15 **Abstract:**

16 The boron isotope composition ( $\delta^{11}\text{B}$ ) of planktic foraminiferal calcite, which reflects  
17 seawater pH, is a well-established proxy for reconstructing palaeo- atmospheric  $\text{CO}_2$   
18 and seawater carbonate chemistry. However, to translate  $\delta^{11}\text{B}$  measurements  
19 determined in calcareous fossils into pH we need to know the boron isotope  
20 composition of the parent seawater ( $\delta^{11}\text{B}_{\text{sw}}$ ). While a number of  $\delta^{11}\text{B}_{\text{sw}}$  reconstructions  
21 exist, the discrepancies between them reveals uncertainties and deficiencies that need  
22 to be addressed. Here we present a new  $\delta^{11}\text{B}_{\text{sw}}$  record based on the  $\delta^{11}\text{B}$  difference  
23 between planktic and benthic foraminifera and an estimate of the pH gradient  
24 between surface and deep water. We then calculate  $\delta^{11}\text{B}_{\text{sw}}$  two different ways. One  
25 variant of our method assumes that the pH gradient between surface and deep has  
26 remained the same as today over the past 23 Ma; the other uses the  $\delta^{13}\text{C}$  gradient  
27 between surface and deep to represent change in the pH gradient through time. The  
28 results of these two methods of calculating  $\delta^{11}\text{B}_{\text{sw}}$  are broadly consistency with each  
29 other, however, based on extensive carbon cycle modelling using CYCLOPS and

30 GENIE we favour the  $\delta^{13}\text{C}$  gradient method. In our favoured  $\delta^{11}\text{B}_{\text{sw}}$  reconstruction,  
31  $\delta^{11}\text{B}_{\text{sw}}$  is around 2 ‰ lower than today at  $\sim 37.5$  ‰ during the early and middle  
32 Miocene and increases to the modern value (39.61 ‰) by  $\sim 5$  Ma. A similar pattern  
33 of change is evident in the seawater composition of three other stable isotope  
34 systems, Mg, Li and Ca. Concurrent shifts in the seawater isotopic composition of all  
35 four of these elements during the late Miocene, suggest a common forcing  
36 mechanism. We hypothesise the most likely cause of these shifts is a change in the  
37 isotopic composition of the riverine input, potentially driven by an increase in  
38 secondary mineral formation since  $\sim 15$  Ma.

## 39 1. Introduction

40 Key to determining the relationship between  $\text{CO}_2$  and climate in the geological past is  
41 the calculation of reliable estimates of absolute  $\text{CO}_2$  through time. In recent years the  
42 boron isotope composition ( $\delta^{11}\text{B}$ ) of foraminiferal calcite has become one of the most  
43 commonly used tools to reconstruct  $\text{CO}_2$  beyond the last 800 kyrs and throughout the  
44 Cenozoic Era (Foster, 2008; Hönisch et al., 2009; Pearson et al., 2009; Bartoli et al.,  
45 2009; Foster et al., 2012; Badger et al., 2013; Henehan et al., 2013; Greenop et al.,  
46 2014; Martínez-Botì, et al., 2015a). Yet long-term change in the boron isotope  
47 composition of seawater ( $\delta^{11}\text{B}_{\text{sw}}$ ) is poorly constrained and represents a major source  
48 of the uncertainty associated with  $\delta^{11}\text{B}$ -determined  $\text{CO}_2$  estimates. In the modern  
49 ocean boron is a conservative element with a spatially invariant isotope ratio  
50 (39.61‰; Foster et al., 2010), but this value is subject to change through geological  
51 time. The residence time of boron in the ocean is estimated to lie between 11 and 17  
52 Myrs (Lemarchand et al., 2002). Therefore we can expect the uncertainty associated  
53 with  $\delta^{11}\text{B}_{\text{sw}}$  to be an important factor in  $\text{CO}_2$  estimates beyond the late Pliocene ( $\sim 4$ -5  
54 Ma, Palmer et al., 1998; Pearson et al., 2009; Foster et al., 2012).

55 The ocean boron budget and its isotopic composition are controlled by a number of  
56 inputs and outputs (Fig. 1). However, because the magnitude of the boron fluxes  
57 between land, the ocean and the atmosphere are still poorly understood, the residence  
58 time and changes in both concentration ( $[\text{B}]_{\text{sw}}$ ) and isotopic composition ( $\delta^{11}\text{B}_{\text{sw}}$ )  
59 through time remain uncertain. The main inputs of B into the ocean are silicate  
60 weathering delivered to the ocean by rivers (Lemarchand et al., 2002), hydrothermal

61 vents (You et al., 1993) and fluid expelled from accretionary prisms (Smith et al.,  
62 1995). The major outputs are oceanic crust alteration (Smith et al., 1995), adsorption  
63 onto sediments (Spivack and Edmond, 1987) and co-precipitation into carbonates  
64 (Hemming and Hanson, 1992). In all three cases the light  $^{10}\text{B}$  isotope is preferentially  
65 removed such that seawater is isotopically heavier (39.61‰) than the inputs (which  
66 average at 10.4‰). Atmospheric boron may also be an important flux both into and  
67 out of the ocean (Park and Schlesinger, 2002). While some studies have suggested  
68 that precipitation within the catchment area may be an important factor controlling  
69 the  $\delta^{11}\text{B}$  in rivers (Rose-Koga et al., 2006), other studies have shown atmospheric  
70 boron to be a secondary control on riverine boron isotope composition (Lemarchand  
71 and Gaillardet, 2006).

72  
73 Unlike many other isotopic systems (e.g. Mg, Ca, Li, Sr) to date no archive has been  
74 discovered that simply records unaltered seawater  $\delta^{11}\text{B}$ . This is a result of the pH  
75 dependency of B speciation in seawater upon which the  $\delta^{11}\text{B}$ -pH proxy is based  
76 (Zeebe and Wolf-Gladrow, 2001) and imparts a pH dependency on all marine  
77 precipitates so far examined. Empirical reconstructions of  $\delta^{11}\text{B}_{\text{sw}}$  must therefore use  
78 “indirect” approaches; so far four methods have been applied to the Cenozoic (0-65  
79 Ma) (Fig. 2). Firstly, geochemical modelling of the changes in the flux of boron into  
80 and out of the ocean through time has been used to suggest that the  $\delta^{11}\text{B}_{\text{sw}}$  increased  
81 from 37‰ at 60 Ma to  $40\text{‰} \pm 1\text{‰}$  today (Lemarchand et al., 2002). However, there  
82 are uncertainties associated with quantification of, and controls on, the oceanic inputs  
83 and outputs of boron (Lemarchand et al., 2002). For instance, it is possible that  
84 subtle variations in poorly constrained factors such as oceanic crustal permeability,  
85 the lifetime of water-rock interactions and the expansion rate of the oceanic ridge can  
86 have a large effect (variations between 30‰ and 50‰ at a 10 million year scale) on  
87 the amount and isotopic composition of the boron removed from the ocean during  
88 oceanic crust alteration (Simon et al., 2006). These issues coupled with uncertainties  
89 in the magnitude of the atmospheric boron flux (Park and Schlesinger, 2002), make  
90 direct geochemical modelling of the evolution of  $\delta^{11}\text{B}_{\text{sw}}$  currently under constrained at  
91 present.

92 The boron isotopic composition of marine halites and sea salts has also been used to  
93 reconstruct the boron isotope composition of the ocean in the past (Paris et al., 2010).

94 Results from studies employing this method suggest that  $\delta^{11}\text{B}_{\text{sw}}$  has varied by 7‰  
95 over the Neogene (Fig. 2) (Paris et al., 2010). Yet brine-halite fractionation offsets of  
96 -20‰ to -30‰ and -5‰ are reported from laboratory and natural environments  
97 respectively casting doubt over the validity of the assumption that no fractionation  
98 occurs during halite formation (Vengosh et al., 1992; Liu et al., 2000). These  
99 fractionations and riverine input during basin isolation will drive the evaporite-hosted  
100 boron to low- $\delta^{11}\text{B}$  isotope values such that the fluid inclusion record likely provides a  
101 lower limit for the  $\delta^{11}\text{B}_{\text{sw}}$  through time (i.e.  $\delta^{11}\text{B}_{\text{sw}}$  is heavier than the halite fluid  
102 inclusions of Paris et al. (2010)). Nevertheless, evaporites form from modified  
103 seawater in isolated basins making them unlikely archives of representative ocean  
104  $\delta^{11}\text{B}$ .

105 An alternative semi-empirical approach makes assumptions regarding the evolution  
106 of Cenozoic deep-ocean pH and a benthic  $\delta^{11}\text{B}$  record to determine changes in  $\delta^{11}\text{B}_{\text{sw}}$   
107 (Fig. 2; Raitzsch and Hönisch, 2013). This method assumes (1) a near linear surface  
108 water pH increase of 0.39 over the past 50 Myrs (Berner and Kothavala, 2001;  
109 Tyrrell and Zeebe, 2004; Ridgwell, 2005), and (2) a constant surface to deep ocean  
110 pH gradient of 0.3 (Tyrrell and Zeebe, 2004, and modern observations). The modeled  
111 surface pH and estimated fixed pH gradient is then used to estimate deep ocean pH,  
112 which can be converted to  $\delta^{11}\text{B}_{\text{sw}}$  based on benthic foraminiferal  $\delta^{11}\text{B}$  measurements.  
113 While this approach yields a qualitative independent check on other approaches (e.g.  
114 halite inclusions, geochemical modeling), as a quantitative record of  $\delta^{11}\text{B}_{\text{sw}}$  through  
115 time, it has a number of drawbacks. Firstly, some of the  $\text{CO}_2$  data used in the  
116 modeling studies is derived using the boron isotope-pH proxy, leading to some  
117 circularity in the methodology. Secondly, given the structure in  $\text{CO}_2$  proxy records,  
118 the assumption that surface ocean pH changed linearly through the Cenozoic is most  
119 likely an oversimplification (Beerling and Royer, 2011). Consequently, while this  
120 method may shed some light on the evolution of  $\delta^{11}\text{B}_{\text{sw}}$  through time, it cannot be  
121 subsequently used to determine pH or atmospheric  $\text{CO}_2$  from  $\delta^{11}\text{B}$  of foraminiferal  
122 calcite because the  $\delta^{11}\text{B}_{\text{sw}}$  record is itself based on assumptions of the secular  
123 evolution of pH and  $\text{CO}_2$ .

124 One of the big challenges of reconstructing a  $\delta^{11}\text{B}_{\text{sw}}$  record empirically is determining  
125  $\delta^{11}\text{B}_{\text{sw}}$  without relying on dependent pH constraints. One way to avoid using absolute

126 pH reconstructions is to exploit the non-linear relationship between  $\delta^{11}\text{B}$  and pH  
127 alongside estimated pH gradients in the ocean to constrain  $\delta^{11}\text{B}_{\text{sw}}$ . The non-linear  
128 relationship between  $\delta^{11}\text{B}$  and pH means that the pH difference between two  $\delta^{11}\text{B}$  data  
129 points varies as a function of  $\delta^{11}\text{B}_{\text{sw}}$  (Fig. 3). Consequently if the size of the pH  
130 gradient can be estimated, irrespective of absolute pH, then there is only one  $\delta^{11}\text{B}_{\text{sw}}$   
131 value that is consistent with the foraminiferal  $\delta^{11}\text{B}$  measurements and the specified  
132 pH gradient (Fig. 3c).

133 Previously this approach has been applied to pH variations in the surface ocean and  
134 used in studies of Cenozoic  $p\text{CO}_2$  to account for changes in  $\delta^{11}\text{B}_{\text{sw}}$  (determined using  
135  $\delta^{11}\text{B}$  in surface and thermocline-dwelling foraminifera) (Fig. 2) (Palmer et al., 1998;  
136 Pearson and Palmer 1999, Pearson and Palmer 2000). This approach uses a constant  
137 pH gradient between the surface and some depth proximal to the oxygen minimum  
138 zone and the boron isotope values of a mixed layer dwelling species and thermocline  
139 dweller to calculate a value for  $\delta^{11}\text{B}_{\text{sw}}$  (Pearson and Palmer, 1999). The resultant  
140 curve produced by this method shows that  $\delta^{11}\text{B}_{\text{sw}}$  varies between 37.7‰ and 39.4‰  
141 through the Neogene (Fig. 2) (Pearson and Palmer, 2000). Unfortunately, the  
142 applicability of this  $\delta^{11}\text{B}_{\text{sw}}$  record (derived from  $\delta^{11}\text{B}$  data measured using NTIMS) to  
143  $\delta^{11}\text{B}$  records generated using the MC-ICPMS is uncertain (Foster et al., 2013). In  
144 addition, this  $\delta^{11}\text{B}_{\text{sw}}$  record is determined using a fractionation factor of 1.0194  
145 (Kakihana et al., 1977), whereas recent experimental data have shown the value to be  
146 higher ( $1.0272 \pm 0.0006$ , Klochko et al., 2006). Thirdly, given our understanding of  
147 the  $\delta^{11}\text{B}$  difference between species/size fractions (Foster, 2008; Henehan et al.,  
148 2013), the mixed species and size fractions used to make the  $\delta^{11}\text{B}$  measurements in  
149 that study may have introduced some additional uncertainty in the reconstructed  
150  $\delta^{11}\text{B}_{\text{sw}}$ . Consequently, while the estimates from Pearson and Palmer (2000) show that  
151 the rationale behind this approach can yield useful  $\delta^{11}\text{B}_{\text{sw}}$  estimates that may be  
152 qualitatively correct, the underlying measurements and some of the key assumptions  
153 have led to uncertainties in the record.

154 The same method, but using planktic-benthic instead of surface planktic- thermocline  
155 planktic  $\delta^{11}\text{B}$  gradients to calculate  $\delta^{11}\text{B}_{\text{sw}}$ , was recently applied to the middle  
156 Miocene where it yielded a  $\delta^{11}\text{B}_{\text{sw}}$  of  $37.6^{+0.4}_{-0.5}$ ‰ (Foster et al., 2012). The major  
157 limitation of these pH gradient approaches is the assumption of a constant pH

158 gradient through time. A useful extension to this method therefore utilises the  $\delta^{13}\text{C}$   
159 in foraminiferal calcite to estimate the surface-to-deep pH gradient and then  
160 determine  $\delta^{11}\text{B}_{\text{sw}}$  (Foster et al., 2012). Here we expand on the study of Foster et al.  
161 (2012) and present a number of new  $\delta^{11}\text{B}_{\text{sw}}$  records based on  $\delta^{11}\text{B}$  measured in  
162 planktic-benthic pairs. In our first treatment of the data we assume that the pH  
163 gradient has remained the same as modern at each site through time. In the second  
164 approach we utilise benthic-planktic  $\delta^{13}\text{C}$  gradients to correct for changes in the pH  
165 gradient. Using a biogeochemical box model and an Earth system model we also  
166 assess the extent to which the relationship between pH and  $\delta^{13}\text{C}$  gradients has  
167 remained constant under a comprehensive range of hypothetical carbon system and  
168 oceanographic states. We also use this model output to determine which pH/ $\delta^{13}\text{C}$   
169 regression is most appropriate for our data. In this study we focus on reconstructing  
170  $\delta^{11}\text{B}_{\text{sw}}$ , whereas implications of our record in terms of the evolution of Neogene  
171 ocean pH and atmospheric  $p\text{CO}_2$  are documented in a follow up study (Sosdian et al.,  
172 *submitted*).

## 173 2. Methods

### 174 2.1 Site Locations and Age Models

175 Foraminifera from four sites are used to construct the planktic-benthic  $\delta^{11}\text{B}$  pairs;  
176 Ocean Drilling Program, ODP, Site 758 and ODP Site 999 for the Pleistocene and  
177 Pliocene samples and ODP Site 926 and Site 761 for the Miocene (this study; Foster  
178 et al., 2012; Martinez-Boti et al., 2015a, Sosdian et al., *submitted*). We also  
179 incorporate the middle Miocene planktic-benthic pair from Site 761 in Foster et al.,  
180 (2012). In order to put all the sites on a single age model at Site 999, Site 926 and  
181 Site 761 the biostratigraphy is used from (Shipboard Scientific Party, 1997),  
182 (Shipboard Scientific Party, 1995; Zeeden et al., 2013) and (Holbourn et al., 2004)  
183 respectively and updated to GTS2012 (Gradstein et al., 2012). At Site 758 the  
184 magnetostratigraphy (Shipboard Scientific Party, 1989) is used and updated to  
185 GTS2012 (Gradstein et al., 2012).

## 186 2.2 Boron Isotope Analysis and pH Calculation

187 The boron isotope measurements (expressed in delta notation as  $\delta^{11}\text{B}$  – permil  
 188 variation) were made relative to the boric acid standard SRM 951; (Catanzaro et al.,  
 189 1970). Boron was first separated from the Ca matrix prior to analysis using the boron  
 190 specific resin Amberlite IRA 743 following Foster et al. (2013). The boron isotopic  
 191 composition was then determined using a sample-standard bracketing routine on a  
 192 ThermoFisher Scientific Neptune multicollector inductively coupled plasma mass  
 193 spectrometer (MC-ICPMS) at the University of Southampton (following Foster et al.,  
 194 2013). The relationship between  $\delta^{11}\text{B}$  of  $\text{B}(\text{OH})_4^-$  and pH is very closely  
 195 approximated by the following equation:

$$pH = pK_B^* - \log \left( - \frac{\delta^{11}B_{SW} - \delta^{11}B_{CaCO_3}}{\delta^{11}B_{SW} - \alpha_B \cdot \delta^{11}B_{CaCO_3} - 1000 \cdot (\alpha_B - 1)} \right) \quad (1)$$

196

197 Where  $pK_B^*$  is the equilibrium constant, dependent on salinity, temperature, pressure  
 198 and seawater major ion composition (i.e., [Ca] and [Mg]),  $\alpha_B$  is the fractionation  
 199 factor between the two boron species and  $\delta^{11}\text{B}_{sw}$  is the boron isotope composition of  
 200 seawater. Here we use a fractionation factor of 1.0272, calculated  
 201 spectrophotometrically (Klochko et al., 2006). Although the  $\delta^{11}\text{B}$  of foraminifera  
 202 correlates well with pH and hence  $[\text{CO}_2]_{aq}$ , the  $\delta^{11}\text{B}_{calcite}$  is often not exactly equal to  
 203  $\delta^{11}\text{B}_{borate}$  (Sanyal et al., 2001; Foster, 2008; Henehan et al., 2013). The planktic  
 204 species used to construct the benthic-planktic pairs changes through time, as a single  
 205 species is not available for the entire Neogene (this study; Foster et al., 2012;  
 206 Martínez-Boti et al., 2015a, Sosdian et al., submitted). Here *Globigerinoides ruber* is  
 207 used for 0 to 3 Ma, *Trilobatus sacculifer* (formally *Globigerinoides sacculifer* and  
 208 including *Trilobatus trilobus*; Hembleden et al., 1987; Spezzaferri et al., 2015) for 0  
 209 to 20 Ma and *Globigerina praebulloides* for 22 to 23 Ma. The calibration for *G.*  
 210 *ruber* (300–355  $\mu\text{m}$ ) is from Henehan et al., (2013), *T. sacculifer* (300–355  $\mu\text{m}$ ) from  
 211 Sosdian et al., (submitted) where the *T. sacculifer* calibration of (Sanyal et al., 2001)  
 212 is used with a modified intercept so that it passes through the core top value for *T.*  
 213 *sacculifer* (300–355  $\mu\text{m}$ ) from ODP Hole 999A (Seki et al., 2010). Unlike the  
 214 asymbiotic modern *T. bulloides*, *G. praebulloides* appears to be symbiotic at least in

215 the latest Oligocene (Pearson and Wade, 2009). Therefore, we apply the *T. sacculifer*  
 216 (300–355µm) calibration to this species. For *T. sacculifer* (500–600µm) at 0.7 Ma, we  
 217 use the calibration from Martinez-Botì et al., (2015b). In order to constrain deep-  
 218 water pH, analysis was conducted on benthic foraminifera *Cibicidoides wuellerstorfi*  
 219 or *Cibicidoides mundulus* depending on which species were most abundant in each  
 220 sample. The  $\delta^{11}\text{B}$  of both *Cibicidoides* species shows no offset from the theoretical  
 221  $\delta^{11}\text{B}$  of the borate ion and therefore no calibration is needed to adjust for species-  
 222 specific offsets (Rae et al., 2011).

223 As mentioned above, in addition to  $\delta^{11}\text{B}_{\text{calcite}}$ , temperature, salinity, water depth  
 224 (pressure) and seawater major ion composition are also needed to calculate pH from  
 225  $\delta^{11}\text{B}$ . We use the MyAMI specific ion interaction model (Hain et al., 2015) to  
 226 calculate the appropriate equilibrium constants based on existing [Ca] and [Mg]  
 227 reconstructions (Horita et al., 2002; Brennan et al., 2013). Sea surface temperature  
 228 (SST) is calculated from tandem Mg/Ca analyses on planktic foraminifera (with a  
 229 conservative  $2\sigma$  uncertainty of 2°C). Adjustments were made for changes in  $\text{Mg}/\text{Ca}_{\text{sw}}$   
 230 using the records of Horita et al. (2002) and Brennan et al. (2013), and correcting for  
 231 changes in dependence on  $\text{Mg}/\text{Ca}_{\text{sw}}$  following Evans and Muller (2012) using  $H =$   
 232 0.41 calculated from *T. sacculifer* (Delaney et al., 1985; Hasiuk and Lohmann, 2010;  
 233 Evans and Muller, 2012) using the equations:

$$\text{Mg}/\text{Ca}_{\text{sw.c}} = (\text{Mg}/\text{Ca}_{\text{sw.a}} / \text{Mg}/\text{Ca}_{\text{sw.m}})^{0.41} \quad (2)$$

234 Where  $\text{Mg}/\text{Ca}_{\text{sw.c}}$  is the correction factor applied to the temperature equation for  
 235 changing  $\text{Mg}/\text{Ca}_{\text{sw}}$ ,  $\text{Mg}/\text{Ca}_{\text{sw.a}}$  is the estimated  $\text{Mg}/\text{Ca}_{\text{sw}}$  for the age of the sample and  
 236  $\text{Mg}/\text{Ca}_{\text{sw.m}}$  is modern  $\text{Mg}/\text{Ca}_{\text{sw}}$ . Temperature is then calculated using the generic  
 237 planktic foraminifera calibration of Anand et al. (2003) and including a correction  
 238 factor for  $\text{Mg}/\text{Ca}_{\text{sw}}$ .

$$\text{Temperature} = \ln(\text{Mg}/\text{Ca}_{\text{test}} / (0.38 * \text{Mg}/\text{Ca}_{\text{sw.c}})) / 0.09 \quad (3)$$

239 Mg/Ca analysis was conducted on a small aliquot of the sample dissolved for isotope  
 240 analysis at the University of Southampton using a ThermoFisher Scientific Element 2  
 241 XR. Al/Ca was also measured to assess the competency of the sample cleaning.  
 242 Because of complications with the Mg/Ca-temperature proxy in *Cibicidoides* species  
 243 (Elderfield et al., 2006), bottom water temperatures (BWTs) are estimated here by

244 taking the global secular temperature change from the Mg/Ca temperature  
245 compilation of Cramer et al. (2011), using the calibration of Lear et al. (2010) and  
246 applying this change to the modern bottom water temperature at each site taken from  
247 the nearest GLODAP site (with a conservative  $2\sigma$  uncertainty of  $2^\circ\text{C}$ ). Salinity is held  
248 constant at modern values determined from the nearest GLODAP site ( $2\sigma$  uncertainty  
249 of  $2\text{‰}$  uncertainty) for the entire record. Note that temperature and salinity have  
250 little influence on the calculated pH and the uncertainty in  $\delta^{11}\text{B}_{\text{sw}}$  is dominated by the  
251 uncertainty in the  $\delta^{11}\text{B}$  measurement and the estimate of the pH gradient.

252 The majority of the  $\delta^{13}\text{C}$  data were measured at Cardiff University on a  
253 ThermoFinnigan MAT 252 coupled with a Kiel III carbonate device for automated  
254 sample preparation. Additional samples were measured on a gas source mass  
255 spectrometer Europa GEO 20-20, University of Southampton National Oceanography  
256 Centre Southampton (USNOCS) equipped with automated carbonate preparation  
257 device and on a Finnigan MAT 253 gas isotope ratio mass spectrometer connected to  
258 a Kiel IV automated carbonate preparation device at the Zentrum für Marine  
259 Tropenökologie (ZMT), Bremen. The Pliocene benthic  $\delta^{13}\text{C}$  from Site 999 was taken  
260 from the nearest sample in Haug and Tiedemann, (1998). Stable isotope results are  
261 reported relative to the Vienna Peedee belemnite (VPDB) standard. An adjustment  
262 for vital effects on the  $\delta^{13}\text{C}$  of *G. ruber* ( $+0.94\text{‰}$ ; Spero et al., 2003), *T.*  
263 *sacculifer*/*G. praebulloides* ( $+0.46\text{‰}$ ; Spero et al., 2003; Al-Rousan et al., 2004;), *C.*  
264 *mundulus* ( $+0.47\text{‰}$ ; McCorkle et al., 1997) and *C. wuellerstorfi* ( $+0.1\text{‰}$ ; McCorkle  
265 et al., 1997) is applied to calculate the  $\delta^{13}\text{C}$  of dissolved inorganic carbon (DIC).

### 266 **2.3 Carbon isotopes as a proxy for vertical ocean pH gradient**

267 The use of  $\delta^{13}\text{C}$  in foraminiferal calcite to estimate the surface to deep pH gradient  
268 requires knowledge of the slope of the pH- $\delta^{13}\text{C}$  relationship in the past. In this section  
269 we briefly outlines the main factors that contribute to the pH- $\delta^{13}\text{C}$  relationship in  
270 order to underpin our analysis of extensive carbon cycle model simulations.

271 The production, sinking and sequestration into the ocean interior of low- $\delta^{13}\text{C}$  organic  
272 carbon via the soft-tissue component of the biological pump (e.g., Hain et al., 2014a)  
273 leads to broad correlation between  $\delta^{13}\text{C}$ ,  $[\text{CO}_3^{2-}]$  and macronutrients in the ocean. The  
274 remineralization of this organic matter decreases  $\delta^{13}\text{C}$  and titrates  $[\text{CO}_3^{2-}]$  so as to

275 reduce pH, while nutrient concentrations are increased. In waters that have  
276 experienced more soft tissue remineralization both pH and  $\delta^{13}\text{C}$  will be lower (Fig.  
277 4a,b), which is the dominant cause for the positive slope between  $\delta^{13}\text{C}$  and pH in the  
278 modern ocean (e.g., Foster et al., 2012; Fig. 4c).

279 Another significant factor affecting the spatial distribution of both  $\delta^{13}\text{C}$  and pH is  
280 seawater temperature, which affects both the equilibrium solubility of DIC and the  
281 equilibrium isotopic composition of DIC. Warmer ocean waters have decreased  
282 equilibrium solubility of DIC and so increased local  $[\text{CO}_3^{2-}]$  and pH (Goodwin and  
283 Lauderdale, 2013), while warmer waters have relatively low equilibrium  $\delta^{13}\text{C}$  values  
284 (Lynch-Stieglitz et al, 1995). This means that a spatial gradient in temperature acts to  
285 drive  $\delta^{13}\text{C}$  and pH in opposite directions: warmer waters tend to have higher pH but  
286 lower  $\delta^{13}\text{C}$ . These opposing temperature effects act to reduce the pH difference  
287 between two points with greatly different temperature to below the value expected  
288 based on  $\delta^{13}\text{C}$  alone. That is, when using  $\delta^{13}\text{C}$  differences to estimate the pH gradient  
289 between the warm low latitude surface and cold deep waters the appropriate pH- $\delta^{13}\text{C}$   
290 relationship will be less than expected when only considering the effect of the  
291 biological pump.

292 In the modern ocean, and for the preceding tens of millions of years, these two  
293 processes are likely dominant in setting spatial variation in  $\delta^{13}\text{C}$  and pH (and  $[\text{CO}_3^{2-}]$ ).  
294 However, other processes will have a minor effect on either pH or  $\delta^{13}\text{C}$ . For instance,  
295 the accumulation of remineralized  $\text{CaCO}_3$  hard-tissue increases  $[\text{CO}_3^{2-}]$  and pH  
296 (Broecker and Peng, 1982), but does not significantly affect  $\delta^{13}\text{C}$  (Zeebe and Wolf-  
297 Gladrow, 2001). Moreover, the long timescale of air/sea isotopic equilibration of  $\text{CO}_2$   
298 is an important factor in setting the distribution of  $\delta^{13}\text{C}$  on a global ocean scale  
299 (Galbraith et al., 2015). The surface  $\text{CO}_2$  disequilibrium also has a substantial effect  
300 on  $\delta^{13}\text{C}$  (Lynch-Stieglitz et al., 1995) while it affects  $[\text{CO}_3^{2-}]$  and pH only marginally  
301 (Goodwin and Lauderdale, 2013).

302

#### 303 **2.4 Modelling the pH to $\delta^{13}\text{C}$ relationship**

304 After correcting for the Suess effect, modern ocean observations demonstrate a near  
305 linear relationship between global ocean data of seawater *in situ* pH and  $\delta^{13}\text{C}$  DIC  
306 with a slope of 0.201 (Foster et al., 2012). This empirically determined slope might  
307 well have been different in past oceans with very different carbon chemistry  
308 compared to today. Here we use an ensemble approach with two independent carbon  
309 cycle models to show that the pH to  $\delta^{13}\text{C}$  slope can only have changed in very tight  
310 limits. Below we provide pertinent information on the GENIE and CYCLOPS model  
311 experiments:

312 We use the Earth System model GENIE-1 (Edwards and Marsh, 2005; Ridgwell et al.  
313 2007) to assess the robustness of the pH- $\delta^{13}\text{C}$  relationship and its sensitivity to  
314 physical and biogeochemical ocean forcing. The configuration used here is closely  
315 related to that of Holden et al. (2013), in which the controls on the ocean's  $\delta^{13}\text{C}$   
316 distribution were assessed, with an energy and moisture balance in the atmosphere,  
317 simple representations of land vegetation and sea ice, and frictional geostrophic  
318 ocean physics. In each of 16 vertical levels in the ocean, increasing in thickness with  
319 depth, there are 36x36 grid cells ( $10^\circ$  in longitude and nominally  $5^\circ$  in latitude, with  
320 higher resolution at low latitudes). Modern ocean bathymetry and land topography is  
321 applied in all simulations. The ocean biogeochemical scheme (Ridgwell et al. 2007)  
322 is based on conversion of DIC to organic carbon associated with phosphate uptake  
323 with fixed P:C:O stoichiometry. Organic carbon and nutrients are remineralized  
324 according to a remineralization profile with a pre-defined *e*-folding depth scale. This  
325 depth scale, as well as the rain ratio of inorganic to organic carbon in sinking  
326 particulate matter, is among the parameters examined in the sensitivity study. In these  
327 simulations, there is no interaction with sediments. As a result of this, a steady state  
328 solution is obtained within the 5000-year simulations; the results presented here are  
329 for the end of the simulations.

330 The sensitivity study consists of seven sets of experiments, each varying a single  
331 model parameter relative to the control simulation with preindustrial atmospheric  
332  $p\text{CO}_2$ . This enables us to assess both which processes, if any, are capable of altering  
333 the ocean's pH- $\delta^{13}\text{C}$  relationship, and the uncertainty in the predictive skill of this  
334 relationship due to spatial variability. These experiments are therefore exploratory in

335 nature and not intended to represent real changes that may have occurred. The seven  
336 parameters varied are (1) the ocean's alkalinity reservoir; (2) the ocean's carbon  
337 reservoir; (3) the parameter "S. Lim gas exchange" which blocks air-sea gas  
338 exchange south of the stated latitude, significant here because of the dependence of  
339  $\delta^{13}\text{C}$  on surface disequilibrium (Galbraith et al., 2015); (4) inorganic to organic  
340 carbon rain ratio, controlling the relationship between DIC and alkalinity  
341 distributions; (5) "Antarctic shelf FWF", a freshwater flux adjustment (always  
342 switched off in control experiments with GENIE) facilitating the formation of brine  
343 rich waters, which produces a high-salinity poorly-ventilated deep ocean at high  
344 values; (6) "Atlantic-Pacific FWF", a freshwater flux adjustment equivalent to  
345 freshwater hosing, leading to a shut-down of the Atlantic meridional overturning  
346 circulation at low values; (7) remineralization depth-scale of sinking organic matter,  
347 which affects the vertical gradient both of pH and  $\delta^{13}\text{C}$ . A wide range of parameter  
348 values is chosen for each parameter in order to exceed any plausible changes within  
349 the Cenozoic.

350 For the second test of the slope of pH- $\delta^{13}\text{C}$  relationship we use the CYCLOPS  
351 biogeochemical 18-box model that includes a dynamical lysocline, a subantarctic  
352 zone surface box and a polar Antarctic zone box (Sigman et al., 1998; Hain et al.,  
353 2010, 2014b). The very large model ensemble with 13,500 individual model  
354 scenarios is designed to capture the full plausible range of (a) glacial/interglacial  
355 carbon cycle states by sampling the full solution space of Hain et al. (2010), and (b)  
356 reconstructed secular changes in seawater [Ca] (calcium concentration), carbonate  
357 compensation depth (CCD), weathering and atmospheric  $\text{CO}_2$ . The following seven  
358 model parameters are systematically sampled to set the 13,500 model scenarios: (1)  
359 shallow versus deep Atlantic meridional overturning circulation represented by  
360 modern reference north Atlantic deep water (NADW) versus peak glacial North  
361 Atlantic intermediate water (GNAIW) circulation; (2) iron driven changes in nutrient  
362 drawdown in the subantarctic zone of the Southern Ocean; (3) changes in nutrient  
363 drawdown of the polar Antarctic; (4) changes in vertical exchange between the deep  
364 Southern Ocean and the polar Antarctic surface; (5) range in seawater [Ca]  
365 concentration from 1x to 1.5x modern as per reconstructions (Horita et al., 2002); (6)  
366 Pacific CCD is set to the range of 4.4-4.9 km via changes in the weathering flux, as  
367 per sedimentological evidence (Pälike et al., 2012); (7) atmospheric  $\text{CO}_2$  is set from

368 200 ppm to 1000 ppm by changes in the ‘weatherability’ parameter of the silicate  
369 weathering mechanism. The ensemble spans predicted bulk ocean DIC between 1500  
370 and 4500  $\mu\text{mol/kg}$ , a wide range of ocean pH and  $\text{CaCO}_3$  saturation states consistent  
371 with the open system weathering cycle, and widely different states of the ocean’s  
372 biological pump.

### 373 **2.5 Assessing uncertainty**

374  $\delta^{11}\text{B}_{\text{sw}}$  uncertainty was calculated using a Monte Carlo approach where pH was  
375 calculated for deep and surface waters at each time slice using a random sampling  
376 ( $n=10000$ ) of the various input parameters within their respective uncertainties as  
377 represented by normal distributions. These uncertainties ( $2\sigma$  uncertainty in  
378 parentheses) are: temperature ( $\pm 2$  °C), salinity ( $\pm 2$  units on the practical salinity  
379 scale) [Ca] ( $\pm 4.5$  mmol/kg), [Mg], ( $\pm 4.5$  mmol/kg),  $\delta^{11}\text{B}_{\text{planktic}}$  ( $\pm 0.15\text{-}0.42$  ‰),  
380  $\delta^{11}\text{B}_{\text{benthic}}$  ( $\pm 0.21\text{-}0.61$  ‰), and either the fixed modern pH gradient at that site ( $\pm 0.05$   
381 pH units) or the pH gradient predicted by the  $\delta^{13}\text{C}$ -pH relationship ( $\pm 0.05$  pH units).  
382 In our first approach we assume the pH gradient at each site has remained the same as  
383 modern through time (gradient estimated from GLODAP; Key et al., 2004). In the  
384 second approach the pH gradient is corrected using the  $\delta^{13}\text{C}$  gradient (where the slope  
385 of the relationship between pH and  $\delta^{13}\text{C}$  is taken from the CYCLOPS model). The  
386 uncertainty in the  $\delta^{11}\text{B}$  measurements is calculated from the long-term reproducibility  
387 of Japanese Geological Survey *Porites* coral standard (JCP;  $\delta^{11}\text{B}=24.3\text{‰}$ ) at the  
388 University of Southampton using the equations:

$$389 \quad 2\sigma = 2.25 \exp^{-23.01[^{11}\text{B}]} + 0.28 \exp^{-0.64[^{11}\text{B}]} \quad (4)$$

$$390 \quad 2\sigma = 33450 \exp^{-168.2[^{11}\text{B}]} + 0.311 \exp^{-1.477[^{11}\text{B}]} \quad (5)$$

391 where  $[^{11}\text{B}]$  is the intensity of  $^{11}\text{B}$  signal in volts and equation (4) and equation (5)  
392 used with  $10^{11} \Omega$  and  $10^{12} \Omega$  resistors, respectively.

393 From the 10,000 Monte Carlo ensemble solutions of our 22 benthic-planktic pairs we  
394 construct 10,000 randomized records of  $\delta^{11}\text{B}_{\text{sw}}$  as a function of time. Each of these  
395 randomized  $\delta^{11}\text{B}_{\text{sw}}$  records is subjected to smoothing using the locally weighted  
396 scatterplot smoothing (LOWESS) algorithm with a smoothing parameter (span) of  
397 0.7, which prevents the smoothed  $\delta^{11}\text{B}_{\text{sw}}$  from changing faster than allowed by

398 seawater boron mass balance ( $\sim 0.1$  ‰ per million years; boron residence time is 11-  
399 17 million years; Lemarchand et al., 2002). As a result of anomalously low  $\delta^{11}\text{B}$   
400 differences between benthic and planktic pairs, two pairs at 8.68 Ma and 19 Ma were  
401 discarded from the smoothing. The spread of the ensemble of smoothed  $\delta^{11}\text{B}_{\text{sw}}$  curves  
402 represents the combination of the compounded, propagated uncertainties of the  
403 various inputs and the additional constraint of gradual  $\delta^{11}\text{B}_{\text{sw}}$  change over geological  
404 time. Various statistical properties (i.e., mean, median, standard deviation ( $\sigma$ ),  
405 various quantiles) of this  $\delta^{11}\text{B}_{\text{sw}}$  reconstruction were evaluated from the ensemble of  
406 smoothed  $\delta^{11}\text{B}_{\text{sw}}$  records. Generally, for any given benthic-planktic pair the resulting  
407  $\delta^{11}\text{B}_{\text{sw}}$  estimates are not perfectly normally distributed and thus we use the median as  
408 the metric for the central tendency.

### 409 **3. Results and Discussion**

#### 410 **3.1 $\delta^{11}\text{B}$ benthic and planktic data**

411 Surface and deep-ocean,  $\delta^{11}\text{B}$ ,  $\delta^{13}\text{C}$  and temperature broadly show a similar pattern to  
412 one another throughout the Neogene (Fig. 5). The  $\delta^{11}\text{B}$  benthic record decreases from  
413  $\sim 15$  ‰ at 24 Ma to a minimum of 13.28 ‰ at 14 Ma before increasing to  $\sim 17$  ‰ at  
414 present day (Fig. 5). This pattern and the range of values in benthic foraminiferal  
415  $\delta^{11}\text{B}$  is in keeping with previously published Neogene  $\delta^{11}\text{B}$  benthic records measured  
416 using NTIMS (Raitzsch and Hönisch, 2013), suggesting that our deep-water  $\delta^{11}\text{B}$   
417 record is representative of large scale pH changes in the global ocean. While the  
418 surface  $\delta^{11}\text{B}_{\text{borate}}$  remained relatively constant between 24 and 11 Ma at  $\sim 16$  ‰, there  
419 is a significant increase in  $\delta^{11}\text{B}$  between the middle Miocene and present (values  
420 increase to  $\sim 20$  ‰) (Fig. 5b). The reconstructed surface water temperatures show a  
421 long-term decrease through the Neogene from  $\sim 28^\circ\text{C}$  to  $24^\circ\text{C}$ , aside from during the  
422 Miocene Climatic Optimum (MCO) where maximum Neogene temperatures are  
423 reached (Fig. 5c). Following Cramer et al. (2011) deep-water temperatures decrease  
424 from  $\sim 12^\circ\text{C}$  to  $4^\circ\text{C}$  at the present day and similarly show maximum temperatures in  
425 the MCO. Surface and deep-water  $\delta^{13}\text{C}_{\text{DIC}}$  both broadly decrease through the Neogene  
426 and appear to covary on shorter timescales (Fig. 5e, f).

427

### 428 3.2 The relationship between $\delta^{13}\text{C}$ and pH gradients

429 In the global modern ocean data, after accounting for the anthropogenic carbon, the  
430 empirical relationship between *in situ* pH and DIC  $\delta^{13}\text{C}$  is well described by a linear  
431 function with a slope of 0.201 (Fig. 4; Foster et al., 2012). In the control GENIE  
432 experiment and in all experiments in which ocean-physics parameters (Antarctic shelf  
433 FWF and Atlantic-Pacific FWF) are varied, the pH/ $\delta^{13}\text{C}$  gradient is slightly greater  
434 than 0.2, with a root-mean-squared error (RMSE) of  $\sim 0.05$  in a reconstruction of the  
435 spatial distribution of pH using this relationship (Fig. 6). Varying the biogeochemical  
436 parameters (gas exchange, rain ratio and remineralizing depth scale) yields some  
437 change in the regressed slope of the pH/ $\delta^{13}\text{C}$  relationship due to decoupled responses  
438 of pH and  $\delta^{13}\text{C}$ , but this gradient remains well within the 0.2  $\pm$  0.05 range, and a  
439 RMSE of 0.05 in the spatial relationship remains robust (Fig. 6). We take this as  
440 evidence that the uncertainty in the pH/ $\delta^{13}\text{C}$  relationship assumed in our carbon  
441 chemistry calculation is well represented by a central value of 0.2 with a 0.025  
442 standard deviation. Experiments at very high DIC or low alkalinity, either of which  
443 yield high atmospheric  $p\text{CO}_2$  and low mean ocean pH, yield gradients slightly outside  
444 the 0.2  $\pm$  0.05 range, with an elevated RMSE. This is probably associated with the  
445 non-linearity of the pH scale, modifying the gradient for a very different pH. It is to  
446 be emphasised that such extreme decoupled changes in DIC and alkalinity are not  
447 plausible within the Cenozoic, and were only possible in these simulations because of  
448 the absence of interactive sediments.

449 The slope of the pH- $\delta^{13}\text{C}$  relationship simulated by our CYCLOPS model ensemble  
450 across a range of perturbed states is 0.2047 ( $1\sigma = 0.0196$ ) (Fig. 7a, 8), in perfect  
451 agreement with modern empirical data and our GENIE experiments. We take this  
452 agreement as evidence that the slope of the pH- $\delta^{13}\text{C}$  relationship is a feature of ocean  
453 biogeochemistry that is relatively conserved even if ocean carbon chemistry and  
454 circulation change drastically. For the purpose of calculating  $\delta^{11}\text{B}_{\text{sw}}$  from our  
455 benthic/planktic foraminifera measurements we need to estimate the pH difference  
456 between the low latitude surface and deep ocean at the sample sites, most of which  
457 are in the subtropical North Atlantic. If we restrict our analysis of the CYCLOPS  
458 ensemble to only the low latitude surface boxes and the corresponding deep ocean  
459 boxes (i.e., Atlantic, Indian, South Pacific and North Pacific) the slope of the

460 applicable pH- $\delta^{13}\text{C}$  relationship is 0.1797 ( $1\sigma = 0.0213$ ) (Fig. 7b, 8), which is  
461 significantly less than the regression based on all 18 model boxes. Further, if only the  
462 Atlantic low latitude surface and deep ocean boxes are used to calculate the slope of  
463 the applicable pH-  $\delta^{13}\text{C}$  relationship declines to 0.1655 ( $1\sigma = 0.0192$ ) (Fig. 7c, 8).  
464 Thus, excluding the polar ocean and the ocean's mid-depth permanent thermocline  
465 from the analysis consistently yields a shallower slope of the pH- $\delta^{13}\text{C}$  relationship,  
466 with some evidence for water mass dependence also in the modern observations (Fig.  
467 4). Here we calculate  $\delta^{11}\text{B}_{\text{sw}}$  for all three estimates of the pH-  $\delta^{13}\text{C}$  slope (global  
468 regression 0.201; low latitude surface and deep regression 0.1797; Atlantic low  
469 latitude surface to deep box gradients 0.1655) assuming a generous uncertainty of  
470 0.05 ( $2\sigma$ ) in all cases, and we provide all three  $\delta^{11}\text{B}_{\text{sw}}$  scenarios as an online  
471 supplement. Overall, the slope between pH and  $\delta^{13}\text{C}$  is dependent on the competition  
472 between spatial variations in remineralized soft tissue, increasing the slope between  
473 pH and  $\delta^{13}\text{C}$ , and seawater temperature, decreasing the slope between pH and  $\delta^{13}\text{C}$ .  
474 The largest concentrations of remineralized soft tissue occur in the thermocline,  
475 suggesting that a relatively steep pH- $\delta^{13}\text{C}$  slope is appropriate for estimating the pH  
476 gradient from the  $\delta^{13}\text{C}$  difference. However, when comparing surface to deep waters,  
477 as is done in this study, the full range of the temperature effect is expressed and a  
478 relatively shallow pH- $\delta^{13}\text{C}$  slope is appropriate. This is particularly true given that  
479 our samples are from the low latitude surface and the cold deep ocean. Since most of  
480 our measurements are from the subtropical Atlantic it is perhaps most appropriate to  
481 use the slope regressed from the low latitude surface and deep boxes from this ocean  
482 basin (i.e.,  $\Delta\text{pH}/\Delta\delta^{13}\text{C} = 0.1655$ ; with  $1\sigma = 0.025$ ) and we will focus on those  
483 calculations in the following discussion (Fig. 9).

### 484 3.3 $\delta^{11}\text{B}_{\text{sw}}$ records through the Neogene

485 The individual  $\delta^{11}\text{B}_{\text{sw}}$  estimates calculated using the modern pH gradient method vary  
486 from 34.9 ‰ to 42.2 ‰ ( $\pm 0.84$ -4.77 ‰) across the Neogene with a predominance of  
487 higher values closer to the modern and lowest values in the middle Miocene (Fig. 9).  
488 After smoothing is applied to satisfy seawater B mass balance, the long-term  $\delta^{11}\text{B}_{\text{sw}}$  is  
489 determined as 37.5 ‰ at 23 Ma, decreases to a minimum of 37.17 ‰ at  $\sim 13$  Ma ( $\pm$   
490 0.34-1.81 ‰), and subsequently increases gradually towards modern values through  
491 the late Miocene, Pliocene and Pleistocene (Fig. 9). The variability in the estimations

492 of  $\delta^{11}\text{B}_{\text{sw}}$  for each individual benthic/planktic foraminifera pair suggest that individual  
493 estimates of  $\delta^{11}\text{B}_{\text{sw}}$  are sensitive to the different input parameters, particularly the  
494 assigned uncertainty in the pH gradient. However, by smoothing the record we  
495 effectively suppress error that is uncorrelated between individual benthic/planktic  
496 pairs of similar age and thereby focus on the effect of changes in  $\delta^{11}\text{B}_{\text{sw}}$  that are  
497 correlated over multi-million year timescales.

498 When using  $\delta^{13}\text{C}$  gradients as predictors for the pH gradient the  $\delta^{11}\text{B}_{\text{sw}}$  values  
499 calculated are broadly similar to the results with assumed constant pH gradient:  
500  $\delta^{11}\text{B}_{\text{sw}}$  varies from 34.1 ‰ to 42.3 ‰ ( $\pm 0.72\text{--}4.0$  ‰) across the Neogene with the  
501 predominance of higher values closer to the modern with the lowest values in the  
502 middle Miocene (Fig. 9). However, when the individual  $\delta^{11}\text{B}_{\text{sw}}$  estimates are  
503 smoothed, while the  $\delta^{11}\text{B}_{\text{sw}}$  calculated using this method is similar to the constant pH  
504 gradient scenario through the late and middle Miocene ( $\sim 37.5$  ‰  $\pm 0.19\text{--}1.28$  ‰),  
505 the subsequent increase occurs more rapidly and the  $\delta^{11}\text{B}_{\text{sw}}$  record reaches modern  
506 values by  $\sim 5$  Ma (Fig. 9). Given the variability we observe in the  $\delta^{13}\text{C}$  derived pH  
507 gradient, and the consistency between the modelled pH gradient using GENIE and  
508 CYCLOPS, we conclude using the benthic-to-planktic pH difference calculated using  
509 the  $\delta^{13}\text{C}$  gradient is indeed an improvement over the assumption that pH gradients  
510 remained constant through time. Therefore, we recommend the use of the  $\delta^{13}\text{C}$ -  
511 corrected  $\delta^{11}\text{B}_{\text{sw}}$  moving forward and in the following discussion we will limit our  
512 attention to this record.

### 513 **3.4 Comparison to other $\delta^{11}\text{B}_{\text{sw}}$ records**

514 The comparison of our new  $\delta^{11}\text{B}_{\text{sw}}$  record to those previously published, reveals that a  
515 common feature of all the existing estimates of Neogene  $\delta^{11}\text{B}_{\text{sw}}$  evolution is an  
516 increase through time from the middle Miocene to present (Fig. 10). Our new  $\delta^{11}\text{B}_{\text{sw}}$   
517 record is broadly similar to previously published estimates calculated using pH  
518 gradients in the surface ocean, in terms of both shape of the record and magnitude of  
519 the reconstructed changes, with the notable exception in the early and middle  
520 Miocene where  $\delta^{11}\text{B}_{\text{sw}}$  in our record is 0.5 ‰ lower (Fig. 10) than the published  
521 estimates of Pearson and Palmer (2000). The  $\delta^{11}\text{B}_{\text{sw}}$  record calculated using benthic  
522  $\delta^{11}\text{B}$  and assumed deep ocean pH changes (Raitzsch and Hönisch, 2013) is also rather

523 similar to the  $\delta^{11}\text{B}_{\text{sw}}$  values reconstructed here, with 9 out of 16 of their individual  
524 samples falling inside our 95% confidence band even before considering the large  
525 individual sample uncertainties reported by Raitzsch and Hönisch (2013). That said,  
526 the polynomial fit to the data applied by Raitzsch and Hönisch (2013) takes no  
527 account of the uncertainties of individual data points and produces an oscillating  
528 pattern that is inconsistent with our new reconstruction (Fig. 10). Furthermore, our  
529 new  $\delta^{11}\text{B}_{\text{sw}}$  record falls within the broad uncertainty envelope of boron mass balance  
530 calculations of Lemarchand et al. (2002), but those modelled values do not show the  
531 same level of multi-million year variability of either Raitzsch and Hönisch (2013) or  
532 our new record, therefore suggesting that some of the controls on ocean inputs and  
533 outputs of boron are not fully understood. In line with the conclusions of previous  
534 studies (e.g., Raitzsch and Hönisch, 2013), our data show that the  $\delta^{11}\text{B}_{\text{sw}}$  signal in the  
535 fluid inclusions (Paris et al., 2010) is mostly likely a combination of the  $\delta^{11}\text{B}_{\text{sw}}$  and  
536 some other factor such as a poorly constrained fractionation factor between the  
537 seawater and the halite.

### 538 **3.5 Common controls on the seawater isotopic ratios of B, Mg, Ca and Li**

539 Our new record of  $\delta^{11}\text{B}_{\text{sw}}$  has some similarities to secular change seen in other marine  
540 stable isotope records (Fig. 11). The  $\delta^7\text{Li}_{\text{sw}}$  (Misra and Froelich, 2012) and  $\delta^{44/40}\text{Ca}_{\text{sw}}$   
541 (Griffith et al., 2008) both increase through the Neogene, whereas  $\delta^{26}\text{Mg}_{\text{sw}}$  decreases  
542 (Pogge von Strandmann et al., 2014) suggesting a similar control on the isotopic  
543 composition of all four elements across this time interval (Fig. 11). To further  
544 evaluate the correlation between these other marine isotope records and  $\delta^{11}\text{B}_{\text{sw}}$ , we  
545 interpolate and cross-plot  $\delta^{11}\text{B}_{\text{sw}}$  and the  $\delta^7\text{Li}_{\text{sw}}$ ,  $\delta^{44/40}\text{Ca}_{\text{sw}}$  and  $\delta^{26}\text{Mg}_{\text{sw}}$  records. This  
546 analysis suggests that the isotopic composition of  $\delta^{11}\text{B}_{\text{sw}}$ ,  $\delta^7\text{Li}_{\text{sw}}$ ,  $\delta^{26}\text{Mg}_{\text{sw}}$  and  $\delta^{44/40}\text{Ca}_{\text{sw}}$   
547 are well correlated through the Neogene, although there is some scatter in these  
548 relationships (Fig. 12). Although the Sr isotope record shows a similar increase  
549 during the Neogene (Hodell et al., 1991), we elect to focus our discussion on  $\delta^{11}\text{B}_{\text{sw}}$ ,  
550  $\delta^7\text{Li}_{\text{sw}}$ ,  $\delta^{26}\text{Mg}_{\text{sw}}$  and  $\delta^{44/40}\text{Ca}_{\text{sw}}$  given that the factors fractionating these isotope systems  
551 are similar (see below).

552 To better constrain the controls on  $\delta^{11}\text{B}_{\text{sw}}$ ,  $\delta^7\text{Li}_{\text{sw}}$ ,  $\delta^{26}\text{Mg}_{\text{sw}}$  and  $\delta^{44/40}\text{Ca}_{\text{sw}}$  it is  
553 instructive to compare the size and isotopic composition of the fluxes of boron,

554 lithium, calcium and magnesium (Table 1). As noted previously, the major flux of  
555 boron into the ocean is via riverine input (Lemarchand et al., 2002), although some  
556 studies suggest that atmospheric input may also play an important role (Park and  
557 Schlesinger, 2002). The outputs are dominated by adsorption onto clays and the  
558 alteration of oceanic crust (Spivack and Edmond, 1987; Smith et al., 1995). Similar  
559 to boron the primary inputs of lithium into the ocean come from hydrothermal  
560 sources and riverine input and the main outputs are ocean crust alteration and  
561 adsorption onto sediments (Misra and Froelich, 2012). The two dominant controls on  
562 magnesium concentration and isotope ratio in the oceans is the riverine input, ocean  
563 crust alteration and dolomitization (Table 1) (Tipper et al., 2006b). The main controls  
564 on the amount of calcium in the modern ocean and its isotopic composition is the  
565 balance between riverine and hydrothermal inputs and removal through  $\text{CaCO}_3$   
566 deposition and alteration of oceanic crust (Fantle and Tipper, 2014, Griffith et al.,  
567 2008). Dolomitization has also been cited as playing a potential role in controlling  
568  $\delta^{44/40}\text{Ca}_{\text{sw}}$ , although the contribution of this process through time is poorly constrained  
569 (Griffith et al., 2008).

570 Analysis of the oceanic fluxes of all four ions suggests that riverine input may be an  
571 important factor influencing the changing isotopic composition of B, Li, Ca and Mg  
572 over the late Neogene (Table 1). In the case of all four elements, a combination of the  
573 isotopic ratio of the source rock and isotopic fractionation during weathering  
574 processes are typically used to explain the isotopic composition of a particular river  
575 system. However, in most cases the isotopic composition of the source rock is found  
576 to be of secondary importance (Rose et al., 2000; Kısakürek et al., 2005; Tipper et al.,  
577 2006b; Millot et al., 2010). For instance, the  $\delta^{11}\text{B}$  composition of rivers is primarily  
578 dependent on isotopic fractionation during the reaction of water with silicate rocks  
579 and to a lesser extent the isotopic composition of the source rock (i.e. the proportion  
580 of evaporites and silicate rocks; Rose et al., 2000). The source rock also appears to  
581 have limited influence on the  $\delta^7\text{Li}$  composition of rivers and riverine  $\delta^7\text{Li}$  varies  
582 primarily with weathering intensity (Kısakürek et al., 2005; Millot et al., 2010). The  
583 riverine input of calcium to the oceans is controlled by the composition of the  
584 primary continental crust (dominated by carbonate weathering) and a recycled  
585 component, although the relative influence of these two processes is not well  
586 understood (Tipper et al., 2006a). In addition, vegetation may also play a significant

587 role in the  $\delta^{44/40}\text{Ca}$  of rivers (Fantle and Tipper, 2014). For Mg, the isotopic  
588 composition of the source rock is important for small rivers, however, lithology is of  
589 limited significance at a global scale in comparison to fractionation in the weathering  
590 environment (Tipper et al., 2006b). Given the lack of evidence of source rock as a  
591 dominant control on the isotopic composition of rivers, here we focus on some of the  
592 possible causes for changes in the isotopic composition and/or flux of riverine input  
593 over the Neogene.

594 In this regard, of the four elements discussed here, the Li isotopic system is the most  
595 extensively studied. Indeed, the change in  $\delta^7\text{Li}_{\text{sw}}$  has already been attributed to an  
596 increase in the  $\delta^7\text{Li}_{\text{sw}}$  composition of the riverine input (Hathorne and James, 2006;  
597 Misra and Froelich, 2012). The causes of the shift in  $\delta^7\text{Li}$  riverine have been variably  
598 attributed to: (1) an increase in incongruent weathering of silicate rocks and  
599 secondary clay formation as a consequence of Himalayan uplift (Misra and Froelich,  
600 2012), (2) a reduction in weathering intensity (Hathorne and James, 2006; Froelich  
601 and Misra, 2014), (3) an increase in silicate weathering rate (Liu et al., 2015) and 4)  
602 an increase in the formation of floodplains and the increased formation of secondary  
603 minerals (Pogge von Strandmann and Henderson, 2014). In all four cases the lighter  
604 isotope of Li is retained on land in clay and secondary minerals. A mechanism  
605 associated with either an increase in secondary mineral formation or the retention of  
606 these minerals on land is also consistent across Mg, Ca and B isotope systems. For  
607 instance, clay minerals are preferentially enriched in the light isotope of B (Spivack  
608 and Edmond, 1987; Deyhle and Kopf, 2004; Lemarchand and Gaillardet, 2006) and  
609 Li (Pistiner and Henderson, 2003) and soil carbonates and clays are preferentially  
610 enriched in the light isotope of Ca (Tipper et al., 2006a; Hindshaw et al., 2013;  
611 Ockert et al., 2013). The formation of secondary silicate minerals, such as clays, is  
612 assumed to preferentially take up heavy Mg isotope into the solid phase (Tipper et al.,  
613 2006a; Tipper et al., 2006b; Pogge von Strandmann et al., 2008; Wimpenny et al.,  
614 2014), adequately explaining the inverse relationship between  $\delta^{11}\text{B}_{\text{sw}}$  and  $\delta^{26}\text{Mg}_{\text{sw}}$ .  
615 Consequently the increased formation or retention on land of secondary minerals  
616 would alter the isotopic composition of the riverine input of all the examined isotope  
617 systems and could potentially explain the trends in all four isotope systems through  
618 the late Neogene (Fig. 12). The increased formation and retention of clays on land  
619 may have been related to the growth of the Himalayan orogeny and increased clay

620 formation in the newly formed floodplains and foreland surrounding the mountains  
621 (Pogge von Strandmann and Henderson, 2014).

## 622 **4 Conclusions**

623 Here we present a new  $\delta^{11}\text{B}_{\text{sw}}$  record for the Neogene based on paired planktic-  
624 benthic  $\delta^{11}\text{B}$  measurements. Our new record suggests that  $\delta^{11}\text{B}_{\text{sw}}$  is  $\sim 37.5\text{‰}$  at the  
625 Oligocene-Miocene boundary and remains low through the middle Miocene.  $\delta^{11}\text{B}_{\text{sw}}$   
626 then increases to the modern value through the late Miocene. This new  $\delta^{11}\text{B}_{\text{sw}}$  record  
627 provides a vital constraint required to estimate Neogene ocean pH, ocean carbon  
628 chemistry and atmospheric  $\text{CO}_2$  using the  $\delta^{11}\text{B}$ -pH proxy. When the new  $\delta^{11}\text{B}_{\text{sw}}$   
629 record is compared to changes in the seawater isotopic composition of Li, Ca and Mg  
630 the shape of the records across the Neogene is remarkably similar. In all four cases  
631 riverine input is cited as one of the key control of the isotopic composition of the  
632 elements in seawater. When we compare the isotopic fractionation of the elements  
633 associated with secondary mineral formation, the trends in the  $\delta^{26}\text{Mg}_{\text{sw}}$ ,  $\delta^{44/40}\text{Ca}_{\text{sw}}$   
634  $\delta^{11}\text{B}_{\text{sw}}$  and  $\delta^7\text{Li}_{\text{sw}}$  records are all consistent with an increase in secondary mineral  
635 formation through time. While a more quantitative treatment of these multiple stable  
636 isotope systems is required, the  $\delta^{11}\text{B}_{\text{sw}}$  record presented here provides additional  
637 constraints on the processes responsible for the evolution of ocean chemistry through  
638 time.

## 639 **Acknowledgements:**

640 This work used samples provided by (IODP, which is sponsored by the U.S.  
641 National Science Foundation and participating countries under the management of  
642 Joint Oceanographic Institutions, Inc. We thank W. Hale and A. Wuelbers of the  
643 Bremen Core Repository for their kind assistance. The work was supported by NERC

985 **Figure Captions:**

986 Figure 1: The oceanic boron cycle. Fluxes are from Lemarchand et al. (2002) and  
987 Park and Schlesinger (2002). Isotopic compositions are from Lemarchand et al.  
988 (2002) and references therein.

989 Figure 2: A compilation of published  $\delta^{11}\text{B}_{\text{sw}}$  records. Seawater composition  
990 reconstructed from foraminifera depth profiles (light blue squares and dark blue  
991 cross) from Pearson and Palmer (2000) and Foster et al. (2012) respectively,  
992 numerical modelling (dark green line), with additional green lines shows  $\pm 1\%$   
993 confidence interval (Lemarchand et al., 2002), benthic  $\delta^{11}\text{B}$  (purple diamonds and  
994 line) from Raitzsch and Hönisch (2013), and halites (orange crosses) from Paris et al.  
995 (2010). All the published  $\delta^{11}\text{B}_{\text{sw}}$  curves are adjusted so that at  $t=0$ , the isotopic  
996 composition is equal to the modern (39.61 ‰).

997 Figure 3: Schematic diagram showing the change in pH gradient with a 3‰ change in  
998  $\delta^{11}\text{B}$  for  $\delta^{11}\text{B}_{\text{sw}}$  of a) 39.6‰ and b) 37.5‰. Note how a  $\delta^{11}\text{B}$  difference of 3 ‰ is  
999 translated into different pH gradients depending on the  $\delta^{11}\text{B}_{\text{sw}}$ . Calculated using  $B_{\text{T}}=$   
1000  $432.6\ \mu\text{mol/kg}$  (Lee et al., 2010) and  $\alpha_{\text{B}}= 1.0272$  (Klochko et al., 2006). (c) The pH  
1001 change for a  $\delta^{11}\text{B}$  change of 3 ‰ at a range of different  $\delta^{11}\text{B}_{\text{sw}}$ .

1002 Figure 4: Latitudinal cross-section through the Atlantic showing (a) pH variations;  
1003 (b) the  $\delta^{13}\text{C}$  composition. Data are plotted using Ocean Data View (Schlitzer 2001).  
1004 pH data are from the CARINA dataset (CARINA group, 2009) and the  $\delta^{13}\text{C}$  data are  
1005 from the GLODAP data compilation (Key et al., 2004); (c) pH and  $\delta^{13}\text{C}_{\text{DIC}}$   
1006 relationships in the modern ocean adapted from Foster et al., (2012). Because of  
1007 anthropogenic acidification and the Seuss effect only data from  $>1500\ \text{m}$  are plotted.  
1008 Also included in the plot are the data from a transect in the North Atlantic (from 0 to  
1009 5000 m) where the effects of anthropogenic perturbation on both parameters have  
1010 been corrected (Olsen and Ninneman, 2010).

1011 Figure 5:  $\delta^{11}\text{B}_{\text{borate}}$ , temperature and  $\delta^{13}\text{C}_{\text{DIC}}$  estimates for the surface and deep ocean  
1012 through the last 23 million years. (a)  $\delta^{11}\text{B}_{\text{borate}}$  surface; (b)  $\delta^{11}\text{B}_{\text{borate}}$  deep (blue) from  
1013 this study and (green) Raitzsch and Hönisch, (2013). The error bars show the  
1014 analytical external reproducibility at 95% confidence; (c) Mg/Ca based temperature  
1015 reconstructions calculated on paired measurements of surface dwelling planktic  
1016 foraminifera; (d) Deep water temperature estimates from Cramer et al. (2011); (e)

1017  $\delta^{13}\text{C}_{\text{DIC}}$  surface record; (f)  $\delta^{13}\text{C}_{\text{DIC}}$  benthic record. Squares depict ODP Site 999,  
1018 triangles are ODP Site 758, diamonds are ODP Site 926, circles are ODP Site 761.

1019 Figure 6: The output from sensitivity analysis of the relationship between pH gradient  
1020 and  $\delta^{13}\text{C}$  gradient from GENIE. The gradient of a linear regression for each  
1021 experiment, with  $\delta^{13}\text{C}$  and pH data taken from each grid square, is plotted. A pre-  
1022 industrial model setup was taken and perturbations were made to alkalinity inventory,  
1023 carbon inventory, Antarctic shelf fresh water flux (Sv), Atlantic-Pacific freshwater  
1024 flux, S. Lim gas exchange (blocks air-sea gas exchange south of the stated latitude),  
1025 remineralisation depth scale (m) and rain ratio – as described in the methods section.  
1026 Blue circles depict the gradient (where the colour reflect the  $\text{CO}_2$  level of each  
1027 experiment) and red open circles show the root mean square of the regression  
1028 (RMSE). The green data points (closed) are the gradient of the linear regression for  
1029 the control experiment conducted at 292.67 ppm  $\text{CO}_2$ . The green (open) points show  
1030 the RMSE for this control run. Inventories are dimensionless (1 is control). For the  
1031 Atlantic-Pacific FWF 1 is equivalent to 0.32 Sv. The alkalinity and carbon inventory  
1032 experiments are very extreme and inconsistent with geologic evidence. All other  
1033 sensitivity test indicate a possible range from 0.195 to 0.205 for the slope of the  
1034  $\text{pH}/\delta^{13}\text{C}$  regression.

1035 Figure 7: The output from sensitivity analysis of the relationship between pH gradient  
1036 and  $\delta^{13}\text{C}$  gradient from the 13700 run CYCLOPS ensemble (see text for model  
1037 details). Panel (a) shows the mean gradient when the result from all 18 ocean boxes  
1038 are included in the regression. Panel (b) shows only the boxes from the low latitude  
1039 ocean from all basins and (c) shows the regression from only North Atlantic low  
1040 latitude boxes. Note the lower  $\Delta\text{pH}/\Delta\delta^{11}\text{B}$  slope at the lower latitudes due to the  
1041 effect of temperature.

1042 Figure 8: The pH gradient between surface and deep through time calculated from the  
1043  $\delta^{13}\text{C}$  gradient and using the whole ocean (blue) (panel (a) Fig. 7), low latitude (green)  
1044 (panel (b) Fig. 7) and low latitude North Atlantic only (red) (panel (c) Fig. 7) based  
1045 regressions from the CYCLOPS model.

1046 Figure 9: The calculated  $\delta^{11}\text{B}_{\text{sw}}$  from the benthic-planktic  $\delta^{11}\text{B}$  pairs assuming (a) a  
1047 pH gradient derived from (a) the modern pH (blue); (b)  $\delta^{13}\text{C}$  (red). The uncertainty  
1048 on each data point is determined using a Monte Carlo approach including

1049 uncertainties in temperature, salinity,  $\delta^{11}\text{B}$  and the pH gradient (see text for details)

1050 The line of best fit is the probability maximum of a LOWESS fit given the

1051 uncertainty in the calculated  $\delta^{11}\text{B}_{\text{sw}}$ . The darker shaded area highlights the 68%

1052 confidence interval and the lighter interval highlights the 95% confidence interval.

1053 The circles highlight the data points that were removed prior to LOWESS smoothing;

1054 (c) shows an expanded view of the smoothed curves for ease of comparison between

1055 the variable pH gradient from  $\delta^{13}\text{C}$  (red) and modern pH gradient (blue).

1056 Figure 10: a) The  $\delta^{11}\text{B}_{\text{sw}}$  curve calculated using the variable pH gradient derived

1057 from  $\delta^{13}\text{C}$ . The median (red line), 68% (dark red band) and 95% (light red band)

1058 confidence intervals are plotted. Plotted with a compilation of published  $\delta^{11}\text{B}_{\text{sw}}$

1059 records. Seawater composition reconstructed from foraminifera depth profiles (light

1060 blue squares and dark blue cross) from Pearson and Palmer (2000) and Foster et al.

1061 (2012) respectively, numerical modelling (dark green line), with additional green

1062 green lines shows  $\pm 1$  ‰ confidence interval (Lemarchand et al., 2002) and benthic

1063  $\delta^{11}\text{B}$  (purple diamonds and line) from Raitzsch and Hönisch (2013). All the published

1064  $\delta^{11}\text{B}_{\text{sw}}$  curves are adjusted so that at  $t=0$ , the isotopic composition is equal to the

1065 modern (39.61 ‰).

1066 Figure 11: a) The  $\delta^{11}\text{B}_{\text{sw}}$  curve calculated using the variable pH gradient derived

1067 from  $\delta^{13}\text{C}$  (the darker shaded area highlights the 68% confidence interval and the

1068 lighter interval highlights the 95% confidence interval),  $\delta^{26}\text{Mg}_{\text{sw}}$  record from Pogge

1069 von Strandmann et al. (2014) (error bars are  $\pm 0.28$  ‰ and include analytical

1070 uncertainty and scatter due to the spread in modern *O. universa* and the offset

1071 between the two analysed species),  $\delta^{44/40}\text{Ca}_{\text{sw}}$  record from Griffith et al. (2008) (error

1072 bars show  $2\sigma$  uncertainty) and  $\delta^7\text{Li}_{\text{sw}}$  record from Misra and Froelich (2012) (error

1073 bars show  $2\sigma$  uncertainty).

1074 Figure 12: Crossplots of the records of  $\delta^{11}\text{B}_{\text{sw}}$  using the variable pH gradient derived

1075 from  $\delta^{13}\text{C}$  (error bars show  $2\sigma$  uncertainty) with  $\delta^{44/40}\text{Ca}_{\text{sw}}$  from Griffith et al. (2008)

1076 (error bars show  $2\sigma$  uncertainty),  $\delta^7\text{Li}_{\text{sw}}$  from Misra and Froelich (2012) (error bars

1077 show  $2\sigma$  uncertainty) and  $\delta^{26}\text{Mg}_{\text{sw}}$  from Pogge von Strandmann et al. (2014) (error

1078 bars are  $\pm 0.28$  ‰ and include analytical uncertainty and scatter due to the spread in

1079 modern *O. universa* and the offset between the two analysed species). The colour of

1080 the data points highlights the age of the data points where red = modern and blue =  
1081 23 Ma.

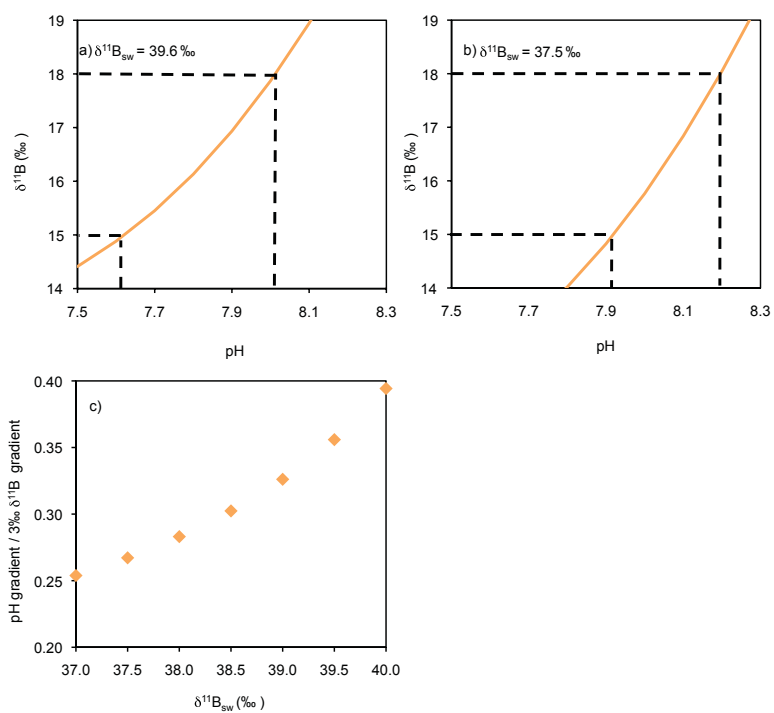

1082 Table 1: The average  $\delta^{11}\text{B}$ ,  $\delta^{26}\text{Mg}$ ,  $\delta^{44/40}\text{Ca}$  and  $\delta^7\text{Li}$  composition of major fluxes into  
1083 and out of the ocean. Colour coding reflects the relative importance of each the  
1084 processes (darker shading reflects greater importance). The colour coding for boron is  
1085 based on Lemarchand et al. (2002) and references therein, lithium from Misra and  
1086 Froelich (2012) and references therein, magnesium from Tipper et al. (2006b) and  
1087 calcium from Fantle and Tipper (2014) and Griffin et al. (2008) and references  
1088 therein. The isotopic ratio of each process is: (a) Lemarchand et al. (2002) and  
1089 references therein; b) Misra and Froelich (2012) and references therein; (c) Burton  
1090 and Vigier (2012); (d) Tipper et al. (2006b); e) Wombacher et al. (2011); f) includes  
1091 dolomitisation; g) removal through hydrothermal activity; h) Griffith et al. (2008); i)  
1092 Fantle and Tipper (2014) and references therein; j) dolomitisation may be an  
1093 important component of the carbonate flux. Modern  $\delta^{26}\text{Mg}_{\text{sw}}$  and  $\delta^{11}\text{B}_{\text{sw}}$  from Foster  
1094 et al. (2010),  $\delta^7\text{Li}_{\text{sw}}$  from Tomascak (2004). The  $\delta^{44/40}\text{Ca}$  presented here was  
1095 measured relative to seawater and hence seawater has a  $\delta^{44/40}\text{Ca}_{\text{sw}}$  of 0 permil by  
1096 definition.

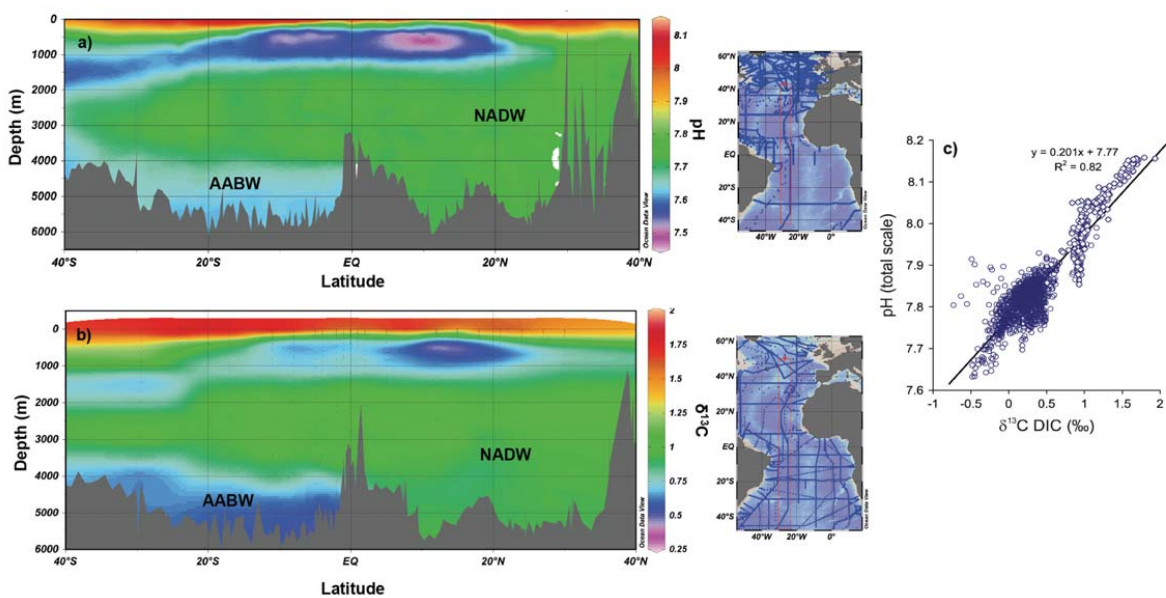

1097
