Abstract

Climatic reconstructions for north-eastern Canada are scarce such that this area is under-represented in global temperature reconstructions. To fill this lack of knowledge and identify the most important processes influencing climate variability, this study presents the first summer temperature reconstruction for eastern Canada based on a millennial oxygen isotopic series ($\delta^{18}O$) from tree rings. For this purpose, we selected 230 well-preserved subfossil stems from the bottom of a boreal lake and five living trees on the lakeshore. The sampling method permitted an annually resolved $\delta^{18}O$ series with a replication of five trees per year. The June to August maximal temperature of the last millennium has been reconstructed using the statistical relation between Climatic Research Unit (CRU TS3.1) and $\delta^{18}O$ data. The resulting millennial series is marked by the well-defined Medieval Warm Anomaly (MWA; AD 1000-1250), the Little Ice Age (AD 1450-1880) and the modern period (AD 1950-2010), and an overall average cooling trend of -0.6°C/millennium. These climatic periods and climatic low frequency trends are in agreement with the only reconstruction available for northeastern Canada and others from nearby regions (Arctic, Baffin Bay) as well as some remote regions like the Canadian Rockies or Fennoscandia. Our temperature reconstruction clearly indicates that the Medieval Warm Anomaly has been warmer than the modern period, which is relatively cold in the context of the last 1000 years. However, the temperature increase during the last three decades is one of the fastest warming observed over the last millennium (+1.9°C between 1970-2000). An additional key finding of this research is that the coldest episodes mainly coincide with low solar activities and the extremely cold period of the early 19th century has occurred when a solar minimum was in phase with successive intense volcanic eruptions. Our study provides a new perspective unraveling key mechanisms that controlled the past climate shifts in northeastern Canada.

1. **Introduction**

The recently published work of the Intergovernmental Panel on Climate Change (IPCC AR5, 2013; PAGES 2K consortium, 2013) has shown that north-eastern Canada is poorly represented among existing millennial temperature reconstructions in the northern hemisphere. For this reason, a better knowledge of regional past climate variations registered in natural archives is needed. The use of natural archives such as trees, sediment or pollen has permitted the reconstruction of temperature variability at regional, hemispheric and global scales for the past millennium (Hegerl *et al.,* 2007; Mann *et al.,* 2009; Moberg *et al.,* 2005; PAGES 2k consortium, 2013). Although some studies have documented past climatic conditions in northern Canada (Moore *et al.,* 2001; Thomas and Briner, 2009; Luckman and Wilson, 2005; Edwards *et al.,* 2008; Viau and Gajewski, 2009; Gajewski and Atkinson, 2003), only one annually-resolved millennial temperature reconstruction based on tree-ring widths exists for eastern Canada (Gennaretti *et al.,* 2014; summer temperature reconstruction for Eastern Canada, STREC), but none has been based on the isotopic approach. Consequently, obtaining millennial-long, high-resolution temperature reconstructions from additional proxies in north-eastern Canada is important to increase our knowledge of the past climate, and better understand the mechanisms of climate change.

Tree-ring isotope series present the advantage that they generally do not need to be detrended; they retain climatic low frequency variations, and require fewer trees compared to classical dendrological methods (Loader *et al.,* 2013; Robertson *et al.,* 1997; Young *et al.,* 2010). Moreover, oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) series have proven their suitability for reconstructing past summer temperatures (Porter *et al.,* 2013; Luckman and Wilson, 2005; Barber *et al.,* 2004; Anchukaitis *et al.,* 2012). Whereas $\delta^{13}C$ series have often been used for long climatic reconstructions, only a few studies have used long $\delta^{18}O$ series (Edwards *et al.,* 2008; Richter *et al.,* 2008; Treydte *et al.,* 2006; Wang *et al.,* 2013). A previous study has already proven that $\delta^{18}O$ is the most suitable isotopic proxy for summer temperature reconstruction in our study region (Naulier *et al.,* 2014; Naulier *et al.,* in press).

In northern Canada, most tree species rarely live more than 300 years (Arseneault *et al.,* 2013). In such regions where old trees are missing, isotopic chronologies can be extended by combining living specimens with subfossil trees preserved in lakes (Boettger *et al.,* 2003;

Gagen *et al.,* 2012; Mayr *et al.,* 2003; Savard *et al.,* 2012), and cross-dating stems to determine subfossil tree ages (Arseneault *et al.,* 2013). For the purpose of paleoclimate studies, subfossil stems can be easily extracted and collected from large stocks of drowned subfossil logs in lakes and can be associated with specific edaphic contexts as most specimens are not redistributed in lakes (Gennaretti *et al.,* 2014a).

After cross-dating, the development of a robust millennial, isotopic chronology from the combination of living and subfossil stems involves replicating specimens in order to retain the climate variability of the study site (Haupt *et al.,* 2014; Loader *et al.,* 2013a). However, the amount of material available is often a constraint because of the short lifespans of trees, the difficulty to separate single and thin rings and obtaining enough cellulose for isotopic analysis (Loader *et al.,* 2013b; Boettger and Friedrich, 2009). To overcome these problems, different pooling methods have been developed such as inter-tree pooling (McCarroll and Loader, 2004; Dorado Liñán *et al.,* 2011), serial pooling of consecutive tree rings within an individual tree (Boettger and Friedrich, 2009), and the "offset-pool plus join-point method" (Gagen *et al.,* 2012). This last method has permitted constructing a millennial $\delta^{13}C$ series with annual resolution and high replication, while reducing the sampling efforts and laboratory analyses (Gagen *et al.,* 2012). Moreover, a statistical analysis of this method has confirmed its robustness and possible application for the production of millennial $\delta^{18}O$ series (Haupt *et al.,* 2014).

The present study aims to produce a new paleoclimatic data set based on tree-ring $\delta^{18}O$ series covering the last millennium in northeastern North America. For this purpose, we develop a 1010-years long $\delta^{18}O$ series using a combination of living trees and submerged subfossil stems from one site, and reconstruct the summer maximal temperature. We analyze the main characteristics of the climatic series and evaluate its robustness by comparison with other reconstructed temperature series. Finally, we explore the potential impact of natural forcing (solar radiation and volcanic eruptions) on past climatic variability in north-eastern Canada.

2. **Materials and methods**

2.1. **Study area**

The study site is located at the center of the Quebec-Labrador peninsula in north-eastern Canada (Figure1A). This area is part of the Precambrian Canadian Shield, mainly constituted of granitic and gneissic rocks. The landscape is characterized by a low altitude plateau (400-600 m), with abundant lakes and wetlands (Dyke *et al.,* 1989). Forests of the area are dominated by black spruce (*Picea mariana* (Mill.) BSP) trees, developed as pure open lichen woodlands on well-drained sites, and spruce-moss woodlands in depressions. Balsam fir (*Abies balsamea* (L.) Mill.) and Tamarack (*Larix laricina* (Du Roi) Koch) also grow in this region. Wildfires are the most important natural disturbances with a rotation period estimated between 250 to 500 years (Boulanger *et al.,* 2012).

The climate is continental and subarctic with short, mild summers and long, cold winters. Environment Canada data (Schefferville station) show that the 1949 to 2010 mean monthly temperature is -22.9°C in January and 13.3°C in July with a mean annual temperature of -3.9°C. Total annual precipitation averaged 640 mm with up to 60% falling in summer (June to September). The mean duration of the frost-free period is 75 days from mid-late June to mid-September. The lakes are generally frozen from mid-October to early June.

The selected lake (L20; 54°56’31’’ N; 71°24’10’’ W) is part of the large network of lakes sampled by our group (Arseneault *et al.,* 2013; Gennaretti *et al.,* 2014a and b). Ecological and morphological criteria have been developed to identify lakes that present the best potential for millennial-long climatic reconstructions (well-preserved subfossil trees) and large stocks of subfossil logs. These lakes are typified by an abrupt lake/forest transition, as well as log accumulation in the lower littoral zone away from ice erosion and waves (Arseneault *et al.,* 2013, Gennaretti *et al.,* 2014a, Gennaretti *et al.,* 2014c). Lake L20 has an altitude of 483 m and an area of 35.1 ha. It is bordered by open spruce-moss with lichen woodlands growing on well-drained podzolic soil and regular slope. The last severe wildfire occurred at about AD 1590 along the southern section of the studied shore segment and more than 1200 years ago along the northern section (Gennaretti *et al.,* 2014c).

2.2. Tree stem selection and sampling strategy

We recently demonstrated that isotopic series from different heights along lakeshore trees provide similar isotopic trends, and indicated that the combination of lakeshore black spruce trees with subfossil stem segments does not introduce artefacts in long $\delta^{18}O$ series, thus permitting their combination for climatic reconstruction (Naulier *et al.,* 2014). In the present study, subfossil stems were selected from a large collection of 586 cross-dated specimens from lake L20, also used in the STREC reconstruction (Gennaretti *et al.,*2014b), based on their excellent degree of preservation (Savard *et al.,* 2012), relatively large ring width (>0.2 mm) and their life span (Supplementary material, Table I). The development of a millennial isotopic series requires choosing an appropriate method to preserve both high and low climate frequencies, while limiting analytical efforts. We decided to adapt the "offset-pool plus join-point method" (Gagen *et al.,* 2012) in order to obtain an annual resolution with a replication of five trees for each year.

According to this sampling method, one cohort is made by selecting segments from five contemporaneous trees such that each cohort overlaps the next one over five years. In our case, five living trees were selected to construct a modern cohort (CV; AD 1860-2006) and 60 well-preserved subfossil stems from the lake floor were used to produce 12 subfossil cohorts (C0 to C11; AD 997-1956; Figure 2). Overall, our cohorts cover between 59 and 111-years and the complete suite of cohorts extends from AD 997 to 2006. Additionally, within every cohort, each tree was divided into five-year blocks which were offset by one year among trees (Supplementary material, Table II). As a consequence, the $\delta^{18}O$ value obtained for a specific year is the mean of the isotopic results from five trees, which represents a triangular centralized nine-year moving average.

2.3. **Laboratory treatment**

We extracted α-cellulose sub-samples according to a standard protocol modified for small samples at the Delta-lab of the Geological Survey of Canada (Green, 1963; Savard *et al.,* 2012). The extracted α-cellulose was dried at 55°C for 12 hours and sub-samples analyzed using peripherals on-line with gas-source isotope ratio mass spectrometers (IRMS). All material was analyzed for $\delta^{18}O$ values with a pyrolysis-CF-IRMS (Delta plus XL). The analytical accuracy of this instrument was 0.2‰ (1σ), as established by using international standards (IAEA-SO-6 and IAEA-NBS-127). All $\delta^{18}O$ measures are reported in permil (‰) relative to the Vienna Standard Mean Ocean Water (VSMOW). A total of 2192 analyses were produced, with, in addition, 24% of all samples retreated and analyzed to determine the external precision (reproducibility) of the complete procedure (0.2‰, 1σ).

2.4. Cohort corrections and climatic reconstruction

When a long isotopic series is produced from trees coming from a random assemblage, joining two successive cohorts may be difficult due to the existence of isotopic offsets between cohorts. An approach to overcome this problem is to use the mean of $\delta^{18}O$ values coming from several tree segments from the overlap period between two successive cohorts which permits to estimate a correction factor for the offset (Gagen *et al.,* 2012). In the present study, the construction of the millennial $\delta^{18}O$ series required such an adjustment for some cohorts. We have adopted the “join-point method” proposed by Gagen *et al.* (2012). A join-point (hereafter JP), corresponds to the mean results of 5-years blocks from several trees overlapping between two cohorts. We have used all available dated trees (between 10 and 24) to produce the required join points (JP 0 to JP 11), and verified several methods to correct for the offsets between cohorts. Hence, every cohort has been corrected by adding the linear regression calculated between the $\delta^{18}O$ values of its two ends.

The integrity of the isotopic signal has been verified elsewhere (Naulier, 2015). The $\delta^{18}O$ values of lignin and cellulose have been analyzed for three contrasted climatic periods of the millennium (AD. 1141-1164, 1741-1761 and 1886-1909), as detected in previous studies (e.g. Savard *et al.,* 2012). The cellulose isotopic integrity of the subfossil stems has been confirmed by the similarity of the Δ values between living trees and subfossil stems for the 1886-1909 period. In addition, the departure between the $\delta^{18}O$ values of lignin and cellulose ($\Delta=\delta^{18}O_{cellulose}-\delta^{18}O_{lignin}$) exhibit no temporal trend.

In previous studies, we have analyzed the relationships between $\delta^{18}O$ series of five living trees and various climatic parameters (temperature, precipitation, vapor pressure deficit, etc). We have established that $\delta^{18}O$ series of black spruce stems sampled at an annual resolution from boreal lakeshore were significantly correlated with June-August (JJA) maximal temperature (Tmax; r=0.54). We have also determined by statistical analysis (Buishand test, Buishand, 1982) that the summers became warmer after 1975 and that the growing season duration and degree-days have increased importantly during the last decade (2000-2010). Moreover, we have demonstrated that during this decade the growing season started sooner and finished later than before, changing the relationship between JJA maximal temperature and $\delta^{18}O$ series (divergence). In other words, this JJA Tmax and $\delta^{18}O$ series relation is stable and strong between 1930 and 2000(r_{mean}= 0.54; 1930-2000), but not after (AD 2000-2010; Naulier *et al.,* 2014; Naulier *et al.,* in press). Therefore, in the present study, we excluded the last decade (divergent years) when calibrating the $\delta^{18}O$ series on temperature data which is assumed to be non-representative of the temperature variation over the last century. The $\delta^{18}O$ series of subfossil cohorts are filtered on 9 years; we have made the choice to pass a 9-years centered-filter on the JJA maximal temperature CRU TS 3.1 in order to use series all treated in the same way for the reconstruction.

In a first step, a simple linear regression and a linear-scaling model were calibrated over the entire 1930-2000 period with climatic data. Climate data from the 1900-1929 period were excluded because no meteorological station was then operating at less than 300 km from the study site. The climatic series was separated into two equal periods (AD 1930-1970 and 1971-2000; Table 1) in order to test the robustness of the two calibration models, using the non-first-differenced reduction of error (RE), the coefficient of error (CE), the raw mean squared error (RMSE) and the coefficient of determination (r^2). The linear regression and the linear-scaling calibration procedures resulted in somewhat different temperature reconstructions of similar robustness with similar RE, CE, r^2 and RMSE coefficients. In both cases, the model residuals satisfy the standard linear regression assumptions of normality, variance and autocorrelation (not shown), but cannot reproduce all attributes of the measured data. We therefore tested the possibility of averaging the two model results, and this option gave the best reproduction of the measured Tmax. Consequently, we averaged results from the two reconstructions in order to obtain one robust reconstruction (Table 1; Supplementary material, Table III).

Then, i-STREC was compared to the only other regional temperature reconstruction (STREC; Gennaretti *et al.,* 2014), which is built from ring width data from 6 lakes, including our site, and with reconstructions based on tree rings from another boreal region (Fennoscandia, Helama *et al.,* 2002; Figure). We also compared i-STREC with independent temperature reconstructions based on other natural archives from North America and the Arctic region (Thomas and Briner, 2009; Kobashi *et al.,* 2011; Luckman and Wilson, 2005; Vinther *et al.,* 2009, Figure 5). Most published reconstructions are based on mean temperatures, except our reconstruction and the one from the Canadian Rockies, which are based on summer maximal temperatures. The influence of climatic forcings was evaluated through the comparison of i-STREC with time series of sulfate emission from volcanic origin (Crowley *et al.,* 2012) and solar radiation series (Bard *et al.,* 2003; Figure 6). The durations of the solar minima have been determined according to existing estimations of solar radiation (e.g., Bard *et al.,* 2003).

3. **Results and discussion**

3.1. **Development of $\delta^{18}O$ chronology**

As the purpose of the reconstruction was to identify contrasted periods and important temperature changes over the last millennium, the choice of the sampling method proposed by Boettger *et al.* (2009) was relevant because it allows for reconstruction of climatic parameters at an annual resolution with a replication of five trees per year. The range of $\delta^{18}O$ values of trees is between 19.5 and 22.0‰, and the largest $\delta^{18}O$ differences among trees within a junction is obtained for JP5 (3.8‰; Figure 3A). This large inter-tree variability can be explained by a combination of causes, including various growing locations along the lakeshore which influence their water supply (Figure 1B), and inter-tree metabolic variability (0.5‰ in Naulier *et al.,* 2014). Such variability confirms the need to take a large number of trees for a millennial reconstruction in order to capture the site signal (Loader *et al.,* 2013a).

The $\delta^{18}O$ values at intersections between two successive cohorts and of the JP $\delta^{18}O$ means are surprisingly matching in most cases (except at the C8/C9 and C3/C4 junctions; figure 3). These observations suggest that offset correction between cohorts is not always necessary. However, we have determined that a modification of the JP adjustment procedure published by Gagen *et al.* (2012) would optimize the correction while conserving the isotopic variability and trends over the millennium (Naulier, 2015). Hence, we have used the mean of

$\delta^{18}O$ values of JP from overlapping cohorts to calculate the required adjustment, this mean being considered as "the adjustment value". Correcting cohort $\delta^{18}O$ series with this method increases the number of trees considered (20 to 33 trees instead of 10 to 23 trees if only JP are used). After correction, the mean of the millennial $\delta^{18}O$ series is 20.8‰. The strong correlation between the $\delta^{18}O$ series of living trees and subfossil stems (r^2=0.70) over their overlapping period (1860-1956) confirms the isotopic integrity of the subfossil stems, and ensures that the climatic reconstruction can be performed over the rest of the millennial $\delta^{18}O$ series.

Although the cohort sampling method has shown many positive points, it is nevertheless important to highlight some concerns about this procedure. Indeed, the sampling strategy produces a $\delta^{18}O$ series smoothed with a centered 9-years filter. This smooting leads in some cases to series requiring more care than non-smoothed series before they can be interpreted or used. For instance, the calibration of our smoothed $\delta^{18}O$ series required a centered 9-years filtering of the climatic series. Consequently, correlations between isotopic and climatic series are generally overestimated. It is important to highlight that even if the correlations are improved by smoothing due to the sampling method; they nevertheless represent a solid and real link, and do not create an artefact (see also the discussion on the calibration/verification method of next section, Naulier *et al.,* 2014).

3.2. Model validation and millennial climatic reconstruction

3.2.1. Model validation

We have compared two methods of sampling and production of the ring series from living trees prior to calibration: (1) separation at an annual resolution without pooling (e.g., Haupt *et al.,* 2013); and (2) sampling with the cohort approach. We have found that the second was best suited because it slightly improved the correlation between $\delta^{18}O$ series and maximal temperatures (r^2=0.64 vs 0.54 with annual resolution), and it allows using $\delta^{18}O$ series compatible with the one used for the millennial subfossil series (9-years moving average). Consequently, the $\delta^{18}O$ series of the living-tree cohort (CV) was used to calibrate the model and to provide a robust reconstruction as it show a strong correlation with the new CRU series (r^2=0.64) for the entire calibration period (1930-2000), which confirmed that the reconstruction of past temperature with the average $\delta^{18}O$ series is suitable (Figure 4A). The RMSE is 0.26, with a RE and a CE of 0.60. However, it appears that the calibration and verification coefficients are significantly changing depending on the period selected for the statistical analysis. This observation implies that the correlation between Tmax and $\delta^{18}O$ series is not stable over the last century even if the correlation stays significant (Naulier *et al*. in press).

These statistical results confirm that the summer temperature reconstructed based on $\delta^{18}O$ values (i-STREC) are representative of the natural variability that existed in north-eastern Canada.

3.2.2. Millennial temperature trends in north-eastern Canada

The i-STREC shows a 0.6°C decrease of maximum summer temperature over the past millennium (

Figure 4B), whereas a millennial 0.2°C cooling is roughly estimated for the mean temperature of northern hemisphere (PAGES 2k consortium, 2013). However, our local temperature decrease is in the same order of magnitude as the decrease of summer-months mean temperature reconstructed using pollen in the North American tundra (Viau *et al.,* 2012), and in northern regions of high latitudes (sediment, tree-ring widths, ice core in Kaufman *et al.,* 2009 and tree-ring widths in Esper *et al.,* 2012). This temperature decline over the last millennium is generally attributed to orbital forcing (PAGES 2k consortium, 2013).

The reconstruction suggests that the maximum summer temperature has varied from a maximum of 17.3°C around AD 1008-1010 to a minimum of 14.8°C around AD 1670-1674. The twentieth century was generally cold (mean of 16°C) with an abrupt warming trend during the last three decades (+0.2°C/10 years between AD 1900-1980 and +0.8°C/decade between AD 1980-2010; CRU TS 3.1 data; Figure 4A). Furthermore, two major climatic episodes were also revealed by i-STREC: a warm period during the eleventh and twelfth centuries (mean of 16.5°C) and a cold period from the early fifteenth to the end of the nineteenth centuries (mean of 15.8°C; Figure 4B). These periods are in agreement with the general knowledge of the temperature trends observed globally for the last millennium and correspond to, the Medieval Warm Anomaly (MWA) and the Little Ice Age (LIA), respectively (IPCC 2013, PAGES 2k consortium, 2013). Based on i-STREC data, we associate these two climatic episodes to the ~ AD 1000-1250 and ~ AD 1450-1880 time periods, respectively.

3.2.3. Evidences of contrasted climatic periods

The high summer temperatures of the 11^{th} century (AD ~ 1000-1250; Figure 4B) coincide with peaks previously observed in our study area based on tree-ring width (Gennaretti *et al.,* 2014b; STREC), as well as in Greenland ice cores (Kobashi *et al.,* 2011; Vinther *et al.,* 2009, 2010), tree-ring series from the Canadian Rockies (Luckman and Wilson, 2005) and Fennoscandia (Helama *et al.,* 2002; Figure 5), and large-scale reconstructions (Mann *et al.,* 2009, Ljungqvist *et al.,* 2012, Kaufman *et al.,* 2009, Trouet *et al.,* 2013). Several hypotheses on the forcing of this warm anomaly have been proposed, including a prolonged tendency towards a positive-phase of the North Atlantic Oscillation (NAO; Trouet *et al.,* 2009; Trouet *et al.,* 2012) or a synchronicity between La Niña phase and a warm phase in the Atlantic Multidecadal Oscillation (AMO; Feng *et al.,* 2011; Mann *et al.,* 2009). In northeastern Canada, the NAO has an important impact on winter temperatures but not for summer (Hurrell *et al.,* 2003). In contrast, the AMO influences spring and summer temperatures (Fortin and Lamoureux, 2009) and is partly responsible for the recent sea surface temperature warming of northeastern Canada (Ding *et al.,* 2014). However, the state of the AMO at the beginning of the millennium being unknown, it is difficult to assess its influence on climate during the MWA. Recently, Sicre *et al*. (2014) have demonstrated that during the MWA, the strong Northern Annular Mode (NAM) was concomitant with a strong ice-loaded Labrador Current (LC). This combination could be responsible for a decrease of fresh air from Arctic to eastern Canada and consequently, for an increased temperature along the continent during a part of the medieval period.

Following the MWA, i-STREC emphasize a cold period between ~ AD 1450 and 1880, which can be attributed to the Little Ice Age (LIA; Figure 4B). It is worth noting that a short warming phase occurred between 1510 and 1590 (Figure 4B). Such warm phase also occurred at the eastern Canadian treeline and included the expansion of upright tree growth forms in lichen-spruce woodland (Payette *et al.,* 1989). Overall, the LIA is recorded in several Northern hemisphere temperature reconstructions based on various proxies, even if its length vary among regions (PAGES 2k consortium, 2013). At the hemispheric scale, the LIA is a well-documented cool period (Moberg *et al.,* 2005; Mann *et al.,* 2009; Hegerl *et al.,* 2007), and several causes may have concurred to trigger its occurrence, including a succession of strong volcanic eruptions (Crowley, 2000; Miller *et al.,* 2012, Gennaretti *et al.,* 2014b), millennial orbital cooling (Kaufman *et al.,* 2009; Esper *et al.,* 2012), and low solar radiation (Bard *et al.,* 1997).

In the present study, we compared the i-STREC mean of maximal summer temperatures for MWA (1000-1250), LIA (1350-1850) and the modern period (1950-2000 as defined in IPCC, 2014) and found that the MWA was warmer than the modern period (+0.2°C) and LIA (+0.4°C) in our study area. These results contrast somewhat with Northern hemisphere temperature reconstructions that have determined that the mean annual temperature of the modern period was the warmest in northern Canada (Mann *et al.,* 2009; Ljungqvist *et al.,* 2012). Indeed, the data available for these hemispheric reconstructions in the last IPCC report are scarce for north-eastern Canada (Viau *et al.,* 2012). Clearly, both the i-STREC and STREC (Gennaretti *et al.,* 2014) results indicate that the MWA in northeastern Canada has been the warmest period of the last millennium (Figure 5). The similarities between MWA and the modern period are not a surprise considering that the MWA has been widely studied for its similarities with the modern warming period. Nevertheless, the causes that triggered these periods are likely different (i.e., Landrum *et al.,* 2013; Way and Viau, 2014). Indeed, if the MWA is only controlled by natural processes, it seems that the warming of the modern period results from a combination of natural and anthropogenic causes (i.e, Mann *et al*., 2009; Viau *et al*., in press). By using empirical statistical modeling and global climate models, Way and Viau (2014) have shown that the variance of annual air temperature over the period 1881-2011 in Labrador was explained at 65% if anthropogenic forcing was also included in the model. Even if summer temperature has increased at a lower rate compared to annual air temperature in Labrador, the observed warming (+1.9°C) between 1970 and 2000 is one of the fastest over the last millennium in the region of L20. In the next decades, if warming continues at this rate, temperature will reach a record for the last millennium.

3.2.4. Climatic forcings of the last millennium

Contrary to previous studies, our isotopic series does not emphasize an abrupt LIA onset in response to volcanic forcing such as the AD 1257 Samalas event (Lavigne *et al.,* 2013; Figure 6). Instead, our data suggest that solar radiation was the most influential forcing on Tmax changes in the studied region. Indeed, the most important cooling phases of i-STREC occurred during periods of low solar activity like the Oort (AD 1040-1080), Dalton (AD 1800-1850), Maunder (AD 1600-1650) and Spörer (AD 1410-1480) minima (Figure 6). A simple re-sampling method involving 1000 iterations of re-sampling (bootstrapped) has demonstrated that the low temperature periods were always associated to low solar radiation periods ($p<0.05$). Proposing that solar radiation represents an important control on temperature in north-eastern Canada is in agreement with the hypothesis that the solar forcing was important during the last millennium (AD 1000 to ~1900), except during the modern period (Breitenmoser *et al.,* 2012; Keller *et al.,* 2004), implying that recent anthropogenic impact is the main control at that time. However, even i-STREC is not significantly influenced by volcanism, as determined by superimposed epoch analysis (results not shown), the possibility that successive strong volcanic eruptions combined with solar minima could have contributed to the important LIA cooling in Northeastern Canada cannot be discarded. Strong eruptions and solar minima coincide during the Maunder minimum with the Kuwae eruption, and the Dalton minimum with the unknown (1809), Tambora (1815) and Cosiguïna (1835) eruptions. The role of coinciding natural forcings is also invoked in other paleoclimatic studies that have compared northern hemisphere reconstructions with solar radiation series (e.g., Bard *et al.,* 2006; Breitenmoser *et al.,* 2012; Crowley *et al.,* 2000; Lean *et al.,* 1995; Shindell *et al.,* 2003). These studies have shown that temperature changes were largely due to solar forcing alone during the first part of the last millennial, and to volcanic and solar forcings (i.e, Breitenmoser *et al.,* 2012), or to volcanic eruptions (i.e., Crowley *et al.,* 2000; Keller *et al.,* 2004) during the end of the LIA (after 1600). In addition, Tingley *et al*. (2014) have demonstrated, by analyzing the ring density in trees growing at high latitude, that the trees recorded not only volcanic eruptions but also variations in light intensity. This finding indicates that both isotopes and density of trees can record changes in solar radiations.

The other temperature reconstruction produced for the studied region (STREC) contains a stronger volcanic signal than i-STREC (Gennaretti *et al.,* 2014b). Considering that the two reconstructions are statistically robust, we can assume that they both reflect real trends. In addition, calibrating STREC using the same approach than for i-STREC (i.e. calibration on maximum temperature over the 1930-2000 time period) indicates that methods cannot account for the main differences between the two reconstructions. Consequently, differences in thermal trends between i-STREC and STREC must be caused by their respective sensitivity to climatic triggers and control mechanisms, ring width and $\delta^{18}O$ values. The first important point to bear in mind is that temperature is the main control on changes in ring widths and $\delta^{18}O$ values, but not the only one. Consequently, other climatic parameters (i.e., precipitations, vapor pressure deficit; Naulier *et al.,* 2014) have also generated short and medium variations on the two series, creating an important “climatic noise” at high and medium frequencies, possibly explaining the differences between the reconstructions. However, it is important to recall that the ring width and $\delta^{18}O$ series used to generate STREC and i-STREC display similar long-term climatic trends. This last point is quite important, considering that our main purpose was to identify long climatic tendencies over the last millennium in northeastern Canada.

The second important aspect to consider is that the temperature-linked processes responsible for the variations of ring widths and $\delta^{18}O$ values slightly differ. In the studied region, rings widths are directly influenced by photosynthetic rates, which generally increase with ambient temperatures. In addition, volcanic aerosols blocking light after a major volcanic eruption may also reduce ring growth concomitantly to reduced temperature, explaining the strong influence of major volcanic events on ring width. In contrast, one of the main control on the final tree-ring $\delta^{18}O$ values is the temperature prevailing regionally during cloud mass distillation, as registered in the raindrop signal and transferred to the source water in soils, then through the root system, to the tree. Moreover, the temperature effects on fractionation during distillation and precipitation (Rayleigh process) is not limited to a temperature range, and may record temperature lows that are not necessarily extreme such as those modulated by solar radiations. When strong volcanic events are combined with minimal solar radiations, the strong influence on regional temperature is also detected by $\delta^{18}O$ values of rain drops. These key differences in mechanisms controlling temperature recorded in ring widths and $\delta^{18}O$ values imply that the two proxies may emphasize forcings in a complementary fashion.

As a summary, it appears that ring widths or $\delta^{18}O$ series have strengths and weaknesses as proxy of past climatic conditions. However, the climatic data that can be extracted from the two series can generate complementary information, permitting to highlight several climatic forcings and identify the main regional control on past, present and future temperatures. Nevertheless, there are still needs for further understanding the differences between processes influencing isotopic assimilation and ring-width growth. Such information would be useful for future climatic reconstruction using a multi-indicator approach.

4. **Conclusion**

1. The cohort sampling method allows reconstructing climatic variability of medium and low frequencies by using fewer samples than other sampling methods, with a high temporal resolution and analytical replication. Our adjustment of the method of joining cohorts, the JP-adjustment method, permits the preservation of $\delta^{18}O$ variability between segments of trees without biasing the millennial $\delta^{18}O$ series.

2. The combination of two statistical models (linear scaling and simple linear regression) has permitted an adequate reproduction of the measured regional temperature, and allowed reconstructing maximum temperature over the last millennium.

3. i-STREC is complementary to the only other reconstruction in the study region (STREC, based on tree-ring width). These two reconstructions should be combined within a multi-parameter approach to increase the proportions of variance explained.

5. i-STREC suggests that the main climatic forcing at play during the last millennium in the studied region was solar activity, but we remain cautious because we base this hypothesis solely on an apparent correlation between reconstructed Tmax and the curve for solar radiations. Clearly, coldest episodes in the L20 area coincide with low solar radiation (Oort, Spörer, Maunder and Dalton), with the exception of an episode in the nineteenth century, during which low solar radiations (Dalton minima) were combined with two successive and strong volcanic eruptions (unknown 1809 and Tambora 1815 eruptions).

6. Overall, i-STREC shows that the Medieval Warm Anomaly (997-1250) was the warmest period of the last millennium in the study region. However, the sudden and rapid temperature increase during the last three decades is one of the fastest over the last millennium (+1.9°C between 1970 and 2000) and if this rapid warming rate persists, the future climate in northeastern Canada may become an issue of concern.

Acknowledgments

The authors would like to thank Anna Smirnoff, Marie-Christine Simard and Marc Luzincourt for their technical support during sample treatment and analyses at the Delta-Lab of the Geological Survey of Canada. We are grateful to Julia Autin, Pierre-Paul Dion and Yves Bouthillier for the sampling of lakeshore trees and subfossil stems. We also would like to thank Dr. Steve Wolfe who made constructive comments during a pre-submission review of this article. This research was supported financially by the NSERC-OURANOS Collaborative Research and Development grant (ARCHIVES project of INRS-ETE), and the Environmental Geoscience Program of the Geological Survey of Canada (ESS contribution number 20140213).

Figure and table captions

Figure 1. A) Site location (black circle) and meteorological stations (black stars). B) Representation of lake L20, also illustrating the sampling location of subfossil stems (brown marks) and living trees (yellow marks).

Figure 2. Illustration of the sampling strategy. From year 1000 to 2006, cohorts are represented in red for subfossil stem segments (C0-C11), and in green for living trees (CV). The join points are in black on the overlapping periods (JP0 to JP12).

Figure 3. A) Millennial raw $\delta^{18}O$ series (1000-2010) with subfossil segment cohorts (cohorts C0 to C11; illustrated with different colors), living tree cohort (CV; dark pink curve), and join points (blue dash), the adjustment means (black dash) and the number of tree segments used per year (straight black line). The grey envelop represents the analytical error (0.2‰). The legend shows the correspondence between the colours curves and cohorts. B) Millennial $\delta^{18}O$ series adjusted (black line) with standard deviation (grey lines). C) Comparison between $\delta^{18}O$ values of living trees and subfossil stem segments over the common time interval (1860-1956).

Figure 4. A) Comparison between reconstructed (i-STREC, black line) and observed (blue line) JJA maximal temperature and mean square values on the entire period of calibration. B) i-STREC (black line) with 21-year moving average (red line) and observed JJA maximal temperature series from CRU TS3.1 (blue line). In both cases, the dark grey shading represents uncertainty with ±1 RMSE calculated on the 21-year filter values.

Figure 5. Comparison between i-STREC and other temperature reconstructions (data obtained from NOAA). (A) i-STREC from in north-eastern Canada. B) STREC from tree-ring width, in the same region. C) July-September temperature from varved sediments, Baffin Island, Arctic Canada. D) annual surface temperature from GISP 2 ice core, in Greenland. E) May-August maximum temperature from maximum latewood density and tree-ring width, Canadian Rockies. F) July temperature from tree-ring width, northern Finland. Shading based on i-STREC is shown to ease comparison with the other reconstructions compiled: warmer (pink, colder (green) and modern periods (yellow). All reconstructions have been smoothed with a 21-years filter and normalized (1960-1991).

Figure 6. Volcanic and solar forcings. A) I-STREC (reconstructed summer temperature, 21-years smoothed; red line), compared with the well-known solar minima (grey bands) and the solar forcing series (black line; Bard *et al.,* 2003). B) I-STREC reconstructed summer temperature (red line) compared with the volcanic aerosols sulfates (Sigl *et al.,* 2013). The major eruptions are marked: (1) 1257/1258= Samalas, (2) 1456= Kuwae, (3) 1783= Laki, (4) 1809= unknown and 1815= Tambora and (5) 1835= Cosigüina).

Table 1. Summary of the verification statistics for calibrations using the linear scaling and simple linear regression methods for different periods, and using the measured maximal temperature series.

SD is the standard deviation, r^2 is the coefficient of determination (R squared), RMSE the raw mean squared error, RE the reduction of error and CE the coefficient of error.
