[Responses are in brackets]

This paper discusses a low-resolution biomarker record (14 samples) from one of the multiple cores taken in a large remote ancient Arctic lake in an impact crater with an objective of "investigating sources of organic matter and carbon cycling". The main motivation for this research was that "the degree to which variations in aquatic productivity, water column anoxia, or methanogenesis may have impacted the sediment

C2851

record is not well understood" (p. 4627). The authors put more emphasis on what kind of processes may have impacted their particular sediment record than on what one may learn about regional climate from the studied proxies.

There appears to be rather little on ‘climates of the past’ in this current manuscript - the scope of the current version of the paper appears more relevant for journals such as *J. Paleolimnology* or *Organic Geochemistry*. Beyond the Introduction, the narrative drifts further and further away from climate issues, the age model is reduced to the most basic stratigraphy of A-B-C intervals and climate is forgotten by the time one gets to the Conclusions and “outstanding questions”. [A synthesis on Lake El’gygytgyn in a paleoclimate context has been added to the discussion in order to bring the focus of the paper explicitly back to a discussion of climate. Discussion of Intervals A-B-C have been defined throughout the manuscript with their corresponding ages in an attempt to clarify that these intervals refer to time periods of differing paleoenvironmental (and paleoclimatic) conditions. This study focuses on environmental change at Lake El’gygytgyn as it relates to a changing regional climate. ]

The dominant factor responsible for the studied biochemical signals appears to be ice cover: the leading hypothesis is that under the conditions of permanent (“perennial”, “interannual”) ice cover during the last glacial the lake water/atmosphere gas exchange was greatly limited, causing dramatic oxygen depletion in the lake. This hypothesis is not original as it derives from earlier observations: oxygen depletion was suggested based on in sediment texture (lamination), magnetic properties (dissolution of magnetite = low magnetic susceptibility MSUS) and high total organic carbon content (TOC) in bulk sediment suggestive of less degradation in the oxygen-depleted water column. The authors of the current contribution were looking for compound-specific signals of anoxia in order to test this earlier hypothesis (p. 4645) but did not really succeed. The discussion therefore revolves around the prior evidence (MSUS,  $\delta^{13}\text{C}$  and TOC) and invokes production (delivery) and preservation as alternative mechanisms responsible for producing a TOC peak, which is recognized as the L[ocal]LGM interval.

C2852

Two significant components which could potentially make the study stronger are unfortunately 'outsourced' to other papers in prep.: (1) diatom record which is expected to constrain the primary production component of the lake's carbon cycle is presented elsewhere (Snyder et al., in prep.), and (2) the age model, which is essential to make a linkage to climates of the past, is also supposedly presented elsewhere (Murdoch et al., in prep; see below for comments on Age Model). A reader may only assume that these papers, when(if) published could strengthen the arguments in the current manuscript. [Discussion of the diatom record has been extended for improved clarity, particularly in section 4.7.1. The core studied here is one of several pilot cores that have been extensively studied and well documented in previously published papers (many of which comprise a special issue of the Journal of Paleolimnology on Lake El'gygytgyn that was published in 2007). The age model, along with more detailed information on its development, is published in companion paper within the same special issue of Climate of the Past to which this manuscript is being submitted. Additional references and language to clarify these important points have been added to the manuscript.]

The manuscript is not acceptable in its current form, it needs to be thoroughly reworked and supplied with a better description of climate, age model, description of the components of present-day carbon cycle in the Arctic to provide a better context for understanding the significance of a rather sparse low-resolution data set presented here. Below I suggest several areas requiring attention and list specific comments.

1. Relationship of proxy signals to past climate [In response to this comment, the authors have added a section (4.7) on the paleoclimate significance of Lake El'gygytgyn, placing it within a context of other Arctic lakes both geochemically and climatically. ]

The focus of the work is on the LGM but there is little description on what the LGM climate may have been in the study area. "The most recent cold period" referred to in conclusions is actually 'the most recent high-TOC and low magnetic susceptibility interval' - no evidence is shown to support the contention that this interval was in fact cold or "coldest". [The LLGM along with evidence that this interval was cold is now

C2853

discussed in section 4.7.2 and appropriate references are provided. The conclusions section has been revised considerably as well.]

Nowhere in the manuscript is there any mention of possible changes in the water budget of the lake during glacial/interglacial cycles and LGM in particular. Has the lake level remained unchanged in the past 60 kyr? Is there any evidence from lithology of the studied core and/or other cores? What kind of effect on the studied proxies may one expect in case of climate-driven changes in lake level (and lake volume)? [Past lake level changes have occurred at Lake El'gygytgyn (Glushkova and Smirnov, 2007 J of Paleolimnology;) and it is thought that lake level was about 10m lower than today during the Late Weichselian (Federov et al., 2012 Climate of the Past Discussions). Since Lake El'gygytgyn is relatively deep (currently 175m), a 10m drop in lake level likely would not have significantly impacted the proxies studied here. ]

The stated relationship of regional proxy records to past global climate changes is not consistent throughout the manuscript. First the authors state that MSUS,  $\delta^{13}C$  and TOC "are closely tied to regional climate variables" (p. 4627) but provide no evidence for this; then they admit that their glacial intervals are in fact "interpreted" (p. 4628) and that "regional cooling ... may or may not have been entirely synchronous with glacial activity" elsewhere (p. 4636). Suddenly, on p. 4637 they state to the contrary that MSUS and TOC variations "are synchronous with MIS boundaries" (no evidence is shown for that either). If the main shift is not "synchronous", Conclusion 1 (p. 4648, line 16) is irrelevant. [The text has been reworked to clarify the idea that shifts in bulk geochemistry at Lake El'gygytgyn have been documented in past studies to correspond with shifts in regional climate. This study shows that there is a broader interval in molecular variability that was not documented in previous studies. These broader intervals do not correspond (and are not synchronous) with bulk geochemical data (and therefore regional climate signals). The conclusions section has been revised.]

The sense of confusion reflected in these contradictory statements on synchronicity (or lack of thereof) naturally follows from the little effort the authors have spent in dis-

C2854

cussing and presenting the age model. Reading the manuscript, one could feel how eager they are to get away from the undesirable age model section to the subjects they are most comfortable with. The problem is that without the age model the Discussion lacks clarity and it is of limited interest to the readership of *Climate of the Past*. [We did not focus on the age model because it is detailed in a companion paper by Murdock et al. (2012), which is in the same special issue of *Climate of the Past* on Lake El'gygytgyn. Additional citations have been added to clarify this point.]

## 2. Age model

Tie points should be shown in respective Figures even if the age model is discussed in detail elsewhere. How many AMS/IRSL dates? If there are none in this particular core, the position of absolute age tie points relative to proxy signals in other cores should be shown for reference. How was "magnetic susceptibility tuned to insolation"? (tie points should be shown in Figures). What is the main assumption underlying the tuning of the magnetite dissolution signal (MSUS) to insolation? Is there any phase lag associated with tuning? Why would dissolution of magnetite in an Arctic lake be "synchronous" with marine oxygen isotope stages? If low insolation is the predictor of persistent/permanent ice cover (dissolution), why is there a strong magnetic susceptibility signal of dissolution (lack of oxygen) in the early Holocene at ca. 9 kyr BP, when insolation is high (Fig. 4)? Why is this Holocene signal similar in amplitude to the magnetic susceptibility signal of the Local LGM when insolation is low? [The age model for LZ1029 is presented in Murdock et al., same volume. This age model was developed by correlation with other cores from the same lake, all of which have been extensively studied and published (Nowackzyk et al., 2002; Nowackzyk et al., 2007; Juschus et al., 2009; Frank et al., same volume). Additional citations have been provided throughout the manuscript to clarify this point.]

In the beginning, quite precise ages are cited (e.g., 43-17 kyr BP) producing an impression of a tight chronology, but then the discussion drops into a very basic stratigraphy (A-B-C intervals). The boundary between intervals C and B appears rather arbitrary:

C2855

one could argue it is better placed at 36 kyr BP or so, not at 43 kyr BP. [The text has been reworked to clarify the point that Intervals A-B-C were chosen based on variability in FAME concentrations and isotope measurements. Given the low resolution of the record, there is room for error in the boundary placement, and the text has been revised to reflect this.]

## 3. Modern processes, values and carbon cycling in the Arctic - ??

The discussion of the present-day conditions and carbon cycle, isotope ratios of organic matter sources today and the significance of proxy signals of the transition from LLGM to the present-day Holocene interglacial is missing entirely. The lack of effort in addressing these questions does not help improving the potential impact of the described findings. Several times unspecified "other lakes" are mentioned in Discussion. What are these lakes? Where are they located? How many "other lakes" did they compare their records to? How many of these "other lakes" are located in the Arctic in similar geographic setting? There must have been studies of similar processes and similar biomarkers in Canadian Arctic in relation to ongoing changes in the permafrost, there must be at least some published lake values for concentrations and isotope ratios. . . Why not review at least some factual supportive evidence to strengthen the Discussion? [A discussion of Lake El'gygytgyn as it compares with other Arctic lakes has been added (section 4.6). ]

4. Production, delivery and/or preservation of organic matter - Conclusions This triangle (production, delivery and/or preservation) forms the framework of the Discussion: which of the mechanisms appears to be dominant in their lake record during the LLGM interval with negative  $\delta^{13}C$  and high TOC. These are the typical mechanisms potentially controlling bulk content and isotope composition of organic matter in lake sediments. The authors imply that different explanations are possible and at the top of p.4637 they challenge a prior idea of increased terrestrial input playing a key role. However, they seem to confirm this same idea on page 4640 (lines 27-28) where they conclude that "LLGM corresponds to the time of maximum terrestrial OM delivery to

C2856

the sediments". In Conclusions, they may want to make it clear that they tested and confirmed the scenario proposed in previous studies. [We have clarified the discussion of a broader interval of molecular variability found in this study. Previous studies have looked only at bulk geochemistry in interpreting organic matter sources and past environmental conditions at the lake. Our compound-specific study has revealed molecular level variability that is not apparent in the bulk geochemistry data sets. This molecular variability has caused the authors to reconsider the timing of environmental change (different from previous studies), as well as the contribution from various organic matter sources (generally the same as previous studies). Our data supports that terrestrial inputs to Lake El'gygytgyn sediments are important throughout the entire record. Various sections of the text have been clarified, as suggested. ]

"Increased productivity [they probably mean production] of aquatic OM" is inferred during LLGM (p.4643, top). This conclusion is further supported by the reference to unpublished observations of "unexpectedly high biogenic silica values" from diatoms during LLGM (p. 4637, lines 9-10 ; - see also a comment below). In their Conclusion 2, however, they favor preservation over production and state that "higher aquatic productivity cannot be discounted" (p. 4649, line 2). There is a notable disconnect between what is stated in the Discussion and in Conclusions ('increased, unexpectedly high but can be discounted . . . or maybe not') - the authors would need to sort this out. [The high biogenic silica values (Snyder et al., 2012) are discussed in section 4.6 and we now note that these values are higher than Holocene values. The text has been reworked to clarify the distinction between terrestrial and aquatic productivity.]

In section 4.6 the authors propose the use of nitrogen stable isotope ratios "to test the original interpretation" suggesting highly anoxic conditions during LLGM interval (p. 4647). The test appears straightforward: one would expect d15N enrichment as a result of denitrification under anoxic conditions (lines 14-15). The test comes in negative: the authors find depletion instead of enrichment. Yet their conclusion is quite puzzling: "results neither support nor preclude the existence of a significant anoxic

C2857

portion of the water column". What use is the "test" if it provides no answer? If it does not it should not be presented as the test, just as another proxy. . . [The word "test" has been removed, as suggested.]

"Isotope mass balance may place bounds on the contribution. . ." (p. 4649) - isotope mass balance calculations are not shown, there was not even an attempt to constrain potential end-member d13C from literature. There is no place for this statement in Conclusions, at best in the Discussion [We introduced a possible isotope mass balance in the Discussion (Section 4.4) and have removed this from the conclusions.]

The remaining "several outstanding questions" (p. 4649) appear to be of little interest to the readership of *Climate of the Past* as being very local and very specific [This paragraph has been removed from the conclusions and added to the discussion on anoxia (section 4.5).]

5. Specific comments: Starting from p. 4636 (line 27) "One interpretation" is described, but further along in the text no 'other interpretation' is given, there is just this "One". Apparently these are leftovers from previous versions of the text which need to be cleaned up [We have revised the text, as suggested (section 4.6).]

p. 4637, lines 9-10 "unexpectedly high biogenic silica values" - how high and why "unexpected"? How much did authors expect, why and how much more silica is actually observed as compared to what they expected to see? Without specifics this phrase does not help the argument [The value for biogenic silica has been added, as suggested. The biogenic silica values were unexpected because they are higher than Holocene values. This is now stated in the text. See Snyder et al, same volume. ]

p. 4640, lines 6-9 "caution must be applied when assigning sources of . . . FAMEs in sediments" - is this the first time ever this has been demonstrated in a lake? Have these compounds always been interpreted in "other lakes" as being purely terrestrial and now, for the first time ever, the results reported in the manuscript suggests that approach used formerly is no longer valid? This finding is implied to be significant as it is featured

C2858

in Conclusions, so the authors need to explain the context better [References to other papers that use long-chain FAMEs as terrestrial indicators are now noted to provide context and clarity, as suggested (section 4.2).]

p. 4648, lines 1-14 - it is not clear what exactly did the authors do to “look to the iron cycle”. This entire paragraph is not supported by any data in this study. Some references are provided following by the "more research is needed" statement. This paragraph can safely removed to save space [This paragraph has been removed, as suggested.]

Figures: the orange frame approximately marking LLGM interval in Figures 2 through 5 appears misaligned with major peaks of TOC and MSUS, the alignment seems to be with bulk d13C record (Fig. 3). For instance, Fig. 4 makes it look like LLGM in the MSUS profile is at 19-25 kyr BP, not at 20-26 kyr BP as currently shown. The explanation needs to be provided for what exactly this orange frame stands for. [The orange frame has been defined, as suggested.]
