

We would like to thank the Referee for the additional comments. Written below are our responses to the Referees' comments. The comments were reproduced and are followed by our responses written with italicized font. Based on the comments, we propose the changes of the manuscript.

1. There are 11 radiocarbon dates for this core (Table 1). The uppermost post-bomb seems reliable and indicates a modern age of the top of the core. And the pair of nearly identical dates from the lowest part of the core (166 and 173 cm) also seem reliable and indicate an age of c. 600 cal yr. BP for the catcher section. There is one obviously redeposited sample (33 cm), which is naturally disregarded. The remaining seven dates (48 cm through 122 cm) range chaotically between c. 300 cal. yr BP and c. 100 cal. yr BP. Instead of explaining explicitly how they deal with the age scatter, the authors prefer to use obscure wording. The statement "Four of 11 samples were in chronological order" is misleading. This wording creates impression that the sequence of dates is something naturally occurring in the dataset. In fact, the authors arbitrary picked out two samples (70 and 122 cm) from the scatter of seven samples (48-122 cm) to make up a believable age model. They could have picked another pair of samples or a single sample out of the scatter 48-122 cm and still have a chronological order (less believable though). The authors should either explain explicitly that the choice of the two samples was a guess (the wording of course should be mild). A reference to the previous paper is not sufficient, as the Chronology section of that paper lacks relevant information. In addition, the authors hide the scale of the age issue saying that the data "should be used with caution" only from the intervals densely packed with detected age inversions (p.9 line 18), implying that similar-size intervals lacking any dates have normal deposition by default. No. The scatter compromise the whole mid part of the record, and the chronology of the whole interval between c. 20 cm and 150 cm is questionable or at least imprecise, unless the authors provide evidence that the two selected dates (70 and 122 cm) are more reliable than the other (see above). It would be fair to show all dates including discarded ones on an age-model plot (e.g. Fig. 2).

*We thank the Referee for a careful analysis of the data on sediment chronology. Among the samples located between 48 and 122 cm sediment depth, we have chosen two of the youngest age that were in the chronological order. In the case when age reversal occurs and the younger samples were located beneath the older ones, it is more likely that the reason was the redeposition of the older samples rather than the downward transport of the younger samples by e.g., bioturbation. It is a standard practice used in the age-depth model construction, so most of the authors do not explain it in detail in the text of the articles. Therefore, the age model would be less reliable, if other dates were used.*

*We have added the information about the potential redeposition of the samples revealing age reversals. Also, the phrases that Referee found misleading have been changed. Now the paragraph "Sediment dating" is as follows:*

*"The age of the studied core was estimated based on high precision AMS <sup>14</sup>C dating performed on bivalves shells, as presented in Pawłowska et al. (2014). Eleven shells identified to the highest possible taxonomic level were selected and processed on a 1.5 SDH-Pelletron Model 'Compact Carbon AMS' (Poznań Radiocarbon Laboratory, Poland). The dates were converted into calibrated ages using the CALIB Rev. 7.0.2 Beta calibration program (Stuiver and Reimer, 1993) and the Marine13 calibration dataset (Reimer et al., 2013). The difference  $\Delta R$  in the reservoir age correction of  $105 \pm 24$  was applied (Mangerud et al., 2006).*

*Four of the eleven samples were used to establish an approximate age model for the sediment core. The upper-most sample contained post-bomb carbon, which indicates a post-*

1960 age. Samples located in the middle part of the core revealed ages that were not in chronological order. All the samples (shells) revealing age reversals were excluded from the age model as they were likely redeposited (Table 1). Samples out of chronological order occurred at the depths of ~ 15-55 cm and ~ 80-115 cm, and, therefore, it is likely that these sediment intervals represent major redeposition events. The age-depth model was made with the use of the CLAM-R software program (Blaauw, 2010; Fig. 2). The age of the oldest layer was estimated to be ~ 965 AD. The sediment accumulation rate (SAR) in the deepest part of the core (i.e., before 1800 AD; up to 120 cm) ranged from 0.1 to 0.125 cm yr<sup>-1</sup>. At ~ 1800 AD (120 cm), the SAR increased to 1 cm yr<sup>-1</sup>. In the upper layers (after ~ 1850 AD; 70 cm), the SAR decreased to 0.3 cm yr<sup>-1</sup>.”

We also agree that the presence of redeposited shells should also be marked on the Figure 2. However, instead of showing the potentially redeposited dates in the age-depth plot, we marked the sediment intervals referring to the major redeposition events. The details about all the dates, including potentially redeposited ones, are already included in the Table 1.

2. This paper focuses on the monothalamid part of the foraminiferal assemblage, whereas the previous paper (Pawłowska et al. 2014) reported the findings on the hard-shelled foraminifera. Naturally, before reading about non-fossilizable monothalamids, the reader expects to see a brief summary of the match between the hard-shell fossil record and the aDNA array. The reader should not be expected to rummage through the previous paper for the relevant summary; all the more so, because such a relevant summary is absent there. The revised manuscript provides a summary: “The study showed that aDNA record detected most of the species reported for Hornsund from previous micropaleontological investigations, including the species that dominate the fossil assemblage... However, the number of aDNA sequences read and fossil specimens differed considerably” (p.4 line 20). In my opinion, this summary is not informative. And this summary conflicts with the data in saying that all dominant fossil species were detected in aDNA. Be specific. Provide numbers. The following information perhaps should be included: the number of fossil species and the number of them detected by aDNA; the list of fossil dominants and which of them showed minor frequencies in aDNA and which of them were missing puzzlingly in the aDNA record. I believe this would be convenient for the reader if the level of match or mismatch between the frequencies of the fossil dominants and the aDNA reads is characterized numerically.

*According to the Referee’s suggestion we have included more detailed description of the work of Pawłowska et al. (2014). We decided to place it in the “Study area” section, as we found it the most suitable for the description of previous investigations in the Hornsund area. The added text is as follows:*

*“The previous aDNA-based investigation on the foraminiferal fauna from Hornsund (Pawłowska et al., 2014) focused mainly on the hard-shelled species. The aDNA sequences assigned to testate foraminifera made 142 out of 394 OTUs (Operational Taxonomic Units). The microfossil record comprised 45 species and 57% of them were found also in the molecular data. Foraminifera detected by both approaches included species reported for Hornsund by previous investigations (e.g., Hald & Korsun 1997; Pogodina 2005) e.g., *Cassidulina* spp, *Cibicides lobatulus*, *Nonionellina labradorica*, *Elphidium excavatum*, *Reophax scopiurus*, *Reophax* sp., *Spiroplectammina* sp., *Cribrostomoides crassimargo* and *Quinqueloculina* sp. Among these, *Cassidulina* spp, *C. lobatulus* and *E. excavatum* were noted frequently in microfossil and sequence data, making 8.8 %, 3.4 % and 2.5 % of the*

*sequences, respectively. However, there were four species that were also frequent in the fossil record, but were represented by less than 1 % of aDNA sequences (N. labradorica and C. crassimargo) or were not sequenced (B. frigida and I. helenae). On the other hand, some taxa belonging to genera Stainforthia, Spiroplectammina, Reophax were found rarely in the microfossil assemblage, but were represented by numerous sequences. The discrepancies between the records were explained by biological features of certain foraminiferal species and by the differences in characteristics of these two approaches (i.e., the analytical procedures)."*

*We have also modified the Introduction section by removing a sentence:*

*"The study showed that the aDNA record detected most of the species reported for Hornsund from previous micropaleontological investigations (e.g., Hald and Korsun, 1997; Pogodina, 2005), including the species that dominate the fossil assemblage (i.e., E. excavatum, C. reniforme, C. lobatulus, and N. labradorica). However, the number of aDNA sequences and fossil specimens differed considerably."*

3. The coordinates of the core would better be removed from the map (Fig. 1) and placed either in the figure caption or in the Material.

*The coordinates have been placed in the Materials and Methods section.*

## 1 **Abstract**

2           This paper presents a reconstruction of climate-driven environmental changes over the  
3 last millennium in Hornsund Fjord (Svalbard), based on sedimentological and  
4 micropalaeontological records. Our palaeo-investigation was supported by an analysis of  
5 foraminiferal ancient DNA (aDNA), focusing on the non-fossilized monothalamous species.  
6 The main climatic fluctuations during the last millennium were the Medieval Warm Period  
7 (MWP, 1000 AD – 1600 AD), the Little Ice Age (LIA, 1600 AD – 1900 AD) and the Modern  
8 Warming (MW, 1900 AD – present). Our study indicates that the environmental conditions in  
9 Hornsund during the MWP and the early LIA (before ~ 1800 AD) were relatively stable. The  
10 beginning of the LIA (~ 1600 AD) was poorly evidenced by the micropalaeontological record  
11 but was well marked in the aDNA data by an increased proportion of monothalamous  
12 foraminifera, especially *Bathysiphon* sp. The early LIA (~ 1600 AD – ~ 1800 AD) was  
13 marked by an increase in the abundance of sequences of *Hippocrepinella hirudinea* and  
14 *Cedhagenia saltatus*. In the late LIA (after ~ 1800 AD), the conditions in the fjord became  
15 glacier-proximal and were characterized by increased meltwater outflows, high sedimentation  
16 and a high calving rate. This coincided with an increase in the percentages of sequences of  
17 *Micrometula* sp. and *Vellaria pellucidus*. During the MW, the major glacier fronts retreated  
18 rapidly to the inner bays, which limited the iceberg discharge to the fjord's centre and caused  
19 a shift in the foraminiferal community that was reflected in both the fossil and aDNA records.

20           The palaeoceanographic changes in the Hornsund fjord over the last millennium were  
21 driven mainly by the inflow of shelf-originated water masses and glacial activity. However,  
22 the environmental changes were poorly evidenced in the micropalaeontological record, but  
23 they were well documented in our aDNA data. We considerably increased the number of  
24 potential proxy species by including monothalamous foraminifera in the palaeoecological  
25 studies.

## 1 **1 Introduction**

2           The general outline of climate development over the last millennium is the Medieval  
3 Warm Period (MWP), followed by cooling during the Little Ice Age (LIA) and warming in  
4 the 20<sup>th</sup> and 21<sup>st</sup> centuries (Modern Warming; MW). In the European Arctic, the temperature  
5 increase during the MWP and MW was correlated with the strong influence of the Atlantic  
6 Water inflow and associated heat transport (Wanamaker et al., 2012). In contrast, the  
7 weakening of the Atlantic Meridional Overturning Circulation (AMOC) and the lower heat  
8 transport to the Arctic might have been responsible for the LIA cooling (Lund et al., 2006).  
9 Changes in the Arctic Ocean heat budget were associated with significant changes in the  
10 cryosphere, especially the gradual decreases in glacier mass balance and the extent of the sea-  
11 ice cover in the last century (e.g., D'Andrea et al., 2012; Jernas et al., 2013).

12           Fjords are a unique form of coastline that are under the influence of the glaciated land  
13 and the ocean. Hence, fjord systems are sensitive indicators of climate change phenomena.  
14 However, the greatest effort in studying the Holocene history of Svalbard has mainly focused  
15 on the shelf area (e.g., Hald et al., 2007; Rasmussen et al., 2012; Łacka et al., 2015). There  
16 have been only a few high-resolution studies of the sedimentary record of the Svalbard fjords  
17 from the last millennium (e.g., Majewski and Zajączkowski, 2007; Majewski et al., 2009).

18           The environmental changes during the last millennium observed in the Svalbard shelf  
19 were correlated with the interplay of Atlantic and Arctic water masses (Kubischta et al., 2011;  
20 Jernas et al., 2013). The Hornsund fjord is strongly influenced by tidewater glaciers, and thus  
21 the sedimentary record in this fjord might indicate that enhanced melt-water delivery  
22 increased the sediment accumulation and restricted the sea productivity during the periods of  
23 glacial retreat. To accurately study climate-driven environmental variability in the past, it is  
24 crucial to create a network of proxies that carry different but complementary information.

1 Foraminifera are widely used as proxies of past and present environmental changes in  
2 all types of marine environments. However, palaeoceanographic reconstructions have focused  
3 on multi-chambered hard-shelled taxa and have ignored soft-walled, monothalamous species,  
4 which often dominate foraminifera assemblages in high latitude regions (Gooday, 2002).  
5 Monothalamous foraminifera with organic or predominantly organic test walls are  
6 traditionally defined as allogromiids (Gooday, 2002). However, morphological and molecular  
7 evidence indicate that ‘allogromiids’ does not refer to a coherent taxonomic group but rather a  
8 group what is scattered between several monothalamous clades (Pawlowski et al., 2002;  
9 Lejzerowicz et al., 2013a). The group includes organic-walled (‘naked’) and agglutinated  
10 forms of various shapes (Cedhagen et al., 2002). Monothalamous foraminifera with a test  
11 build of agglutinated particles are referred to as ‘saccamminids’ or ‘psammosphaerids.’ The  
12 term ‘allogromiid’ is sometimes applied to monothalamous taxa, irrespective of wall type.  
13 Therefore, literature reports might include saccamminids and psammosphaerids in the  
14 allogromiids group (Gooday, 2002).

15 Previous studies have shown that it is possible to consider monothalamous and  
16 polythalamous foraminifera (Lejzerowicz et al., 2013b) and other groups of non-fossilized  
17 eukaryotes (e.g., Coolen et al., 2013, 2006; Boere et al., 2011) in palaeoecological surveys  
18 using an ancient environmental DNA (aDNA) approach. To include monothalamids in  
19 palaeoecological studies of Arctic foraminifera, we analysed the ancient foraminiferal DNA  
20 record from the last millennium from Hornsund (Pawłowska et al., 2014). ~~The study showed~~  
21 ~~that the aDNA record detected most of the species reported for Hornsund from previous~~  
22 ~~micropalaeontological investigations (e.g., Hald and Korsun, 1997; Pogodina, 2005),~~  
23 ~~including the species that dominate the fossil assemblage (i.e., *E. excavatum*, *C. reniforme*, *C.*~~  
24 ~~*lobatulus* and *N. labradorica*). However, the number of aDNA sequences read and fossil~~  
25 ~~specimens differed considerably.~~ The richness of the foraminiferal communities revealed by

1 the molecular analysis was much higher than that in the fossil record, mainly due to the  
2 detection of a high number of monothalamous species that were not preserved during the  
3 fossilization process and small-size species that are not retained on micropalaeontological  
4 sieves.

5 The aim of this study was to reconstruct the climate-driven environmental changes  
6 over the last millennium in Hornsund, with decadal to multi-decadal resolution. The  
7 promising results of our previous study (Pawłowska et al., 2014) encouraged us to use our  
8 aDNA data to supplement the palaeoclimatic record based on traditional proxies. We  
9 evaluated the potential use of monothalamous foraminifera as palaeoceanographic proxies,  
10 showing that they might provide valuable environmental information that is complementary to  
11 the data obtained with traditional microfossil proxies.

12

## 13 **2 Study area**

14 Hornsund is the southernmost fjord of Spitsbergen. It is connected to the open sea by a  
15 wide no-sill outlet. The fjord's coastline encompasses several glacier - proximal basins that  
16 are separated by sills. In its central part, the water depth exceeds 200 m and varies from 55 m  
17 to 180 m in the glacier - proximal basins (Fig. 1).

18 The hydrology of the fjord is under the influence of two main exogenous water  
19 masses: the Atlantic Water (AW) and the Arctic Water (ArW). The AW is warm and saline,  
20 and its temperature and salinity are usually defined as  $\geq 3^{\circ}\text{C}$  and  $\geq 34.9$ , respectively. The  
21 ArW is colder and fresher, and its salinity varies along the Spitsbergen shelf due to the  
22 freshwater outflows from fjords (Cottier et al., 2005). The AW and ArW mix over the  
23 continental shelf to form the Shelf Transformed Water (STW), which has a temperature and  
24 salinity of  $1^{\circ}\text{C}$  and 34.7, respectively. The STW mainly occupies the outer and central parts of  
25 the fjord. The Local Water (LW) is formed directly in the fjord by convectional mixing during

1 cooling in the fall and winter or the interaction between the warmer fjord water and glacier  
2 fronts (Svendsen et al., 2002).

3 Seventy percent of the Hornsund catchment area is covered by glaciers (Hagen et al.,  
4 1993). The melting of the eight major tidewater glaciers results in an important sediment  
5 delivery to the fjord. The modern sediment accumulation rate varies from 0.5 to 0.7 cm yr<sup>-1</sup> in  
6 the central and inner parts, respectively (Szczuciński et al., 2006).

7 During the last millennium, Hornsund was subjected to major environmental changes,  
8 including the MWP, cooling and glacial advances during the LIA, which culminated in the  
9 period from 1600 AD to 1900 AD, and warming and massive glacial retreats during the 20<sup>th</sup>  
10 and 21<sup>st</sup> centuries (MW; Ziaja, 2001; Pälli et al., 2003). These changes were correlated with  
11 the variability in the inflow of the cold ArW and warm AW and were recorded in foraminifera  
12 assemblages and the stable isotope compositions from foraminiferal tests (Majewski et al.,  
13 2009).

14 The previous aDNA-based investigation on the foraminiferal fauna from Hornsund  
15 (Pawłowska et al., 2014) focused mainly on the hard-shelled species. The aDNA sequences  
16 assigned to testate foraminifera made 142 out of 394 OTUs (Operational Taxonomic Units).  
17 The microfossil record comprised 45 species and 57% of them were found also in the  
18 molecular data. Foraminifera detected by both approaches included species reported for  
19 Hornsund by previous investigations (e.g., Hald & Korsun 1997; Pogodina 2005) e.g.,  
20 *Cassidulina* spp, *Cibicides lobatulus*, *Nonionellina labradorica*, *Elphidium excavatum*,  
21 *Reophax scorpiurus*, *Reophax* sp., *Spiroplectammina* sp., *Cribrostomoides crassimargo* and  
22 *Quinqueloculina* sp. Among these, *Cassidulina* spp, *C. lobatulus* and *E. excavatum* were  
23 noted frequently in microfossil and sequence data, making 8.8 %, 3.4 % and 2.5 % of the  
24 sequences, respectively. However, there were four species that were also frequent in the fossil  
25 record, but were represented by less than 1 % of aDNA sequences (*N. labradorica* and *C.*

1 *crassimargo*) or were not sequenced (*B. frigida* and *I. helenae*). On the other hand, some taxa  
2 belonging to genera *Stainforthia*, *Spiroplectammina*, *Reophax* were found rarely in the  
3 microfossil assemblage, but were represented by numerous sequences. The discrepancies  
4 between the records were explained by biological features of certain foraminiferal species and  
5 by the differences in characteristics of these two approaches (i.e., the analytical procedures).

6

### 7 **3 Material and methods**

8 A 2 m long sediment core HF\_2011 was taken with a gravity corer from the R/V  
9 Oceania during a cruise in July 2011. The sampling station was located in the central basin of  
10 the fjord, in a flat seabed area at a depth of 135 m (76° 57.238'N; 15° 41.782'E; Fig. 1). The  
11 core was subsampled onboard for aDNA analyses and frozen at -20°C until further analyses  
12 were conducted at the Institute of Oceanology, Polish Academy of Sciences (Sopot, Poland),  
13 as described in Pawłowska et al. (2014). After thawing at 4°C, the core was split into two  
14 parts longitudinally, and each half was cut into 1 cm slices for micropalaeontological and  
15 sedimentological analyses. Carbonate shells were picked for accelerator mass spectrometry  
16 (AMS) <sup>14</sup>C dating.

17

#### 18 **3.1 Grain-size and stable isotope analyses**

19 The grain size analysis of the sediment slices was conducted using a Mastersizer 2000  
20 laser analyser coupled with a HydroMU device (Malvern Instruments, Malvern, UK) and  
21 supported by the wet sieving of fractions larger than 250 µm. The granulometric data were  
22 analysed with the use of the GRADISTAT 8.0 software program (Blott and Pye, 2001). Dried  
23 and weighted sediment fractions > 250 and 500 µm were used for IRD analyses, and at least  
24 500 mineral grains from each fraction were counted under a stereomicroscope. The IRD was

1 expressed as the number of grains per gram of sediment (grain g<sup>-1</sup>) and number of grains per  
2 square centimetre per year (grain cm<sup>-2</sup> y<sup>-1</sup>).

3 Stable isotope analyses were performed on foraminiferal tests selected from 54  
4 sediment layers. From each layer, 10 to 12 well-preserved specimens of *Cibicidoides*  
5 *lobatulus* were selected. The measurements were performed on a Finnigan-MAT 253 mass  
6 spectrometer coupled to a Kiel IV carbonate preparation device (Thermo Fischer Scientific,  
7 University of Florida). The resulting values were compared to isotopic standard NBS-19 and  
8 expressed in standard  $\delta$  notation relative to Vienna Pee Dee Belemnite (VPDB).

9

### 10 **3.2 Foraminiferal counts and molecular analysis**

11 Prior to the analysis of the fossil foraminiferal assemblages, 74 selected sediment  
12 samples were dried, weighed and wet-washed through sieves with 500 and 100  $\mu$ m openings.  
13 Each sample was divided using a dry microsplitter, and at least 300 specimens from each  
14 sample were counted. The foraminiferal counts were reported as percentages of the total  
15 assemblage and as the number of individuals per square centimetre per year. The fossil  
16 foraminifera assemblage was analysed with an orthogonally rotated (varimax) Q-mode  
17 Principal Component (PC) analysis, using commercially distributed software (SYSTAT 11).  
18 Taxa with abundances > 2 % of the total assemblage in at least one sample were analysed.  
19 Each PC was defined by the dominant (and eventually accessory) species. The PCs were  
20 referred to foraminiferal assemblages (FA) named after the dominant species. The PC scores  
21 showed the contribution of the selected species to each PC. PC loadings higher than 0.4 were  
22 regarded as statistically significant (Malmgren and Haq, 1982).

23 The analysis of molecular data from 12 selected layers was described in detail in  
24 Pawłowska et al. (2014). Briefly, the total DNA of each of the 12 sediment samples was  
25 extracted with a PowerSoil DNA kit (MoBio). A 3' SSU rDNA fragment including the

1 foraminifera-specific 37f hypervariable region (Pawlowski and Lecroq, 2010) was PCR  
2 amplified from environmental DNA. The SSU rDNA sequences were then obtained either  
3 based on cloning and Sanger sequencing or after library-preparation and Illumina high-  
4 throughput sequencing.

5 For the cloning-based Sanger sequencing, the environmental DNA was PCR amplified  
6 with s14F3 forward primer combined with s17, s15.2 or s15ROTEX as reversed primers. The  
7 sizes of the resulting fragments were of ca. 400 bp for s14F3/s17 and ca. 200 bp for both the  
8 s14F3/s15.2 and s14F3/s15ROTEX amplifications. Nested PCR was performed for samples  
9 with s14F3/s17 with the use of a s14F1/s17 primer combination. Positive and controlled PCR  
10 products of expected sizes were cloned and Sanger sequenced as in Pawlowski et al. (2011).  
11 The resulting raw sequences were manually corrected and edited using Codon Code Aligner  
12 and Seaview 4.0 (Gouy et al. 2010).

13 For high-throughput sequencing (HTS), s14F0 and s15 primers tagged with unique  
14 sequences of 5 nucleotides were used. The size of the obtained fragment was ca. 100 bp. The  
15 amplicons were quantified and pooled in equimolar quantities. A library preparation was  
16 performed using a TruSeq library-preparation kit (Illumina) and was loaded onto a HiSeq  
17 instrument for a paired-end HTS run of 2\*100 cycles at Fasteris SA (Plan-les-Ouates,  
18 Switzerland). The processing of the HTS sequence data, including quality filtering, sample  
19 demultiplexing, strict dereplication into unique sequences and operational taxonomic units  
20 (OTUs) selection was realized according to Lejzerowicz et al. (2013a), except that unique  
21 sequences that were composed of up to 10 reads in a sample were removed. The results were  
22 presented as OTUs-to-samples tables and transformed in terms of the number of OTUs and  
23 the relative abundance (%) of sequences.

#### 24 **4 Sediment dating**

1 The age of the studied core was estimated based on high precision AMS  $^{14}\text{C}$  dating  
2 performed on bivalves shells, as presented in Pawłowska et al. (2014). Eleven shells identified  
3 to the highest possible taxonomic level were selected and processed on a 1.5 SDH-Pelletron  
4 Model 'Compact Carbon AMS' (Poznań Radiocarbon Laboratory, Poland). The dates were  
5 converted into calibrated ages using the CALIB Rev. 7.0.2 Beta calibration program (Stuiver  
6 and Reimer, 1993) and the Marine13 calibration dataset (Reimer et al., 2013). The difference  
7  $\Delta R$  in the reservoir age correction of  $105 \pm 24$  was applied (Mangerud et al., 2006).

8 Four of the eleven samples ~~were in chronological order~~ and were used to establish an  
9 approximate age model for the sediment core. The upper-most sample contained post-bomb  
10 carbon, which indicates a post-1960 age. ~~Six samples revealed~~ Samples located in the middle  
11 part of the core revealed ages that were not in chronological order. All the samples (shells)  
12 revealing age reversals were excluded from the age model as they were likely redeposited  
13 which suggests redeposition events (Table 1). ~~These~~ Samples out of chronological order  
14 occurred at the sediment depths of  $\sim 15\text{-}55$  cm and  $\sim 80\text{-}115$  cm, and, therefore, it is likely  
15 that these sediment intervals represent major redeposition events the data from these two  
16 intervals should be used with caution. The age-depth model was made with the use of the  
17 CLAM-R software program (Blaauw, 2010; Fig. 2). The age of the oldest layer was estimated  
18 to be  $\sim 965$  AD. The sediment accumulation rate (SAR) in the deepest part of the core (i.e.,  
19 before 1800 AD; up to 120 cm) ranged from 0.1 to  $0.125 \text{ cm yr}^{-1}$ . At  $\sim 1800$  AD (120 cm),  
20 the SAR increased to  $1 \text{ cm yr}^{-1}$ . In the upper layers (after  $\sim 1850$  AD; 70 cm), the SAR  
21 decreased to  $0.3 \text{ cm yr}^{-1}$ .

22

## 23 **5 Foraminifera as environmental indicators**

24 Due to the differences in the ecological tolerances of particular species, foraminifera  
25 are indicators of glaciomarine conditions, Atlantic and Arctic water masses and bottom

1 currents. Herein, we followed the classification that Majewski et al. (2009) established based  
2 on ecological and palaeoenvironmental studies from Greenland, Svalbard, Novaya Zemlya  
3 and the Kara Sea region (see Majewski et al., 2009 and references therein).

4 The glaciomarine group comprised *Cassidulina reniforme*, *Elphidium excavatum* and  
5 *Quinqueloculina stalkerii*. The characteristic species of the Atlantic water mass are  
6 *Nonionellina labradorica*, *Bolivina pseudopunctata*, *Buccella frigida*, *Adercotryma*  
7 *glomerata*, *Ammotium cassis* and *Recurvoides turbinatus*. We decided to exclude *Reophax*  
8 *fusiformis* and *Reophax pilulifer* from this group because there were only 2 specimens of *R.*  
9 *fusiformis* in the HF\_2011 core, and *R. pilulifer* was not reported. The Arctic water group was  
10 composed of *Islandiella norcrossi*, *Elphidium spp* (excluding *E. excavatum*), *Stainforthia*  
11 *feylingi*, *Stainforthia loeblichii*, *Spiroplectammina bififormis* and *Spiroplectammina earlandi*.  
12 We decided to add *Islandiella helenae* to this group based on Kelly et al. (1999). The bottom  
13 current indicator group consisted of *Cibicidoides lobatulus* and *Astrononion gallowayi*.

14

## 15 **6 Results**

16

### 17 **6.1 Sediment age and characteristics**

18 The sediment was composed mainly of glaciomarine mud, with low sand content.  
19 Before 1600 AD (145 cm), the mean grain size fluctuated slightly, except for one peak at ~  
20 1450 AD (160 cm), which reached 4.5  $\phi$ . In ~ 1600 AD, the mean grain size increased  
21 slightly to 6.2  $\phi$ . After 1800 AD (122 cm), it varied within a broader range of values and  
22 presented three slight peaks between 1800 and 1850 AD (120 cm, 100 cm and 70 cm). A  
23 decrease in the mean grain size was observed from the mid to the end of the 20<sup>th</sup> century (25-0  
24 cm; Fig. 3).

1 From 1000 AD to 1800 AD (200-122 cm), the IRD flux was relatively stable and did  
2 not exceed 2 grains  $\text{cm}^{-2} \text{yr}^{-1}$ . After that period, the IRD delivery increased considerably,  
3 reaching up to 28 grains  $\text{cm}^{-2} \text{yr}^{-1}$ . From ~ 1900 to the end of the 20th century, the IRD flux  
4 varied from 0.24 to 10 grains  $\text{cm}^{-2} \text{yr}^{-1}$  (Fig. 3). There were three distinctive periods when  
5 the amount of IRD in the sediment considerably increased (Fig. 3): 1) at the transition from  
6 the MWP to the LIA (160-130 cm; up to 30 grains  $\text{g}^{-1}$ ), 2) in the late LIA (115-80 cm; up to  
7 24 grains  $\text{g}^{-1}$ ) and 3) in the early 20<sup>th</sup> century (60-20 cm; up to 24 grains  $\text{g}^{-1}$ ).

## 8 **6.2 Stable isotopes**

9 From 1000 to 1600 AD (200-145 cm),  $\delta^{18}\text{O}$  showed relatively stable values varying  
10 slightly from 2.63 ‰ vs. VPDB to 3.32 ‰ vs. VPDB. After 1600 AD, it fluctuated distinctly  
11 from 2.23 to 3.50 ‰ vs. VPDB. Larger  $\delta^{18}\text{O}$  values were observed before 1600 AD and in  
12 the 20<sup>th</sup> century. The period from 1600 to 1900 AD (145-60 cm) was characterized by a  
13 smaller  $\delta^{18}\text{O}$ , with significant peaks at the beginning of the LIA (~ 1600 AD; 145 cm) and  
14 during the late LIA (05 cm and 90 cm). The measured values of  $\delta^{13}\text{C}$  varied from 0.54 ‰ vs.  
15 VPDB to 1.59 ‰ vs. VPDB and fluctuated along the core. The most important fluctuations  
16 occurred between ~ 1600 and 1900 AD (145-60 cm), with  $\delta^{13}\text{C}$  values ranging from 0.54 to  
17 1.48 ‰ vs. VPDB (Fig. 3).

18

## 19 **6.3 Foraminiferal abundance and taxonomic composition revealed by the fossil record**

20 The foraminiferal flux varied from 1 to 86 ind  $\text{cm}^{-2} \text{yr}^{-1}$ . The most noticeable shift  
21 occurred at ~ 1800 AD (120 cm), when it increased from 2.8 to 81 ind  $\text{cm}^{-2} \text{yr}^{-1}$  (Fig. 3). The  
22 number of foraminifera per gram of sediment varied from 86 to 3838 ind  $\text{g}^{-1}$ . The highest  
23 values were observed before ~ 1850 AD (70 cm). After 1850 AD, the number of foraminifera  
24 declined and did not exceed 1742 ind  $\text{g}^{-1}$  (Fig. 3).

1 A total of 28,771 individuals were assigned to 72 species and 38 genera. Most of the  
2 species belonged to Rotaliida (34), Textulariida (12) and Lagenida (12). The other species  
3 were identified as Miliolida (10), Lituolida (2) and Globigerinida (Table S1 in the  
4 Supplement). The most abundant species were *Elphidium excavatum*, *Cassidulina reniforme*,  
5 *Cibicides lobatulus* and *Nonionellina labradorica* (Fig. 4). The fossil assemblage was  
6 strongly dominated by *E. excavatum* and *C. reniforme*, which together comprised up to 82 %  
7 of the total abundance. The abundance of *C. lobatulus* and *N. labradorica* varied slightly  
8 along the core, and no evident faunal changes were observed. The highest percentages of *N.*  
9 *labradorica* were noted after ~ 1800 AD and at the beginning of the 20<sup>th</sup> century (110 cm, 50  
10 cm and 25 cm), when its relative abundance reached up to 25 %. The highest percentages of  
11 *C. lobatulus* were noted before 1600 AD (145 cm), and a notable decrease in that species  
12 occurred in the latter part of the 20<sup>th</sup> century (25-0 cm). The percentage of agglutinated taxa  
13 did not exceed 25 % and reached its highest values between 1600 and 1800 AD (145-120 cm)  
14 and after ~ 1930 AD (25 cm; Fig. 4).

15 The proposed 4-factor PC explained 98.5 % of the total variability of the tested  
16 dataset. The most important PC analysis assemblages were (1) the *E. excavatum* FA, which  
17 explained 40.8 % of the total foraminiferal variance, (2) the *C. reniforme* FA, with *E.*  
18 *excavatum* as an accessory species, which explained 34.8 % of the variance, (3) the *N.*  
19 *labradorica* FA, with *C. lobatulus* as an accessory species, which explained 20.1 % of the  
20 variance, and (4) the *C. lobatulus* FA, which explained 2.8 % of the total variance (Table 2).  
21 The HF\_2011 core was dominated by the *E. excavatum* FA and the *C. reniforme* FA  
22 throughout. The *E. excavatum* FA showed the highest factor loadings during the LIA (i.e.,  
23 between 1600 and 1900 AD). In the uppermost part of the core, the *E. excavatum* factor  
24 loadings decreased, and the role of the *C. reniforme* FA increased. The *N. labradorica* FA  
25 was significant during the MWP and the early LIA (before ~ 1800 AD) and was not

1 significant during the late LIA (after ~ 1850 AD). The *N. labradorica* factor loadings started  
2 to increase at the beginning of the 20<sup>th</sup> century. The *C. lobatulus* FA was significant only in  
3 two layers dated to the MWP (Fig. 5).

4

#### 5 **6.4 Foraminifera in the ancient DNA record**

6 The results of the aDNA analysis are described in detail in Pawłowska et al. (2014).  
7 Herein, we summarize the results, focusing on monothalamous foraminifera.

8 We used Sanger and high-throughput sequencing (HTS) to obtain 717 and 8,700,815  
9 sequences, respectively. A total of 394 operational taxonomic units (OTUs) were obtained  
10 from the sequence clustering. The majority of the OTUs were assigned to Monothalamea (96  
11 OTUs) and Rotaliida (93 OTUs). The remaining OTUs were assigned to Textulariida (33  
12 OTUs), Miliolida (10 OTUs), Globothalamea (10 OTUs), Robertinida (1 OTU) and  
13 Globigerinida (5 OTUs); 146 OTUs remained unassigned (Table S2). Although the sequences  
14 of the species that dominated the fossil record were present in most of the samples, their  
15 abundances did not reflect the abundances in the fossil specimens (see Pawłowska et al.,  
16 2014).

17 The 96 OTUs assigned to monothalamids comprised 39.4 % of the sequences. The  
18 percentage of monothalamous sequences varied along the core from 3.5 % to 65 %. (Fig. 5)  
19 There were 7 OTUs constituting more than 3 % of all the sequences in at least one sample.  
20 They were referred to *Bathysiphon* sp. (clade BM), *Micrometula* sp. (clade BM, 2 OTUs),  
21 *Toxisarcon* sp. (clade C) and monothalamous foraminifera of undetermined phylogenetic  
22 origin (3 OTUs; Table S2).

23 Monothalamid sequences were assigned to 14 clades, including 10 that were  
24 represented by more than 5 % of the monothalamid sequences in at least one sample. The  
25 assemblage of monothalamous foraminifera was strongly dominated by clade BM (genera

1 *Micrometula* and *Bathysiphon*), which together comprised up to 90 % of the sequences of  
2 monothalamids (Fig. 5). *Bathysiphon* sp. was the most abundantly sequenced in the samples  
3 spanning the MWP and the early LIA, whereas sequences of *Micrometula* sp. dominated in  
4 the samples spanning the 20<sup>th</sup> century. The monothalamous assemblage during the MWP was  
5 dominated by *Toxisarcon* sp. and environmental monothalamous sequences belonging to  
6 clade V. The early LIA (1600 – 1800 AD; 150-125 cm) was marked by an increased  
7 proportion of sequences of *Hipocrepinella hirudinea* (clade D) and *Cedhagenia saltatus*  
8 (clade O). The monothalamous assemblage during the beginning of the MW (~ 1900 AD; 50  
9 cm) was strongly dominated by *Micrometula* sp. (which made up to 75 % of the  
10 monothalamous sequences), together with *Vellaria pellucidus*. In the late MW, a high number  
11 of monothalamid sequences occurred that belonged to environmental clades or were of  
12 undetermined phylogenetic origin (Fig. 6).

13

## 14 **7 Discussion**

15 Previous studies on the Svalbard Holocene history reported ‘unstable environmental  
16 conditions’ during the last thousand years (e.g., Berben et al., 2014; Groot et al., 2014),  
17 reflecting the major climatic changes: the MWP (~ 900 – 1500 AD), the LIA (~ 1500 – 1900  
18 AD) and the MW (~ 1900 – present) (Oerlemans, 2005). The Svalbard ice core records and  
19 sediment records from the shelf adjacent to Hornsund suggested that prolonged cooling  
20 started ~ 1600 AD, and the most severe conditions occurred during the 19<sup>th</sup> century (Isaksson  
21 et al., 2003; Majewski et al., 2009). On the contrary, the reconstruction of the Earth’s surface  
22 air temperature from Svalbard (Divine et al., 2011) constituted the cooling stage between 800  
23 and 1800 AD, with no clear signs of the onset of the LIA. Our foraminiferal and  
24 sedimentological records from Hornsund matched the trend described by Divine et al. (2011),  
25 as it revealed a sharp change in environmental conditions at ~ 1800 AD.

## 7.1 The Medieval Warm Period and the early Little Ice Age (~ 1000 AD - ~ 1800 AD)

The period from ~ 1000 to ~ 1800 AD was characterized by low and stable fluxes of IRD and foraminifera and slightly heavier  $\delta^{18}\text{O}$  (Fig. 3). This might indicate the influence of warmer and more saline waters, probably of Atlantic origin, and low glacial activity (Jernas et al., 2013). The fossil foraminiferal assemblage was fairly stable during the MWP (i.e., before 1600 AD) and there was no clear evidence of faunal change. Conversely, the foraminiferal aDNA record featured a high percentage of *Toxissarcon* sp. (Clade C) at ~ 1000 AD (Fig. 5). As reported by Gooday et al. (2005), *Toxissarcon* sp. are commonly found in the Svalbard fjords. In the case of our study, the increase in the *Toxissarcon* sp. percentage coincided with the peak of light  $\delta^{18}\text{O}$ , followed by lighter  $\delta^{13}\text{C}$ , which might suggest the presence of a highly productive zone of frontal contact of the AW and ArW water masses. Voltski et al. (2014) noted the presence of diatom frustules in the cytoplasm of *Toxissarcon* sp.. Therefore, we concluded that the occurrence of *Toxissarcon* sp. might be related to the phytoplankton-originated organic matter input.

Our data showed a slight peak of lighter  $\delta^{18}\text{O}$  at 1600 AD (Fig. 3), which could indicate an increase in melt water delivery to Hornsund, but it was not followed by increases in sediment accumulation and IRD flux. Therefore, we concluded that lighter  $\delta^{18}\text{O}$  at ~ 1600 AD showed the increased ArW inflow from the Barents Sea to the Svalbard shelf and Hornsund, which is in agreement with previous  $\delta^{18}\text{O}$  and fossil foraminiferal records obtained from the outer fjord (Majewski et al., 2009). This event occurred within a period of significant climate changes connected to the transition from the MWP to the LIA. The Humlum et al. (2005) investigation of the frozen *in situ* vegetation below Longyearbyen glacier (central Spitsbergen) indicated the advance of that glacier during the last ~1100 years. Based on the terrestrial record from Hornsund, the WMP was interrupted 600 years ago by an

1 advance of glaciers (Marks and Pękala, 1986; Linder et al., 1990) that lasted until the  
2 beginning of the 20<sup>th</sup> century.

3         The most pronounced changes that occurred at ~ 1600 AD in the HF\_2011 fossil  
4 assemblage were slight peaks in the abundances of *N. labradorica*, *I. norcrossi* and *I. helena*.  
5 Moreover, an increase in the percentage of agglutinated taxa was noted between 1600 AD and  
6 1800 AD (Fig. 4). *Nonionellina labradorica* is an AW indicator usually found in relatively  
7 warm and saline waters (Lloyd, 2006; Majewski et al., 2009). However, the abundances of  
8 these three species seemed to be controlled more by the food supply than by water  
9 temperatures (Hald and Korsun, 1997; Lloyd, 2006; Ivanova, 2008). The presence of  
10 *Islandiella* spp might indicate a highly productive environment related to the Polar Front  
11 (Steinsund, 1994). This supports the evidence of the inflow of the colder and less saline ArW  
12 at ~ 1600 AD, which changed the water mass balance and productivity in the fjord.

13         The foraminiferal flux before ~ 1800 AD was low (Fig. 3) and could be explained by  
14 the presence of species with low fossilization potential, e.g., agglutinated taxa (Wollenburg  
15 and Kuhnt, 2000). The percentage of agglutinated taxa was relatively low during the MWP  
16 and increased significantly after 1600 AD (Fig. 4), which likely reflected the inflow of the  
17 ArW and relatively low glacial activity (Hunt and Corliss, 1993; Hald and Korsun, 1997). Our  
18 aDNA data suggests that the abundance of agglutinated foraminifera was higher than that  
19 shown by the fossil record. Three agglutinated taxa were detected in both the fossil and aDNA  
20 record: *C. crassimargo*, *Reophax* spp and *Spiroplectammina* spp (Tables S1 and S2).  
21 However, only *C. crassimargo* was detected by both approaches in the corresponding layers.  
22 *Reophax* spp and *Spiroplectammina* spp sequences were recorded in all the examined  
23 samples, but they were relatively rare or absent in the fossil material (Pawłowska et al., 2014),  
24 probably due to the degradation of their tests. Korsun and Hald (2000) regarded *S. biformis*  
25 and *S. earlandi* as typical for glaciomarine habitats. They noticed an increase in the

1 abundance of those agglutinated species off glacier. Korsun et al. (2005) and Hald and Korsun  
2 (1997) reported *Reophax* spp and *Spiroplectammina* spp in the outer parts of the glacially fed  
3 fjords of Svalbard and Novaya Zemlya. Zajaczkowski et al. (2010) noted a decrease in the  
4 abundance of agglutinated foraminifera in Hornsund with increasing water turbidity. Thus, the  
5 presence of those species might indicate a glacier-distant environment.

6 Furthermore, the transition to the LIA between ~ 1600 and ~ 1800 AD was well  
7 marked by the increase in the percentage of monothalamous foraminifera aDNA sequences  
8 (Fig. 6). Monothalamids are highly adaptable and occur in environments where conditions  
9 may be extreme (Gooday, 2002; Sabbattini et al., 2010), which makes them effective  
10 colonizers. It is likely that the change in the hydrology and productivity in Hornsund at ~  
11 1600 AD might have created a new ecological niche, which was effectively settled by  
12 monothalamids. The monothalamous assemblage during the early LIA (from ~ 1600 to ~  
13 1800 AD) was dominated by taxa belonging to clade BM, mainly from genus *Bathysiphon*  
14 (Fig. 6). Gooday et al. (2005) reported *Bathysiphon* sp. in two glacial influenced fjords, Van  
15 Mijenfjorden and Kongsfjorden, at glacier distant sites. Moreover, a sharp peak of heavier  
16  $\delta^{13}\text{C}$  was noted in Hornsund at ~ 1600 AD, which might suggest the short-term suppression of  
17 primary productivity that resulted in the presence of degraded organic matter and  
18 phytodetritus that seemed to be favourable for *Bathysiphon* sp. (Alve et al., 2010). The  
19 presence of sequences of *Bathysiphon* sp. and agglutinated *Spiroplectammina* spp and  
20 *Reophax* spp support our conclusion that at the onset of the LIA (~ 1600 - ~ 1800 AD), the  
21 position of the glacier fronts was relatively distant to the fjord centre, which resulted in a low  
22 SAR and a low IRD flux, whereas the fjords' water masses were influenced by the ArW.

23 The transition to the LIA (~ 1600 - ~ 1800 AD) was also marked by increased  
24 percentages of sequences assigned to the monothalamid clade D (mainly *Hippocrepinella*  
25 *hirudinea*) and to clade O (mainly *Cedhagenia saltatus*; Fig. 5). *Cedhagenia saltatus* is a

1 species recently found by Gooday et al. (2011) in the Black Sea. Little is known about the  
2 environmental tolerance of *C. saltatus*. However, its presence in the area is strongly impacted  
3 by human activity, which suggests that it is an opportunistic species that has a high tolerance  
4 to environmental disturbance. *Hipocrepinella hirudinea* was noted in the fjords of Svalbard  
5 by Majewski et al. (2005) and Gooday et al. (2005). It appeared in the central and outer parts  
6 of the studied fjords, mainly in the shallow water sites. Korsun et al. (2005) noted the  
7 presence of the genus *Hipocrepinella* in Novaya Zemlya; however, it may not have referred to  
8 *H. hirudinea*. The scarce data on the ecological tolerances of *H. hirudinea* and *C. saltatus*  
9 precluded making any general conclusions.

10

## 11 **7.2 The late Little Ice Age (~ 1800 AD - ~ 1900 AD)**

12 The late LIA was characterized by an increased sediment accumulation rate and  
13 strongly fluctuating IRD delivery (Fig. 3). These changes were linked to changes in the  
14 particulate matter flux, which in subpolar fjords was governed by glacial meltwater discharge  
15 (Syvitski, 1989). Substantial amounts of suspended sediment and IRD might be released from  
16 glaciers during rapid deglaciation and during glacial surges (Koppes and Hallet, 2002).  
17 Moreover, sediment might be stored in the proglacial zones of land-based glaciers, from  
18 where could be eroded, particularly under conditions of increased glacial meltwater runoff  
19 and increased precipitation (Szczuciński et al., 2009). Next, the sediment could be redeposited  
20 from the sublittoral zone by storm waves. During the LIA, glacial extent reached its Holocene  
21 maximum (D'Andrea et al., 2012); thus, calving and melt water delivery could have occurred  
22 close to the central part of the fjord. Noticeably, the increase in the IRD delivery during the  
23 late LIA was not followed by an increase in the mean grain size, as was observed in both the  
24 precedent and following periods. It is likely that the amount of fine-grained sediment

1 delivered to the sea bottom significantly exceeded the amount of coarse ice-rafted sediment  
2 (i.e., IRD) and, consequently, almost no change in the mean grain size was observed.

3 Our data showed a 20-fold increase in the foraminiferal flux at ~ 1800 AD (Fig. 3),  
4 whereas the species diversity was relatively low due to the dominance of glaciomarine  
5 species, especially *E. excavatum* and *C. reniforme* (Figs. 4 and 5). As a consequence of the  
6 maximal range of the glaciers, conditions throughout the fjord became more glacier-proximal.

7 The aDNA revealed the dramatic increase in the percentage of sequences of  
8 monothalamous foraminifera at ~ 1900 AD (Fig. 6). Previous studies revealed that the  
9 distribution of monothalamids in Svalbard was closely related to the distance from the glacier  
10 at the head of the fjord. The study conducted by Majewski et al. (2005) in Kongsfjorden and  
11 Isfjorden showed a distinctive faunal gradient along the fjord axes, with three different  
12 monothalamous assemblages at subtidal, shallow-water and deep-water sites. Korsun et al.  
13 (2005) and Korsun and Hald (1998, 2000) reported that allogromiids constituted up to 99 %  
14 of living foraminifera in the stations close to the glacier termini in Novaya Zemlya and  
15 Spitsbergen. Sabbattini et al. (2007) attributed the occurrence of monothalamids in the  
16 Svalbard region to inputs of fresh water and a high, changeable sedimentation rate. Gooday et  
17 al. (2005) noted that the inner parts of Tempelfjorden and Kongsfjorden, fjords headed by  
18 tidewater glaciers, were dominated by organic-walled allogromiids and saccamminids. This  
19 was reflected in our data as the percentage of allogromiids (mainly *Micrometula* sp.)  
20 increased significantly from 40 % at ~ 1850 AD to 80 % at ~ 1900 AD (Fig. 5). Moreover, the  
21 late LIA and the early MW were marked by an increase of the percentage of sequences  
22 assigned to clade E, mainly *Vellaria pellucidis*. Majewski et al. (2005) noted the presence of  
23 *Vellaria* sp. in subtidal and shallow areas of the Spitsbergen fjords. The increase in the  
24 percentage of *Micrometula* sp. and *V. pellucidis* in the period of the highest glacial activity  
25 suggests that those species were potential indicators of glacier-proximal settings.

### 7.3 The Modern Warming (~ 1900 AD – present)

The sedimentary record of the MW featured a decrease in the SAR and a lower but variable IRD flux (Fig. 3). Peaks in the IRD flux coincided with the increased mean grain size (Fig. 3). This trend was opposite to that of the late LIA, where no clear correlation between the IRD flux and mean grain size was observed. The post-LIA glacial retreat led to an increased distance between the coring station and the main tidewater glacier front. In the Spitsbergen fjords, fine-sized particles from glacial outflows are deposited close to the source (Szczeniński et al., 2009); therefore, the HF\_2011 station was impacted mainly by ice-rafted, coarser particles. The IRD flux gradually diminished in the late 20<sup>th</sup> century, which was probably a result of retreat of the tidewater glaciers' fronts to the inner bays, which limited iceberg drift to the fjord centre. The most noticeable changes in the fossil foraminifera community occurred in the late 20<sup>th</sup> century, with the gradual increase of *B. frigida* and *I. norcrossi* and the decrease of *C. lobatulus* (Fig. 4). *Islandiella norcrossi* and *B. frigida* typically occupied the distal sections of the glacial fjords of Svalbard and Novaya Zemlya (Korsun et al., 2005; Hald and Korsun, 1997; Korsun and Hald, 2000; Pogodina, 2005). Steinsund (1994) linked the presence of *I. norcrossi* and *B. frigida* with high productivity related to a polar front position and seasonal sea-ice cover. Thus, we concluded that since the mid-20<sup>th</sup> century, Hornsund and the adjacent shelf remained under the influence of the AW, which formed a frontal zone with local waters. This conclusion is supported by the PC analysis, which showed that the significance of the *N. labradorica* FA was increasing during the 20th century (Fig. 5). *Cibicides lobatulus* is a relatively shallow-water species and takes advantage of vigorous bottom waters (Hald and Korsun, 1997; Lloyd, 2006); however, it is an epiphytic species that needs a hard substrate to stay attached to the bottom surface. Therefore, the decrease in the percentage of *C. lobatulus* could be connected to a decrease in

1 the near-bottom currents and a low IRD flux and, consequently, an increase in the fine  
2 sediment fraction (Fig. 3). The increased abundance of species typical of glacier-distal faunas  
3 was followed by a decrease in the abundance of species considered to be bottom current  
4 indicators (Fig. 4). These results support our evidence for a rapid glacier retreat, coupled with  
5 the decreasing influence of glaciomarine sedimentation and enhanced productivity. It was also  
6 reflected in the molecular record, where the number of OTUs and the percentage of  
7 monothalamids decreased after ~ 1920 AD, reaching values similar to those during the MWP  
8 (Fig. 6). The second half of the 20th century was marked by a significant increase in the  
9 unassigned monothalamids sequences belonging to environmental clades. However, without  
10 an accurate identification of sequences, it is not possible to make any palaeoecological  
11 interpretations.

12         The use of the approach based on aDNA allows the hidden diversity of benthic  
13 foraminifera communities to be assessed and, therefore, the information based on traditional  
14 palaeoceanographic proxies to be refined. However, current methodological biases associated  
15 with the environmental DNA sequencing approach preclude comprehensive analyses of  
16 sequence abundance data. The aDNA data should be interpreted carefully as it is not possible  
17 to establish the direct relationship between the number of  
18 specimens and the number of ribosomal sequences. Some aspects of quantitative DNA  
19 analyses were discussed in Weber and Pawlowski (2013). One of the conclusions was that  
20 when the species is very abundant, its sequences are also numerous. Therefore, the genuinely  
21 dominant species might be associated with high sequence occurrences in the sequencing data.

22

## 23 **8 Conclusions and Perspectives**

24         The main climatic fluctuations of the last millennium (the MWP, the LIA and the  
25 MW) were reflected in the fjord water mass balance and glacial activity. The marine

1 environmental conditions during the MWP and the early LIA were relatively stable, with a  
2 low SAR and low IRD flux. The beginning of the LIA (~ 1600 AD) was poorly supported by  
3 the fossil record, but it was well evidenced in the aDNA data. It was marked by the increased  
4 percentage of sequences of monothalamous foraminifera, mainly *Bathysiphon* sp., which  
5 supports our assumption that the terminal positions of the glaciers were relatively distant at  
6 the onset of the LIA. The early LIA (~ 1600 – ~ 1800 AD) was also marked by high  
7 percentages of *H. hirudinea* and *C. saltatus*. The late LIA (after ~ 1800 AD) was  
8 characterized by the increased proximity of tidewater glaciers' fronts, which increased  
9 sedimentation from suspension and from the icebergs; thus conditions in the fjord centre  
10 became glacier-proximal. The end of the LIA ( ~ 1900 AD) was marked by increased  
11 percentage of *Micrometula* sp. and *V. pellucidus*. Those results revealed their potential as  
12 indicators of glacier-proximal environments, which were characterized by melt water  
13 outflows, a high sedimentation rate and increased calving. During the MW, the major  
14 glaciers' fronts retreated rapidly to the inner bays, limiting the iceberg discharge to the fjord  
15 centre and causing the shift in the foraminiferal community reflected in the fossil and aDNA  
16 records.

17         The present study was the first attempt to implement an aDNA foraminiferal record for  
18 palaeoclimatic reconstruction. The data inferred from the molecular analyses correlated well  
19 with environmental changes. The aDNA record even revealed small environmental changes  
20 that were not clearly indicated by the fossil record. By including monothalamous foraminifera  
21 identified in the aDNA record, we considerably increased the number of potential proxy  
22 species. However, to fully benefit from this new source of information, it is essential to  
23 improve knowledge of the ecology of monothalamids. The positive results of the present  
24 study encourage further applications of ancient foraminiferal DNA sequences to reconstruct  
25 past environmental changes in polar regions.

 2 **Figure 1.** Bathymetric map of Hornsund with sampling station HF 2011. The position of core  
 3 HR 3 studied by Majewski et al. (2009) is shown. Glaciers are shown in white. WSC – West  
 4 Spitsbergen Current, ESC – East Spitsbergen Current.

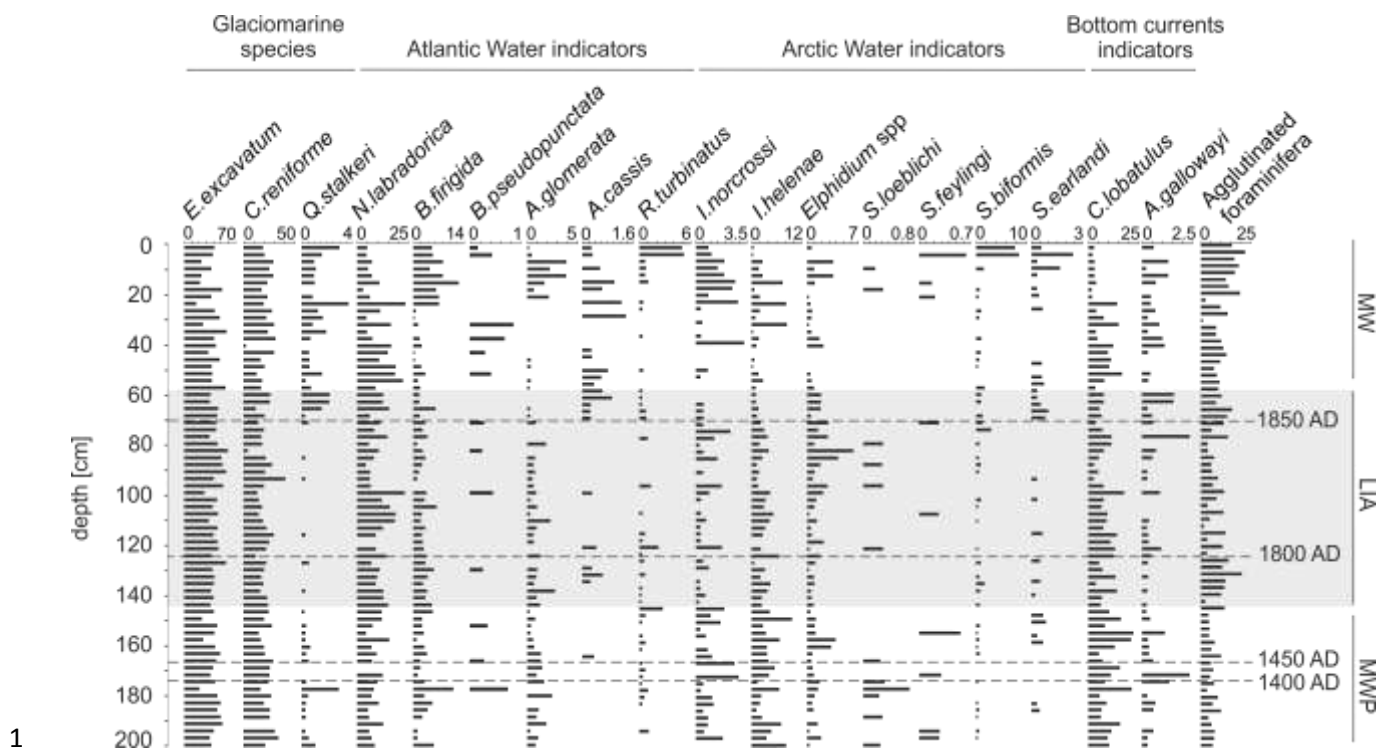

1  
 2 **Figure 2.** Age model of the studied core. The black line indicates the age-depth model  
 3 derived from a linear interpolation. The grey fields show the probability distributions of  
 4 calendar dates obtained by the calibration of individual  $^{14}\text{C}$  dates used for the age model. The  
 5 shaded areas mark sediment intervals which most likely represent major redeposition events  
 6 (after Pawłowska et al. 2014, modified).

1  
2 **Figure 3.** Sediment accumulation rate (A), IRD delivery, expressed as IRD flux (B) and  
3 number of IRD grains per gram of sediment (C), mean grainsize (D), stable oxygen (E) and  
4 carbon (F) isotopes, flux of total fossil foraminifera (G) and number of foraminifera per gram  
5 of sediment (H). MWP: Medieval Warm Period, LIA: Little Ice Age, MW: Modern Warming.  
6 The time ranges of the MWP, LIA and MW are presented after Majewski et al. (2009).

7

1  
2 **Figure 4.** The abundances of selected foraminifera species expressed as percentages (%) of  
3 the total assemblage. The foraminiferal taxa were grouped based on their ecological  
4 tolerances (see Sect. 5: Foraminifera as palaeoenvironmental indicators). MWP: Medieval  
5 Warm Period, LIA: Little Ice Age, MW: Modern Warming. The time ranges of MWP, LIA  
6 and MW are presented after Majewski et al. (2009).

 2 **Figure 6.** The relative abundance of the monothalamid sequences, expressed as the  
 3 percentage of all foraminiferal sequences, and the composition of the monothalamid  
 4 assemblage, expressed as percentages of sequences within clades. Clades that constitute more  
 5 than 5 % of the monothalamid sequences in at least one sample are presented. ‘Environmental  
 6 clades’ relate to foraminifera known only from environmental sequencing.
