six) simulation members.

376   Water isotope tracers are incorporated into the model's atmosphere, land surface,

377   sea ice, and ocean. These isotopes are advected and tracked through every stage of the

378   hydrologic cycle. At each phase change (including precipitation, evaporation, ice

379   formation or melting) an appropriate fractionation factor is applied (Schmidt et al., 2005)

380   and all freshwater fluxes are tagged isotopically. Stable isotope results from the lineage

381   of GISS models have a long history of being tested against observations and proxy

382   records (e.g., Schmidt et al., 2007; LeGrande and Schmidt, 2008, 2009; Lewis et al., 2010,

383   2013, 2014; Field et al., 2014).

384   Crowley and Unterman (2013) discuss the details behind the LM Aerosol Optical

385   Depth (AOD) reconstruction that defines the volcanic forcing time-series in ModelE2-R

386   (Figure 1). This estimate is derived from sulfate peaks in ice cores, which are relatively

387   well dated and referenced to the historical record during the satellite era. Crowley and

388   Unterman (2013) provide an AOD history over 4 latitude bands (from 0-30° and 30-90°

389   in both hemispheres). ModelE2-R uses a cubic spline to interpolate this forcing dataset

390   over 24 latitude bands. The choice of volcanic eruptions used for the LM analysis

391   (section 2.2 below) is based on the AOD dataset from this 24-latitude grid.

392   In addition to the model, we briefly explore post-L20 eruption results in the

393   instrumental record. To do this, we take advantage of the NASA GISS Surface

394   Temperature analysis (GISTEMP) land-ocean index (Hansen et al., 1999), and Global

395   Precipitation Climatology Centre (GPCC) v6, a monthly precipitation dataset over land

17

396 (Schneider et al., 2011). For Figures 2 and 3 where ocean climatological data is shown,

397 we use the Global Precipitation Climatology Project (GPCP) version 2.2 (Adler et al.,

398 2003), a combined land station and satellite product available since 1979. These datasets

399 are called upon to gauge the tropical climate response following the three L20 eruptions.

400 We use the 2.5° resolution GPCC dataset, as that is comparable to the GISS model and

401 what is justified by the station coverage in this part of the world. The GPCC product

402 offers considerably better global and South American coverage than other precipitation

403 datasets, although observational density for rainfall is still considerably more problematic

404 over South America than for many other regions of the globe. There is a sharp drop-off in

405 the number of rain gauge stations used earlier in the 20th century over much of the South

406 American continent. Figure S1 shows the station density at the time of each L20 eruption,

407 as well as the total number of land stations over South America with time.

408   Finally, in section 3.1 we present data from the Global Network of Isotopes in

409 Precipitation (GNIP) accessible from the International Atomic Energy Agency (IAEA)

410 for $\delta^{18}O_p$, as a test of the model's ability to track the seasonal hydrologic cycle in the

411 form of its isotopic response over South America before discussing the Last Millennium

412 results. Unfortunately, there is considerable spatial and temporal heterogeneity in the

413 GNIP data over South America. In fact, only a few stations have data overlap with one or

414 two eruptions and with a sufficient number of $\delta^{18}O_p$ data points to establish reasonable

415 seasonal or annual statistics. Additionally, the post-volcanic (L20) anomalous isotope

416 field over South America strongly resembles the ENSO expression on the isotope field

417 (Vuille et al., 2003a) and with large spread between events (not shown). This suggests

418 that internal variability (ENSO) dominates the forced (volcanic) response in this very

18

419   small historical sample size, thereby leaving little hope that the prevailing network of

420   observations is suitable for hypothesis testing and model validation in our context.

421

422   2.2 Super-posed Epoch and Composite Analysis

423

424   We present the spatial pattern of observed and simulated response for temperature

425   and precipitation over land for two L20 eruptions (El Chichón and Mt. Pinatubo). Results

426   are shown for annual-means in 1983 and 1992. We choose only two for brevity, as our

427   argument that assessing the signal in any specific region is difficult in a small sample of

428   eruptions is unaffected. Because of the dominant influence of unforced variability on

429   tropical South American climate (Garreaud et al., 2009) overriding the volcanic signal

430   during the L20 eruptions, we instead present a superposed epoch anomaly composite of

431   the tropical-mean temperature anomaly, zonally averaged from 30°S to 30°N. Results are

432   shown for years -3 to +5, with zero defining the time of the eruption. This composite is

433   formed for all three L20 eruptions. In all cases, the five years prior to the eruption were

434   subtracted from the superposed composite. Other sensible choices for the non-eruption

435   reference period do not significantly change the results.

436   For the full LM spatial composites, we use only eruptions where vertically

437   integrated (15 to 35 km) stratospheric AOD averaged from 30°N to 30°S exceeds 0.1 for

438   at least 12 consecutive months in the simulation (top panel in Figure 1). For the LM

439   composites, we focus only on seasonal (DJF and JJA) composites, and a given season

440   will enter the composite if at least 2/3 months meet the AOD threshold; this criterion

441   yields 15 eruptions since 850 C.E. The selection of events used in the LM composite is

19

442   very weakly sensitive to this choice of latitude band. Mt. Pinatubo is the only L20

443   eruption in this composite, and is actually one of the smallest eruptions in this selection

444   based on the maximum AOD encountered near the time of the eruption (see Table 1 for

445   dates of each event). We believe sampling a larger number of events with greater forcing

446   is a better way to understand the volcanic response in this model, rather than increasing

447   the ensemble size for the L20 events. We do stress, however, that there is considerable

448   forcing uncertainty during the LM and so the model results ought to be viewed as a slave

449   to the imposed AOD and particle size distribution.

450   For the LM "non-eruption" fields, we use 15 years prior to the eruption as a

451   reference period to calculate the anomaly for each event, unless another event occurs

452   during that time (overlap occurs only once for eruptions in 1809 and 1815) in which case

453   the pre-1809 climatology is used twice. The exception is for Mt. Pinatubo, which again

454   uses the previous five years to calculate the anomaly. When constructing seasonal

455   averages of $\delta^{18}O_p$, the oxygen isotope value for each month is weighted by the

456   precipitation amount during that month, at each grid cell.

457   Since each post-eruption difference field is computed using the immediate

458   response minus a local 15-year climatology, time is not relevant in this analysis and so

459   we use all three members with the Crowley forcing (representing over 3,000 years of

460   simulation time) to generate a composite that features 45 volcanic "events" (15 eruptions

461   in each of the three members). In the historical (post-1850) extension of these runs, the

462   coding error that resulted in a mis-implementation of the Gao forcing is not an issue, and

463   so we use six ensemble members each (three volcanic events in six ensemble members)

464   for the L20 results.

20

465   The ensemble-mean composite results displayed for the LM eruptions include

466   contributions from three members that differ not just in the internal variability, but also in

467   their solar and land-use forcing. Similarly, the L20 results are from model runs that also

468   include other transient historical forcings occurring at the time of the eruption, including

469   greenhouse gas increases throughout the duration of the event (although these forcings

470   are the same among all ensemble members). However, in all cases we focus only on the

471   immediate years after the eruption. Since the primary signal of interests is expected to be

472   large compared to the impact of more slowly varying and smaller-amplitude forcings, the

473   ensemble spread for a given eruption can be interpreted as a sampling of the model

474   internal variability coincident with the event. We have tested our composite results using

475   the same dates as our volcanic events in simulations with other varying forcings but with

476   no volcanoes (there are no volcano-only runs with this model version for the LM), and

477   the results are indistinguishable from noise (not shown). The LM composite results are

478   discussed in section 3.2.

479   Finally, it is now well appreciated that any climate response under investigation

480   will be shackled to the spatial structure of the forcing imposed on a model. For example,

481   preferential heating/cooling of one hemisphere will induce different tropical precipitation

482   responses than a well-mixed gas that behaves CO_2-like (Kang et al., 2008, 2009; Frierson

483   and Hwang, 2012; Haywood et al., 2012). Figures S2 and S3 show the latitudinal AOD

484   distribution structure for all eruptions used in the generation of the LM composites within

485   ModelE2-R. The mean of all events is rather symmetric between hemispheres (though

486   somewhat skewed toward the Southern Hemisphere tropics), and similar to the pattern

487   expected with CO_2 change, the forcing is largest in the tropics. Thus, the resulting climate

21

488 responses outlined in this paper ought to be viewed as a response consistent with a

489 forcing that is relatively symmetric about the equator. Results from volcanic eruptions

490 with emphasis on the spatial structure of forcing will be reported in a separate paper.

491

492 2.3. Influence of ENSO on the Late 20th Century (L20) eruptions

493

494   For the L20 volcanic events, El Niño events are occurring quasi-simultaneously

495 with the eruption. This introduces a pervasive issue when attempting to isolate the

496 volcanic signal (e.g., Robock, 2003; Trenberth and Dai, 2007; Joseph and Zeng, 2011)

497 and is particularly important over South America (e.g. Garreaud et al., 2009).

498   In order to remove the effects of ENSO from the super-posed epoch and spatial

499 composite analyses described above in the GISTEMP and GPCC data, we first perform a

500 multiple regression with the variable of interest over the period 1951-2005 using a linear

501 time trend and the Niño 3 index as predictors (5°N-5°S, 150°W -90°W, data from

502 http://www.cpc.ncep.noaa.gov/data/indices/) over the same period, excluding two years

503 of data after each L20 eruption. At each grid cell, the Niño 3 index is lagged from 0-6

504 months and the correlation coefficient with the maximum absolute value (since a positive

505 index can induce a negative anomaly in the variable of interest) is found. This is similar

506 to the approach used in Joseph and Zeng (2011), allowing the maximum ENSO influence

507 to be removed at each grid point at the expense of contemporaneous relationships. The

508 lagged Niño index is then regressed against the time series of each variable and the

509 residual from this regression is retained. This approach assumes a linear relationship

510 between ENSO and the climate response over South America, an assumption that appears

22

511   justified on inter-annual to decadal time scales (Garreaud et al., 2009).

512   For each of the six ensemble members used in the model L20 composite, a similar

513   procedure is performed in which the Niño 3 index (consistent with the realization of the

514   Niño 3 domain SSTs in that model simulation) is calculated and regressed out in the same

515   manner. For the full LM computations, the number of larger-amplitude events in the

516   three-ensemble member composite should help average out the influence of Pacific SST

517   variability, and no ENSO removal procedure is applied.

518

519   **3. Results and Discussion**

520

521   3.1.   L20

522

523   Figure 3 illustrates that ModelE2-R reproduces the seasonal cycle of

524   climatological rainfall (comparing Figure 3a with 3b) and oxygen isotope distribution

525   (comparing Figure 3c with 3d) with some fidelity over South America. This includes a

526   meridional migration of the ITCZ toward the summer hemisphere and an intensification

527   of the South American monsoon during DJF. Where data permit (Figure 3c) there is good

528   agreement between model and observations, both displaying oxygen isotope DJF

529   enrichment relative to JJA in the tropics north of the equator and the higher latitudes

530   south of 30°S, and depletion in the continental interior south of the equator associated

531   with the monsoon wet season. ModelE2-R (Figure 3b) tends to produce too much

532   precipitation over northeastern Brazil although the gross features of the seasonal

533   migration in rainfall are well captured. This ability to accurately simulate the seasonality

23

534   of $\delta^{18}O_p$ over the tropical Americas has also been noted in two atmospheric GCMs with

535   no coupled ocean (NASA-GISS II and ECHAM-4, see Vuille et al., 2003a).

536   Figure 4 shows the ENSO-removed super-posed epoch analysis for tropical

537   temperature associated with the recent three L20 eruptions. There is good agreement

538   between the observed and modeled temperature response, both in amplitude and recovery

539   timescale. The tropical-mean cooling is on the order of several tenths of a degree, and

540   larger after Mt. Pinatubo (not shown individually).

541   The spatial structure of the post- El Chichón and Pinatubo events in land

542   observations and the individual model realizations are shown in Figures 5 and 6,

543   respectively. Observations exhibit cooling over much of the globe, especially after Mt.

544   Pinatubo that is largely reproduced by the model. However, there is considerable spread

545   among the individual ensemble members and between the two events, indicating a large

546   role for internal variability in dictating the observed spatial pattern following these events.

547   This is also true over South America.

548   In GISTEMP, the high-latitudes of South America cool more than the tropical

549   region of the continent after Mt. Pinatubo. There is still a residual signal from ENSO in

550   tropical South America following both L20 eruptions that is not reproduced by the model.

551   This is not unexpected, since ENSO events comparable to the magnitude of the historic

552   realizations due not occur coincident with the volcanic forcing in the individual ensemble

553   members. The magnitude of this signal is sensitive to the Niño index used in the

554   regression method described above. Without ENSO removal, tropical South America

555   warms following the two eruptions (not shown). The influence of ENSO appears minimal

556   over the higher latitude sectors of the continent.

24

557   The precipitation pattern following the L20 eruptions exhibits substantial

558   variability in space and across eruptions, with a general drying pattern over land in

559   tropical latitudes. South America experiences less precipitation near the equator after Mt.

560   Pinatubo (see also Trenberth and Dai, 2007), a pattern reproduced in some of the

561   ensemble realizations.

562   It should be noted that model-observation comparison is hindered not just by

563   internal variability, but also by the specified historical volcanic forcing in the model. In

564   fact, the Stratospheric Aerosol and Gas Experiment (or SAGE) II satellite sensor was

565   saturated by the aerosol cloud after Mt. Pinatubo; subsequent work (Santer et al., 2014;

566   Schmidt et al., 2014c) suggests that the forcing following Pinatubo is too large in the

567   CMIP5 generation of models. It is likely that CMIP6/PMIP4 will feature a reduced AOD

568   and different particle size.

569   Because of the considerable variability seen in observations (following historical

570   eruptions) and also across ensemble members, it is evident that a larger signal-to-noise

571   ratio than is available from the L20 eruptions alone is required to help isolate any

572   volcanic signal. ModelE2-R is the laboratory from which we proceed to sample a larger

573   number of events, some of which contain larger amplitude than the L20 eruptions.

574

575   3.2. Last Millennium Composites

576

577   3.2.1. Temperature and Precipitation

578

579   Figure 7 shows the LM post-volcanic temperature composite for all 45 events.

580   During both seasons, cooling is statistically significant over virtually the entire continent

581   (stippling indicates significance at the 90% level, t-test). The temperature response is

582   strongest in the interior of the continent, particularly during the austral winter. The

583   enhanced high-latitude cooling exhibited in the observations after Mt. Pinatubo does not

584   emerge in the model composite.

585   The precipitation anomalies for the LM composite are shown in Figure 8. As

586   expected, there is a distinct seasonal structure in the response, with the largest anomaly

587   concentrated in a narrow region north of the equator during austral winter, coincident

588   with the location of climatological rainfall maxima in the region. During JJA,

589   precipitation increases in the North Atlantic region following volcanic eruptions, while

590   very strong and statistically significant precipitation reductions occur just north of the

591   equator (including over northern Brazil, Ecuador, Venezuela, Colombia, and Guyana)

592   and encompassing the northern Amazon Basin. This signal is consistent with a

593   weakening of the moisture flux owing to the decrease in saturation vapor pressure due to

594   cooling that is demanded by Clausius-Clapeyron (Held and Soden, 2006). During this

595   season, the precipitation response is significant virtually everywhere in northern South

596   America. Supplementary Figure (S5) further illustrates that the JJA precipitation response

597   is remarkably robust to all eruptions that enter into the composite.

598   Figure 9b illustrates the relationship between area-averaged precipitation from

599   20°S to 0°, 77.5°W to 45°W (for DJF) and 0° to 10°N, 77.5°W to 52.5°W (for JJA) and

600   the maximum AOD encountered for each eruption. These two regions were selected to

601   reflect the seasonal migration of rainfall (Figure 2, 3). 15 eruptions are displayed with the

26

602   three-member ensemble spread given for each. Precipitation only increases north of the

603   equator during austral winter in a few model realizations. Moreover, the magnitude of the

604   precipitation response during JJA scales with the size of the eruption, particularly for

605   very large eruptions (e.g., comparing five eruptions with AOD > 0.3 vs. those with

606   smaller perturbations, although the spread amongst the ensemble members is large). The

607   spatial composite for each individual eruption (each averaged over the three ensemble

608   members) is shown in Figure S5.

609   The precipitation response during austral summer is more difficult to interpret

610   (Figure 8a). During this season, the zonally oriented Atlantic ITCZ migrates southward

611   and the SACZ becomes more intense as it is connected with the area of convection over

612   the central and southeastern part of the continent. It is noteworthy that the land cools

613   substantially more than the surrounding ocean (Figure 7), which one could expect to

614   weaken the monsoon-sourced precipitation during DJF. While precipitation is indeed

615   reduced over the tropical continent, the response is weaker than in JJA and less spatially

616   coherent, with many areas failing to meet statistical significance. An analysis of the

617   individual responses reveals that the signal is more eruption-dependent during DJF than

618   during JJA (see Figure S4), with a few events actually exhibiting modest increases in

619   precipitation. Nonetheless, there is a clear tendency for reduced DJF precipitation within

620   the SAMS region, although there is little to no dependence of the mean rainfall anomaly

621   on the magnitude of the AOD perturbation, at least above the 0.1 threshold used in this

622   study (Figure 9b), unlike for equatorial South America during JJA. Conversely, the

623   temperature response (Figure 9a) depends on the size of the eruption in both seasons, as

624   is expected.

627

628   3.2.2. Tropical Hydroclimate Response

629

630   Since the South American climate is intimately linked to large-scale tropical

631   dynamics, the global precipitation composite is shown in Figure S6 to better inform the

632   model response. The most robust signal is characterized by a reduction in tropically

633   averaged precipitation and the tendency for wet regions to become drier, and dry regions

634   to become wetter (see also Iles et al., 2013; Iles and Hegerl, 2014), in contrast to the

635   anticipated hydrologic response in a future, higher-CO_2 world (Held and Soden, 2006).

636   This pattern is a thermodynamic effect linked to reduced moisture convergence

637   within the convergence zones and to reduced moisture divergence in the descending

638   zones of the Hadley cell, which reduces the contrast in values of precipitation minus

639   evaporation (P-E) between moisture convergence and divergence regions (Chou et al.,

640   2009). The complete hydrologic response of the ΔP-E field (not shown) has the same

641   spatial structure as the ΔP field, since evaporation is decreasing nearly everywhere in the

642   tropics. Because both P and E are decreasing on the equator-ward flank of the ITCZ the

643   ΔP-E signal is rather weak in the deep tropics, while ΔP-E increases more rapidly than ΔP

644   in the subtropics.

645   The tendency for modest precipitation anomalies over the continent during DJF

646   appears to be part of a pattern that spans a broad swath of longitudes across the entire

647   deep tropics in association with the seasonal cycle. Nonetheless, the response during DJF

648   is weaker over land.

649

28

650   3.2.3. Oxygen Isotope Anomalies

651

652   In order to relate the responses discussed in the previous sections back to a

653   potentially observable paleoclimate metric, we show the composite $\Delta\delta^{18}O_p$ field for the

654   DJF and JJA seasons in South America (Figure 10). It should be cautioned that much of

655   the isotopic variability that can be observed in proxies within the continental interior or

656   high-elevation glacier sites will likely be seasonally biased toward the wet season months

657   (Hardy et al., 2003).

658   During the JJA season, there is a strong enrichment of the $\delta^{18}O_p$ pattern that is

659   zonally extended over equatorial South America. In addition, there is a corresponding

660   $\delta^{18}O_p$ depletion in the adjacent North Atlantic sector. This response is inextricably

661   coincident with the strong change in precipitation in the ITCZ domain that was assessed

662   in Figure 8, and is broadly consistent with a "rainfall amount" control on the isotopic

663   imprint (Dansgaard, 1964). South of approximately 15°S, the sign of the anomaly

664   reverses to a depletion of the heavy isotope.

665   During the austral summer, volcanic eruptions lead to a clear negative excursion

666   in $\delta^{18}O_p$ over virtually the entire SAMS region, including the Amazon basin, tropical

667   Andes, and eastern Brazil. The statistical significance of the resulting isotopic anomaly

668   extends throughout most of the landmass within the tropics and in the North Atlantic.

669   There are small but non-significant exceptions (positive $\delta^{18}O_p$ excursions) such as in

670   eastern Brazil. The negative excursions also include regions outside of the SAMS belt in

671   the subtropics and mid-high latitudes of South America.

29

The austral summer $\delta^{18}O_p$ depletion is the opposite sign from what one would expect if the reduced precipitation were driving the isotopic response. Thus, it may well be that the strong temperature response to volcanic eruptions dominates the continent-wide oxygen isotope depletion during the DJF season and in the extratropics during JJA over the relatively weak precipitation response. Precipitation on the other hand appears to be the primary control knob of $\Delta\delta^{18}O_p$ during JJA within the ITCZ region.

The correlation between $\Delta\delta^{18}O_p$ and temperature or precipitation, based on a regression using all 45 volcanic events, is reported in Figure 9, using the same domains for DJF and JJA described in section 3.2.1. In the case of volcanic forcing it appears that the amplitude of the temperature response to volcanic eruptions over tropical South America is larger than the rather weak and spatially incoherent precipitation signal, although both the temperature and precipitation coefficients must be considered to characterize the isotopic variability during this season (Figure S7). This may explain why the DJF isotopic signal related to volcanic eruptions seems to respond to atmospheric cooling, even in the tropics, where isotopic variability is usually more closely associated with changes in the hydrologic cycle. During JJA, the isotopic enrichment is much more closely associated with precipitation reduction north of the equator, whereas the JJA $\Delta\delta^{18}O_p$-temperature relationship is weak and non-significant.

Taken together, these results suggest that the primary controls on oxygen isotope variability are forcing and event-dependent, rather than being determined inherently by the latitude of interest (e.g., "precipitation driven" in the tropics and "temperature driven" in the extratropics). This conclusion is compelled by the fact that the precipitation production and distribution in proxy records are the result of an interaction between

30

698   multiple scales of motion in the atmosphere, the temperature of air in which the

699   condensate was embedded, and exchange processes operating from source to sink of the

700   parcel deposited at a site. Thus, a consistent description of how to interpret oxygen

701   isotopes into a useful climate signal cannot be given without considering all of these

702   processes and the target process of interest.

703   To further complement the spatial analysis, a composite Hovmöller diagram is

704   utilized (Figure 11) in order to illustrate the time-evolution of the temperature,

705   precipitation, and oxygen isotope response. For this plot, the start of each eruption is

706   defined as the closest January to the first month in which AOD reaches 0.1 in order to

707   illustrate the seasonal evolution (rather than compositing by "month from each eruption"

708   as in Figure 3). Therefore, for all 45 events in the composite, the local AOD may reach

709   this threshold within five months (before or after) of the January baseline point (eruptions

710   in June are rounded up to the following January). The Hovmöller composites are plotted

711   for ten years (beginning January three years prior to the eruption). The closest January

712   point to the start of each eruption occurs in the 37th month of the Hovmöller (solid black

713   line in Figure 11a,b,d). Results are zonally averaged from 77.5°W to 45°W.

714   Figure 11a demonstrates a substantial temperature anomaly that peaks south of

715   10°S (compare also to Figure 7). The cooling lasts for several years following the

716   eruption, and decays gradually until most of the signal is lost (~4 years after the eruption

717   in the South American sector), but remains 0.1-0.2°C colder than the pre-eruption

718   climatology. The zonally averaged peak reductions in South American precipitation

719   anomalies occur over the tropical latitudes and last for a comparable period of time as the

720   maximum temperature response. The precipitation anomaly itself migrates synchronously

31

Chris Colose 2/19/2016 6:33 PM
Deleted: , across the SAMS region.

722   with the seasonal cycle (red line in Figure 11c maps out the latitude of maximum

723   climatological precipitation averaged over all 15 year climatologies of each 45-member

724   event, as a function of time of year). Figure 11b indicates that the largest precipitation

725   response is confined to the equatorial and northern regions during JJA, with weak

726   protrusion into higher tropical latitudes only 1-2 years after the eruption. The JJA isotopic

727   enrichment in northern South America lasts for two seasons in our composite, while there

728   is sustained isotopic depletion during DJF in the SASM region for about three years

729   (Figure 11d)

730   Figure 12 provides additional statistical insight into the magnitude of the

731   excursions described in this section. Here, we sampled 100 random 45-event composites

732   in a control simulation with no external forcing (each "event", two seasons in length, is

733   defined as an anomaly expressed relative to a pre-eruption climatology as done

734   previously). The anomalies were averaged over the same areas as in Figure 9, with

735   different domains for DJF and JJA. Notably, for both seasons and for all three variables

736   examined, the single 45-event post-volcanic composite (purple square) lies outside the

737   distribution of all sampled 45-event composites constructed with no external forcing.

738   Nonetheless, the distribution for a smaller sample of events (black circles denote the data

739   for each (15) eruption, each averaged over the three ensemble members) shows

740   considerable spread.

741   The $\delta^{18}O_p$ anomalies discussed above result from changes in the isotopic content

742   of precipitation, which may be due to changes in precipitation amount or to other changes

743   in the isotopic composition of the water vapor that condensed to form the precipitate. The

744   changes are not determined by changes in the seasonality of the precipitation. To

32

illustrate this (Figure S8), we decomposed the $\Delta\delta^{18}O_p$ field (see Liu and Battisti, 2015) by

weighting the monthly oxygen isotope field by the pre-eruption precipitation values. The

results are indistinguishable from the total $\Delta\delta^{18}O_p$ field, suggesting that any changes in

monsoon seasonality are negligible in contributing to the isotopic signal, unlike the

orbital case considered in Liu and Battisti (2015).

4. Conclusions

In this study, we have analyzed the response of temperature, precipitation, and

$\delta^{18}O_p$ over South America to volcanic forcing associated with large tropical eruptions

during the Last Millennium. It is now well known that volcanic eruptions lead to large-

scale cooling throughout the tropics, and this result extends to most of the South

American continent as well, except in regions that may be simultaneously affected by

opposing ENSO behavior. In general, the precipitation response has been more enigmatic,

though our results are in broad agreement with numerous other studies showing that there

is a substantial decline in tropical-mean precipitation.

However, the immediate post-volcanic impact over South America has a complex

seasonal and spatial structure. During the austral winter, the precipitation response over

the continent is slaved to the response of the large-scale circulation, including a

weakening of rainfall intensity within the ITCZ that is migrating northward. In the

extratropics, the continent cools and exhibits slight precipitation declines nearly

everywhere. Our results suggest the seasonal monsoon precipitation (during DJF) in

ModelE2-R exhibits a fairly weak response that is scattered across the continent. It

769 appears that volcanic forcing preconditions the tropical rainfall over the continent to

770 decline during the wet season, but that this response is likely to be eruption-dependent

771 and may be overwhelmed by internal variability.

772 A unique aspect of this study was to probe the $\delta^{18}O_p$ response to volcanic

773 eruptions. During JJA, isotopes become heavily enriched in northern South America as

774 convective activity produces substantially less precipitation. No such relation was found

775 during the monsoon season, even within the tropics, where the large cooling appears to

776 lead to more depleted $\delta^{18}O_p$, despite a weakened hydrologic cycle and reduced monsoon

777 precipitation. In the extratropics, it appears that the temperature decline is driving

778 isotopes toward more depleted values.

779 Unfortunately validation of our model results is hindered by the paucity of

780 observational stable isotope data and by the coincidence of volcanic eruptions with

781 ENSO events over the 20th century. Nonetheless our results may provide some guidance

782 in the search of volcanic signals in high-resolution isotopic proxy data from South

783 America. Given the importance of volcanic forcing for climate variability over the past

784 millennium, and in particular the LIA period, which has been identified as a period of

785 significant climatic perturbation in isotopic proxies from South America, a better

786 understanding of the climatic response to volcanic forcing over this region is urgently

787 needed.

1137

List of Figure Captions

Figure. 1. Aerosol Optical Depth (AOD) used to force the NASA GISS ModelE2-R over the Last Millennium and (bottom) zoomed in on the period 1950-1999 (Crowley+Sato) as discussed in text. AOD is the vertically integrated (15-35 km) and latitudinal average from 30°S to 30°N. Note difference in vertical scale between graphs. Orange dashed line marks the AOD threshold for defining a LM eruption in the present study. Eruption events defined in text must sustain the threshold AOD for at least one year, so not all events above the orange dashed line are used in the composites.

Figure. 2. (Top) Observed Climatological Precipitation for DJF (shading, in mm day^{-1}). SAMS box is drawn over the domain from 20°S to 0°, 77.5°W to 45°W and used for Figure 9 and 12. Data from the GPCP product, long-term climatological rainfall derived from years 1981 - 2010. (Bottom) As above, except for JJA. Box from 0° to 10°N, 77.5°W to 52.5°W used in averaging for Figures 9 and 12.

Figure. 3. Seasonal cycle (DJF minus JJA) of precipitation in **a)** GPCP precipitation product, from data in Figure 2 **b)** in ModelE2-R c) $\delta^{18}O_p$ in GNIP data d) and $\delta^{18}O_p$ in ModelE2-R. GNIP data only shown for stations with at least 90 reported $\delta^{18}O_p$ values at a given station from 1960-present, in addition to at least ten data values for each month: December, January, February, June, July, and August. Stations with seasonal differences of less than +/- 1.0 per mil are also omitted in panel (c).

1161   **Figure. 4**. Composite tropical (30°S to 30°N) temperature response following the L20

1162   volcanic eruptions. Fill colors denote observed monthly anomalies using GISTEMP, with

1163   24-month running average shown as solid black line. ModelE2-R ensemble mean is

1164   shown as solid orange line and dashed grey lines indicate the six individual ensemble

1165   members. Anomalies are referenced to 5 years prior to eruptions (years -5 to 0). Dashed

1166   purple lines encompass the 5-95% interval for monthly tropical-mean temperature

1167   anomalies (relative to the previous five-year mean) in the GISTEMP product from 1950-

1168   present. The calculation of this range omits data two years after the L20 eruptions. The

1169   range is not symmetric about zero due to the tropical warming trend during this interval.

1170   All data are based on the ENSO-removal technique discussed in text.

1171
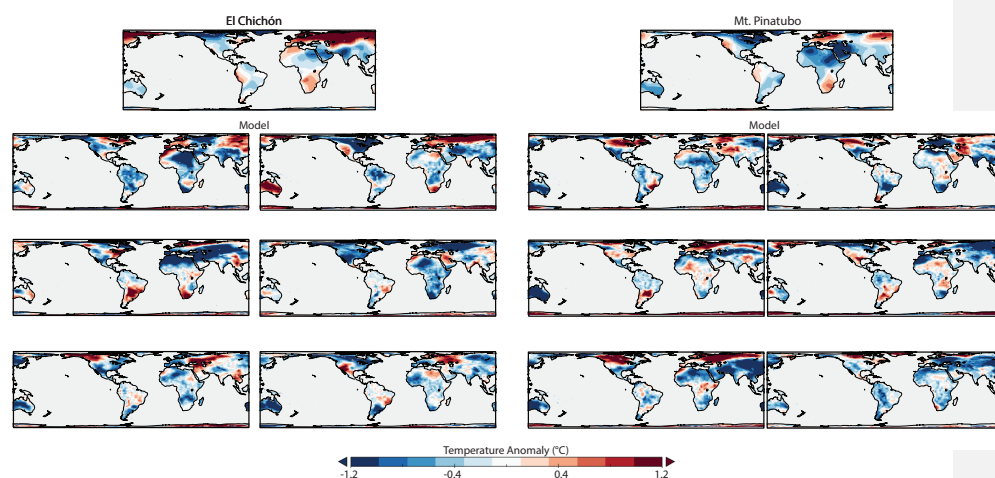

1172   **Figure 5.** Annual-mean temperature change (°C, ocean masked) for each L20 eruption

1173   (labeled on plot) in GISTEMP (top row) and each ModelE2-R ensemble member, as

1174   discussed in text. All plots use ENSO-removal procedure described in text.

1175

1176   **Figure. 6**. As in Figure 5, except for precipitation change (mm day^{-1}).

1177

1178   **Figure. 7**. Last Millennium post-volcanic temperature composite (°C) averaged over all

1179   45 events during **a)** DJF and **b)** JJA from GISS ModelE2-R using procedure described in

1180   text. Stippling highlights areas with anomalies significant at $p<0.1$.

1181

53

1182 **Figure. 8**. Last Millennium post-volcanic precipitation composite (mm day^{-1}) with all

1183 eruption events during **a)** DJF and **b)** JJA from GISS ModelE2-R using procedure

1184 described in text. Stippling highlights areas with anomalies significant at p<0.1.

1185

1186 **Figure. 9**. **a)** Average temperature anomaly during DJF within the SAMS region (red,

1187 20°S to 0°, 77.5°W to 45°W) and equatorial South America during JJA (blue, 0° to 10°N,

1188 77.5°W to 52.5°W) plotted against the peak AOD for all 15 eruptions (each point

1189 averaged over three ensemble members with the three member spread shown as

1190 horizontal bars) and **b)** As in a), but for precipitation. Dashed horizontal lines indicate the

1191 5-95% range for a two-season average of each variable relative to the previous 15 years

1192 (averaged over the same domain) in the entire control simulation with no external forcing.

1193 In both panels, the correlation coefficient and p-value are reported for a) temperature and

1194 b) precipitation vs. $\Delta\delta^{18}O_p$ in each season and over the same domain. The regression uses

1195 all 45 volcanic events.

1196

1197 **Figure. 10**. Last Millennium post-volcanic oxygen isotope in precipitation ($\Delta\delta^{18}O_p$)

1198 composite (per mil) with all eruption events during **a)** DJF and **b)** JJA from GISS

1199 ModelE2-R using procedure described in text. Stippling highlights areas with anomalies

1200 significant at p<0.1.

1201

1202 **Figure. 11**. Last Millennium Hovmöller diagram (10 years, time moving forward going

1203 upward, with year number labeled next to each month) for **a)** temperature anomaly (°C)

1204 **b)** precipitation anomaly (mm day^{-1}) using procedure described in text. Solid black lines

1205   mark closest January to start of each eruption used in composite. **c)** Same as panel b,

1206   except zoomed in on 10 °S to 10 °N and over 3 years of time beginning with the January

1207   closest to each eruption. Red line in panel c shows latitude of maximum climatological

1208   precipitation as a function of time of year. All results zonally averaged in model from

1209   77.5°W to 45°W. **d)** Last Millennium Hovmöller diagram for oxygen isotopes in

1210   precipitation (per mil).

1211

1212   **Figure. 12**. Frequency distribution of 100 random 45-event composites in LM control

1213   simulation of ModelE2-R (blue) for temperature (top row), precipitation (middle), and

1214   oxygen isotopes in precipitation (bottom) for DJF (left column) and JJA (right column).

1215   Results averaged over same domains as in Figure 9. Normal distribution with a mean and

1216   standard deviation equal to that of the data shown in red. Purple square shows the single

1217   45-event composite used in this study, with the distribution of individual 15 volcanic

1218   eruptions (each averaged over three ensemble members) in black dots.

-1.0   -0.3   0.3   1.0

Figure. 6. As in Figure 5, except for precipitation change (mm day^{-1}).

LM Composite: Post-Volcanic Temperature Anomaly
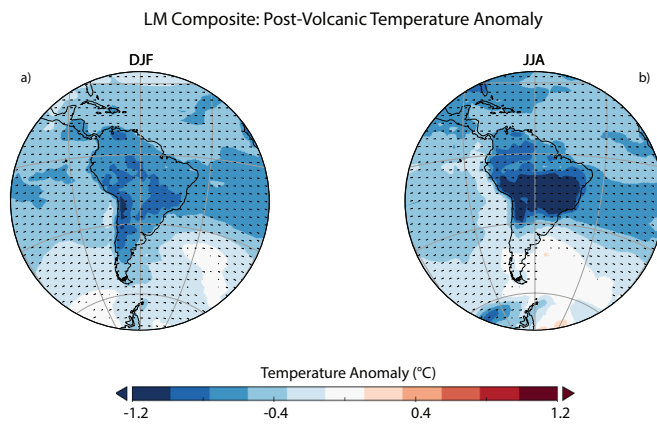

Figure. 7. Last Millennium post-volcanic temperature composite (°C) averaged over all 45 events during **a)** DJF and **b)** JJA from GISS ModelE2-R using procedure described in text. Stippling highlights areas with anomalies significant at $p<0.1$.

LM Composite: Post-Volcanic Precipitation Anomaly

Figure. 8. Last Millennium post-volcanic precipitation composite (mm day^{-1}) with all eruption events during **a)** DJF and **b)** JJA from GISS ModelE2-R using procedure described in text. Stippling highlights areas with anomalies significant at p<0.1.
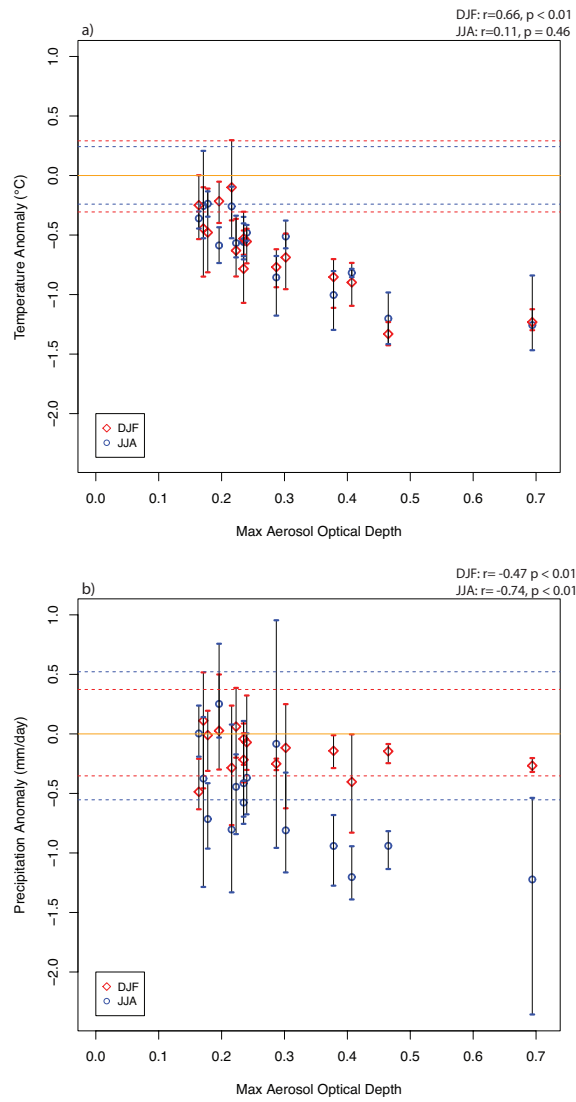

Figure. 9. **a)** Average temperature anomaly during DJF within the SAMS region (red, 20°S to 0°, 77.5°W to 45°W) and equatorial South America during JJA (blue, 0° to 10°N, 77.5°W to 52.5°W) plotted against the peak AOD for all 15 eruptions (each point averaged over three ensemble members with the three member spread shown as horizontal bars) and **b)** As in a), but for precipitation. Dashed horizontal lines indicate the 5-95% range for a two-season average of each variable relative to the previous 15 years (averaged over the same domain) in the entire control simulation with no external forcing. In both panels, the correlation coefficient and p-value are reported for a) temperature and b) precipitation vs. $\Delta\delta^{18}O_p$ in each season and over the same domain. The regression uses all 45 volcanic events.

Temperature Anomalies Precipitation Anomalies Oxygen Isotope Anomalies
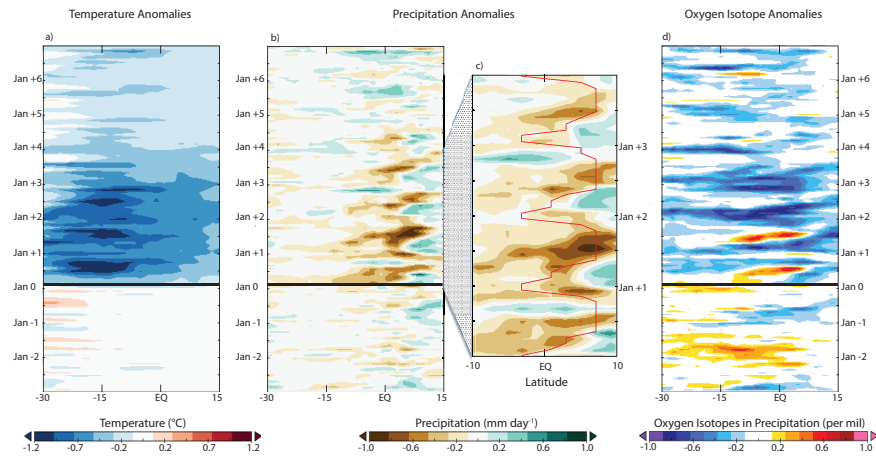

Figure. 11. Last Millennium Hovmöller diagram (10 years, time moving forward going upward, with year number labeled next to each month) for **a)** temperature anomaly (°C) **b)** precipitation anomaly (mm day^{-1}) using procedure described in text. Solid black lines mark closest January to start of each eruption used in composite. **c)** Same as panel b, except zoomed in on 10 °S to 10 °N and over 3 years of time beginning with the January closest to each eruption. Red line in panel c shows latitude of maximum climatological precipitation as a function of time of year. All results zonally averaged in model from 77.5°W to 45° W. **d)** Last Millennium Hovmöller diagram for oxygen isotopes in precipitation (per mil).

Supplemental Figure Captions

Fig. S1. Number of rain gauges per grid box for selected months (during eruption events) in the GPCCv6 network. Bottom right panel shows a time-series of the total number of stations over the range 90° to 30° W and 60°S to 20° N.

Fig. S2. Zonally averaged latitudinal AOD distribution for all 15 events used in each ensemble member for DJF. Mean of all curves shown in red.
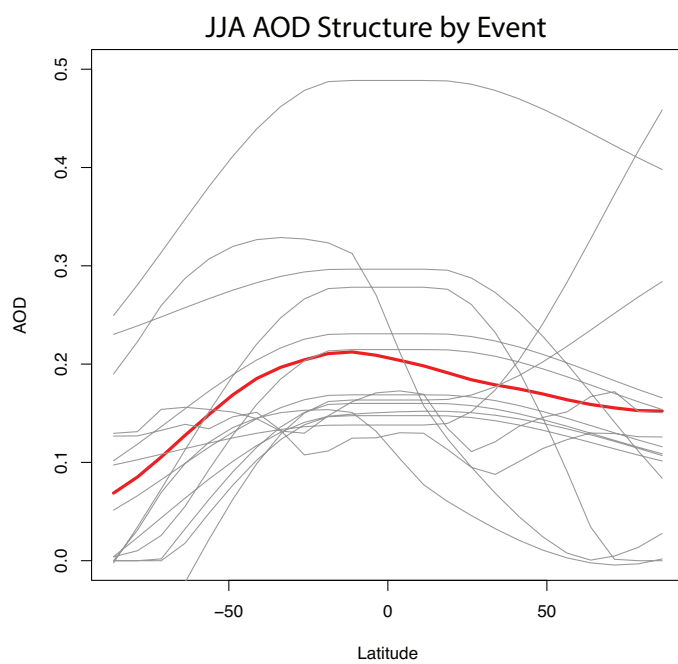

Fig. S3. As in Figure S2, but for JJA.

Fig. S4. Precipitation anomaly (mm day^{-1}) for each volcanic eruption used in LM composite (each averaged for the three ensemble members used) during DJF.

Fig. S5. As in Figure S4, but for JJA.

Fig. S6. Global-scale precipitation anomaly (mm day^{-1}) in the LM composite for (top) DJF and (bottom) JJA.

Fig. S7. Regression of spatially-averaged DJF $\delta^{18}O_p$ anomaly vs. temperature (black squares) or precipitation (red squares). The regression uses all 45 LM volcanic events and averaging is done over the SAMS domain defined in the text. Black and red lines are the corresponding (least-squares) regression lines.

Fig. S8. a) DJF total $\delta^{18}O_p$ anomaly **b)** DJF $\delta^{18}O_p$ anomaly due to isotopic composition change in precipitation, holding precipitation seasonality fixed at pre-eruption values. **c)** As in a) except for JJA. **d)** As in b) except for JJA. Total isotopic changes in left column reproduced from Figure 10 in text.
