12

13 **Abstract**

14 Reconstruction of past changes in Arctic sea ice extent may be critical for understanding its future
15 evolution. Methanesulphonate (MSA) and bromine concentrations preserved in ice cores have both
16 been proposed as indicators of past sea ice conditions. In this study, two ice cores from central and NE
17 Greenland were analysed at sub-annual resolution for MSA (CH_3SO_3H) and bromine, covering the time
18 period 1750-2010. We examine correlations between ice core MSA and the HadISST1 ICE sea ice
19 dataset and consult back-trajectories to infer the likely source regions. A strong correlation between the
20 low frequency MSA and bromine records during preindustrial times indicates that both chemical species
21 are likely linked to processes occurring on or near sea ice in the same source regions. The positive
22 correlation between ice core MSA and bromine persists until the mid-20th century, when the acidity of
23 Greenland ice begins to increase markedly due to increased fossil fuel emissions. After that time, MSA
24 levels decrease as a result of declining sea ice extent but bromine levels increase. We consider several
25 possible explanations and ultimately suggest that increased acidity, specifically nitric acid, of snow on
26 sea ice stimulates the release of reactive Br from sea ice, resulting in increased transport and deposition
27 on the Greenland ice sheet.

28

29 **1 Introduction**

30 Atmospheric chemistry in the polar regions is strongly modulated by physical, chemical, and biological
31 processes occurring in and around sea ice. These include sea salt aerosol generation, biogenic emissions
32 of sulphur-containing gases and halogenated organics, and the photochemical/heterogeneous reactions
33 leading to release of volatile, reactive bromine species. The resulting chemical signals influence the
34 chemistry of the aerosol deposited on polar ice sheets. For this reason ice core measurements of sea salt
35 ions, methanesulphonate (MSA), and bromine have been examined as potential tracers for sea ice extent
36 (Abram et al., 2013; Spolaor et al., 2013b, 2016; Wolff et al., 2003). The interpretation of such tracers
37 is complicated by the fact that their source functions reflect changes in highly complex systems, and
38 signals are further modified by patterns of atmospheric transport and deposition.

39 MSA is produced by the atmospheric oxidation of DMS ($(CH_3)_2S$). DMS is produced throughout the
40 world's oceans as a breakdown product of the algal metabolite DMSP, $((CH_3)_2S^+CH_2CH_2COO^-)$.
41 DMS emissions are particularly strong in marginal sea ice zones (Sharma et al., 2012), and this source
42 is believed to be a dominant contributor to the MSA signal in polar ice (Curran and Jones, 2000). Ice
43 core MSA records have been used extensively in Antarctica as a proxy for local sea ice dynamics.
44 Although the specifics of the relationship are highly site-dependent (Abram et al., 2013; Curran et al.,
45 2003) MSA has been proven to be a reasonably good proxy for sea ice conditions (e.g., (Curran and
46 Jones, 2000)). In the Arctic, the relationship between MSA and sea ice conditions is less straightforward
47 due to the likelihood of multiple source regions with different sea ice conditions contributing to the ice
48 core archived MSA (Abram et al., 2013). Until now, a significant, but rather weak ($r = -0.37$)
49 relationship between ice core MSA and Arctic sea ice has only been established for a record from a
50 Svalbard ice core (O'Dwyer et al., 2000). In this study we analyse the direct correlations between the
51 MSA records from two Greenland ice core sites and the surrounding sea ice conditions in order to
52 demonstrate the utility of MSA as a local sea ice proxy.

53 In this study, all dissolved or suspended bromine species are measured (including organic bromine) and
54 shall be referred to as "bromine". The primary source of total inorganic bromine (e.g. Br_2 , Br^- , HBr)
55 in the marine boundary layer (MBL) is the ocean (Parrella et al., 2012; Sander et al., 2003). At
56 concentrations of less than 0.2% that of sodium (Na), bromide (Br^-) makes a small contribution to
57 ocean salinity. Br^- can be concentrated in the high latitude oceans when the sea water is frozen, since
58 the formation of the ice matrix exudes the sea-salts in the form of brine (Abbatt et al., 2012). Small, sea-
59 salt aerosol particles blown from the surface of sea ice are typically enriched with bromine (Sander et
60 al., 2003) and satellite imagery has revealed that plumes of bromine (as BrO) are photo-chemically

61 released from sea-ice zones in spring (Nghiem et al., 2012; Schönhardt et al., 2012; Wagner et al., 2001).
62 Recently, studies have begun to link ice core records of bromide enrichment (relative to sea water Na
63 concentrations) preserved in polar ice sheets to that of local sea ice conditions (Spolaor et al., 2013a,
64 2013b, 2014). Spolaor and co-workers demonstrated the spring-time Br^-/Na that is preserved in the
65 ice core is a record of bromine explosion events over adjacent seasonal sea ice. A Br^-/Na enrichment
66 would therefore indicate a larger seasonal sea ice extent or conversely a shorter distance between the
67 ice edge and the ice core site due to decreased multi-year sea ice (Spolaor et al., 2013a). However, like
68 MSA, it is likely that the bromine – sea-ice relationship in the Arctic is complicated by the myriad of
69 bromine source regions which influence an ice core record in addition to factors which influence the
70 degree of enrichment of the aerosol as it travels to the ice core site. In this study we compare ice core
71 records of bromine to those of MSA and other common MBL species in order to determine the influence
72 of sea ice conditions and other factors on bromine concentrations.

73 Here we present measurements of MSA, bromine, and elemental tracers of sea salt and crustal input in
74 two Greenland ice cores covering the time period 1750-2010 C.E.. These ice core records represent the
75 first continuous, sub-annual resolution records of bromine in polar ice to extend beyond the satellite era.
76 We examine the relationship between these two sea ice-modulated tracers, their relationship to
77 independent historical estimates of sea ice distribution, and the influence of industrialization on
78 atmospheric and ice core chemistry.

79 **2 Methods**

80 **2.1 Ice cores**

81 The 87 m ‘Summit-2010’ ice core was collected in 2010 close to Summit Station, Greenland (72°20'N
82 38°17'24"W). The average snow accumulation at Summit is ~ 0.22 m yr^{-1} water equivalent, with few
83 instances of melt. Due to the relatively high snow accumulation rate, seasonal analysis of the sea salt
84 species concentrations was feasible. The 213 m Tunu core was collected in 2013 (78° 2' 5.5"N, 33° 52'
85 48"W), approximately 3 km east of the Tunu-N automatic weather station, part of the Greenland Climate
86 Network. The average snow accumulation at Tunu is ~ 0.11 m yr^{-1} water equivalent. The Summit-2010
87 and Tunu cores were dated using well-known volcanic horizons in sulfur (S). The dating of Summit-
88 2010 was refined by annual layer counting using seasonal cycles in the ratio of non-sea salt S/Na (Sigl
89 et al., 2015).

90 2.2 Sampling and analysis

91 The ice cores were sampled from 33x33 mm cross-section sticks using a continuous melter system
92 (McConnell et al., 2002). The silicon carbide melter plate provides three streams from concentric square
93 regions of the ice core sample: an innermost stream (with a cross sectional area of 144 mm²), an
94 intermediate stream (340 mm²) and an outer stream that was discarded along with any contaminants
95 obtained from handling of the ice core. The innermost melt stream was directed to two inductively
96 coupled plasma-mass spectrometers (ICP-MS, Thermo Element II high resolution with PFA-ST
97 concentric Teflon nebulizer (ESI)) run in parallel. All calibrations and runtime standards were run on
98 both instruments and several elements were also measured in duplicate (Na, Ce, Pb) to ensure tracking
99 between both ICP-MS. In addition, an internal standard of yttrium flowed through the entire analytical
100 system and was used to observe any change in system sensitivity. The instrument measuring bromine
101 was run at low resolution to get the highest sensitivity and there were no mass interferences observed at
102 the bromine isotope mass monitored (79 amu). The sample stream was acidified to 1% HNO₃ to prevent
103 loss of less soluble species, degassed just prior to analysis to minimize mixing in the sample line and
104 sampled at a rate of 0.45 ml min⁻¹ (McConnell et al., 2002; Sigl et al., 2013). The following elements
105 were measured by ICP-MS: Br, Cl, Na, Ca, S, Ce, and Pb. Calibration of the ICP-MS was based on a
106 series of 7 mixed standards measured at the start and end of each day for all elements except for the
107 halides. Due to the high volatility of acid halides, a set of 4 bromine and chlorine standards were made
108 individually in a 1% UHP HNO₃ matrix from fresh, non-acidified intermediate stock solution (Inorganic
109 Ventures) every day. The intermediate melt stream was directed to a continuous flow analysis (CFA)
110 system on which nitrate ion (NO₃⁻) and snow acidity (sum of soluble acidic species) were measured
111 using the technique described by Pasteris (2012) in addition to other atmospheric species of interest
112 (Röthlisberger et al., 2000).

113 A portion of the debubbled CFA melt stream (150 µl min⁻¹) was subsampled using a peristaltic pump
114 for continuous on-line analysis of methanesulfonate by electrospray triple-quad mass spectrometer
115 (ESI/MS/MS; Thermo-Finnigan Quantum). This subsample was mixed with pure methanol (50 µl min⁻¹)
116 delivered using an M6 pump (VICI). The methanol was spiked with an internal standard of deuterated
117 MSA (CD₃SO₃⁻; Cambridge Isotopes) at a concentration of 52 nM. The isotope standard was calibrated
118 against non-deuterated MSA standards prepared in water from non-deuterated MSA (CH₃SO₃⁻; Sigma
119 Aldrich). MSA was detected in negative ion mode using the CH₃SO₃⁻/SO₃⁻ transition (m/z 95/80) and
120 CD₃SO₃⁻/SO₃⁻ (m/z 98/80). The concentration of MSA in the sample flow was determined from the ratio
121 of the non-deuterated and deuterated signals after minor blank corrections. The analysis of MSA by
122 batch analysis using ESI/MS/MS has been reported previously (Saltzman et al., 2006). This study is

123 the first use of the technique for ice core MSA analysis in a continuous, on-line mode. The uncertainty
 124 in the MSA intensity as calculated from the standard calibrations is 1%.

125 **2.3 Calculation of anthropogenic Pb, non sea-salt S, and Br enrichment**

126 The Pb derived from anthropogenic sources (exPb) was calculated as the difference between total lead
 127 and that from dust sources:

$$129 \quad \text{exPb} = [\text{Pb}]_{\text{obs}} - [\text{Ce}]_{\text{obs}} \times \left(\frac{[\text{Pb}]}{[\text{Ce}]} \right)_{\text{dust}}$$

128 (1)

130 Where the $([\text{Pb}]/[\text{Ce}])_{\text{dust}}$ mass ratio has the constant value of 0.20588 (Bowen, 1979).

131 Similarly the amount of non-sea salt sulphur (nssS) was calculated relative to the sea-salt sodium, ssNa:

$$136 \quad \text{nssS} = [\text{S}]_{\text{obs}} - [\text{ssNa}] \times \left(\frac{[\text{SO}_4^{2-}]}{[\text{Na}]} \right)_{\text{seawater}}$$

132 (2)

133 Where the $\left(\frac{[\text{SO}_4^{2-}]}{[\text{Na}]} \right)_{\text{seawater}}$ mass ratio has the constant value of 0.252 (Millero, 1974). ssNa was
 134 calculated by comparison with calcium as both have sea salt and dust origins (Röthlisberger et al., 2002):
 135

$$138 \quad \text{ssNa} = \frac{[\text{Na}_{\text{obs}} \times R_t - \text{Ca}_{\text{obs}}]}{[R_t - R_m]}$$

137 (3)

139 Where R_t and R_m are the Ca/Na mean crustal and mean marine mass ratios of 1.78 and 0.038,
 140 respectively, (Millero, 1974).

141 Bromine enrichment factors relative to sea water concentrations were calculated using the following:

$$143 \quad \text{Br}_{\text{enrich}} = \left(\frac{[\text{Br}]}{[\text{Na}]} \right)_{\text{obs}} / \left(\frac{[\text{Br}]}{[\text{Na}]} \right)_{\text{seawater}}$$

142 (4)

144 where the $([\text{Br}]/[\text{Na}])_{\text{seawater}}$ mass ratio is 0.00623 (Millero, 1974).

145 **2.4 Air mass- back trajectories**

146 To identify the likely sea ice source regions of MSA and Br deposited at the ice core sites, we perform
147 10 day air-mass back trajectories of boundary layer air masses from each ice core site using the GDAS1
148 archive dataset in the Hysplit4 software (Draxler and Hess, 1998). The starting height of the back
149 trajectories was 500 m to ensure that the monitored air masses travelled close enough to the surface at
150 the ice core site to potentially deposit aerosols. The vertical velocity field was taken from the
151 meteorological data files. Air mass back trajectories were started every 12 hours and allowed to travel
152 for 10 days (total number of trajectories hours = 14400 hours per month). The number of hours that the
153 trajectories spent in a 2°x2° degree grid was summed over all of the trajectories for that month between
154 the years 2005-2013. Previous work showed that the rapid advection of MBL air was the likely source
155 of reactive halogens at Summit (Sjostedt et al., 2007).

156 **2.5 Sea Ice Correlation mapping**

157 In order to assess the relationships between sea ice conditions and ice core chemistry, correlation maps
158 were generated between annual MSA concentrations and monthly sea ice using the HadISST1 ICE
159 dataset at 1° latitude-longitude monthly resolution (Rayner, 2003). Pre-1979 sea ice datasets were
160 interpolated from sea ice extent maps compiled by Walsh (1978) which incorporate a variety of
161 empirical observations. The data were later bias corrected using modern satellite data (Rayner, 2003).
162 Correlations were performed separately for the satellite period (1979-2012) and for the extended record
163 (1900-2012), excluding the period 1940-1952 when the record has no variability due to scarcity of data
164 (Rayner, 2003). Because strong DMS emissions occur in marginal sea ice zones (Sharma et al., 2012),
165 we considered both sea ice concentration (SIC) and the area of open water in the sea ice pack (OWIP)
166 which represents the size of the marginal sea ice zone. OWIP is defined as the difference between sea
167 ice area (calculated from sea ice concentration over the area of the grid cell) and sea ice extent (NSIDC).
168 A SIC of 15% was used as the threshold for a grid cell to contribute to sea ice extent. The area of OWIP
169 was calculated within the coastal areas as defined by the results of the air-mass back trajectories (Sect.
170 3.4).

171 Correlations were performed on an annual rather than seasonal basis because the seasonality of ice core
172 MSA is distorted due to post depositional migration of MSA signal at depth in the snow pack (Mulvaney
173 et al., 1992) (Fig. 3, S3). Outliers were removed from the MSA time series (see Fig. 2) before the
174 correlations were performed using the technique described by Sigl (2013) for identifying volcanic
175 signals using a 25 year running average filter.

176

177 **3 Results**

178 **3.1 Bromine**

179 Ice core measurements of bromine at Summit and Tunu covering the period 1750-2010 are shown in
180 Fig. 2. Ice core Br levels at each site were stable until ~1830 when they decreased by ~1 nM,
181 establishing a new baseline that was stable until the early 1900s. Both ice cores also show a Br peak in
182 the late 20th century. A summary of the timing of inflections and concentrations can be found Table S1.

183 Sea-salt transport onto the Greenland ice sheet occurs predominantly during winter. Historically the
184 winter-time sea-salt maximum was believed to be due to increased cyclonic activity over the open
185 oceans (Fischer and Wagenbach, 1996) though more contemporary studies show that blowing snow
186 from the surface of sea-ice may be a significant source (Rankin et al., 2002; Xu et al., 2013; Yang et al.,
187 2008, 2010). At Summit, a winter-time maximum is observed in the most abundant sea salts, Na and Cl
188 (Fig. 3). Bromine also shows a significant winter-time signal, however the annual maximum appears in
189 mid-summer - at concentrations ~70% above winter levels (Fig. 3a). Comparison with Br measured in
190 weekly surface snow samples collected from Summit (from 2007-2013; GEOSummit project) confirms
191 that this summer signal is real and not a result of post-depositional modification of seasonality of the
192 bromine signal (Fig. S1). The results from that study confirm that total Br concentrations peak in
193 summer on the ice sheet closely following the Br cycle observed in the Summit-2010 ice core. In
194 addition to the comparison with the Geosummit data, in the ice cores studied here there are routinely
195 more than 10 measurements made within a yearly layer of snow giving confidence to the allocation of
196 a summer maximum in bromine at Summit. Analysis of the annual cycle of bromine in the Tunu ice
197 core also shows a summer maximum when averaged over the entire ice core time series but with
198 significantly larger error than observed at Summit. The timing of this peak suggests a predominant
199 summer source of bromine that dwarfs that from winter sea salt sources.

200 The shape of the annual bromine cycle does change slightly over the course of the Summit record (see
201 Fig. 3). Starting in the early 1900s the annual bromine cycle slowly becomes broader. A slight shift in
202 the maximum from a solely summer peak in the preindustrial era towards a broad summer-spring peak
203 by 1970 is observed (Fig. 3 lower plot). Comparison with the sea salt tracer, sodium, which does not
204 undergo the large temporal shift and broadening of its seasonal cycle shows that this change in bromine
205 seasonality is not linked to changes in production or transport of sea-salt aerosols or even dating
206 uncertainties in the ice core but perhaps the introduction of an additional, smaller bromine source in the
207 spring-time during the industrial era.

208 Both ice cores show a predominantly positive Br enrichment throughout the year (Fig S2) relative to

209 both sea salt elements chlorine and sodium. This enrichment reaches a maximum in mid to late summer
210 at Summit (Fig 3). We assume that this enrichment reflects Br enrichment in the aerosol transporting
211 Br to the ice sheet. However, post-depositional reduction of the bromine concentration is a possibility
212 during the summer months due to photolytic processes at the snow surface. This may be the cause of
213 the noisiness of the bromine signal within the lower accumulation, Tunu core. However, the increased
214 snow accumulation that occurs during the summer months in both central and northern Greenland (Chen
215 et al., 1997) should act minimise these bromine depleting effects driven by increased insolation in
216 summer.

217 A summer time maximum in Br enrichment was also observed by Spolaor (2014) in a short segments
218 of Antarctic Law Dome ice core as well as two Arctic ice cores. Spolaor et al. believe that the main
219 source of the inorganic bromine originated from spring-time bromine explosion events above sea ice
220 and the summertime maximum could possibly be an indication of lag-time between bromine containing
221 particles becoming airborne and their deposition. Further investigation is needed to definitively establish
222 the seasonality of bromine deposition at the poles. However the results of the Arctic ice cores studied
223 here suggest that the summer maximum in bromine deposition is indeed real.

224 In the Tunu ice core, 2% of the monthly bromine enrichment measurements (relative to Cl) were
225 negative (less than the Br/Cl seawater ratio, Fig S2). In a comprehensive review of global aerosol Br
226 measurements, Sander (2003) concluded that in general, aerosols which showed positive Br enrichment
227 factors were of sub-micrometer size. These small aerosols can travel further (lifetimes of around 5-10
228 days) and due to their larger surface/volume ratio may experience more atmospheric processing than
229 larger aerosols, resulting in the positive enrichment. It is possible that the negative enrichment values
230 observed in the Tunu ice core are therefore a result of larger aerosols (> micrometer) reaching the site
231 due to its proximity to the coast (and thus the likely sea ice aerosol source region) in comparison to
232 Summit.

233 **3.2 MSA**

234 The Summit-2010 MSA record (Fig. 2) replicates that measured by Legrand in 1993 (Legrand et al.,
235 1997) and extends it an additional 17 years. The Tunu measurements represent the first MSA profile at
236 this location. At Summit, MSA concentrations averaged 48 nM in the late 18th century, compared with
237 just 27 nM at Tunu. From 1878-1930 MSA concentrations at Summit plateaued at 36 nM after which
238 they began to drop rapidly, at a rate of 0.27 nM/year, reaching 18 nM by 2000. Large fluctuations in
239 the MSA record after this time make it difficult to assess the most recent trend in Summit MSA
240 concentrations. MSA concentrations in the Tunu core showed a similar variability to those in the

241 Summit record, and until the mid-20th century, were consistently lower in magnitude. MSA
242 concentrations only began to decline consistently at Tunu after 1984, almost 50 years after the rapid
243 decline observed in the Summit record. After 2000, large fluctuations in concentration were again
244 observed making the modern-day trend in MSA concentration at Tunu difficult to establish.

245 Comparison with the total sulfur record (Fig. 4) reveals that during the preindustrial period, MSA
246 contributes to ~12% and ~7% of the total sulfur signal at Summit and Tunu, respectively, compared
247 with <2% at the height of industrial period (1970 C.E.) at both sites.

248 The low frequency, preindustrial trend in MSA concentrations seen in these ice core records closely
249 follows that of bromine; particularly distinct is the decrease in both MSA and bromine at both sites in
250 the early 1800s (Tables S1 and S2). In the early 1900s, however, both sites show a divergence between
251 the MSA and Br records—as MSA begins to decline, Br concentrations increase.

252 A dramatic shift in the ‘timing’ of the annual MSA maximum in Summit-2010 ice core is illustrated in
253 Figs. 3c and S3. The signal shifts gradually and continuously along the length of the the entire Summit-
254 2010 record from a spring to winter maximum (Fig. S3). This phenomenon has previously been
255 observed in several Antarctic ice cores and has been attributed to post-depositional migration within the
256 ice due to salt gradients (Mulvaney et al., 1992; Weller, 2004).

257 3.3 Acidic Species

258 In winter, with the collapse of the polar vortex, polluted air masses enter the Arctic region as the
259 phenomenon known as the Arctic haze (Barrie et al., 1981; Li and Barrie, 1993). SO_2 and NO_x from the
260 haze are deposited on the ice/snow and oxidised to sulphuric (H_2SO_4) and nitric acid (HNO_3). There are
261 also natural sources of SO_2 (biomass burning, volcanic eruptions, oceans (Li and Barrie, 1993;
262 McConnell et al., 2007; Sigl et al., 2013) and NO_x (microbial activity in soils, biomass burning, lightning
263 discharges (Vestreng et al., 2009) as well as other snow/ice acidifiers including MSA, hydrogen chloride
264 and organic acids released from biogenic or biomass burning sources (Pasteris et al., 2012).

265 Total snow acidity was stable at both sites from 1750 through to ~1900 except for sporadic, short-lived
266 spikes due to volcanic eruptions. The average preindustrial acidity was the same at both sites (~1.8 μM).
267 Both records also show two distinct maxima in acidity centred on 1920 and 1970 (Fig. 4) with Tunu
268 displaying higher acidity than Summit over the entire industrial period. Overlaid with the acidity is the
269 total sulphur (S) record for both ice cores. The high correlation between the acidity and S records
270 illustrates that the sulphur species are the dominant natural and anthropogenic acidic species in the ice
271 cores. The trend in acidity closely follows the global SO_2 emissions with maxima from coal (~1920)
272 and fossil fuel combustion (~1970), respectively (Smith et al., 2011). After 1970 the records of acidity

273 and S deviate. This deviation can be attributed to the presence of nitric acid that remains at a relatively
274 high concentration in the late 20th century whilst sulphur species reduce in concentration (Fig. 4).

275 NO_3^- concentrations show no trend during the preindustrial era in either ice core records, averaging
276 $1.1(\pm 0.02)$ μM and $1.3(\pm 0.03)$ μM for Summit and Tunu, respectively. The higher signal-to-noise ratio
277 in the Summit-2010 record reveals a small peak in NO_3^- concentrations centred on ~ 1910 . The Tunu
278 record also shows elevated NO_3^- concentrations over this period. However the large variability in the
279 signal makes it difficult to establish a higher resolution temporal trend. Both records clearly show a
280 large increase in NO_3^- after 1950, peaking in ~ 1990 and followed by a general decreasing trend with the
281 average until 2010 C.E. NO_3^- levels still double that of preindustrial concentrations: $2.1\mu\text{M}$ and $2.3\mu\text{M}$
282 at Summit and Tunu, respectively.

283 The nitrate records from both sites follow the trend in northern hemisphere NO_x emissions with a peak
284 in ~ 1910 and 1990 C.E.– a result of emissions from increases in both Northern Hemisphere fertilizer
285 usage and biomass and fossil fuel combustion (Felix and Elliott, 2013).

286 3.4 Air mass back trajectories

287 Air mass back trajectory results demonstrate that air masses reaching the Summit-2010 site between
288 March and July originate primarily from the South/South-East of the ice core site (Fig. 5a). Previous
289 back trajectory analyses by Kahl *et al.* (1997) also linked individual spikes in their Summit MSA record
290 to air masses that had passed over this same region of coast (SE Greenland) within the previous 1-3
291 days. Similar back trajectories were calculated for Summit-2010 at heights of 500 and 10,000m (Fig. 5a,
292 S4a) illustrating that air masses that travel in the free troposphere and lower troposphere follow similar
293 back trajectories and likely share the same source regions.

294 The results for Tunu indicate that air masses arrive primarily from the west coast of Greenland, passing
295 over the Baffin Bay area, but there is also significant contribution from both the SE and NE (in May)
296 coastal areas (Fig. 6b, S4b). Of these two secondary areas it is likely that aerosols transported from the
297 NE would have a greater influence on the ice core concentrations due to proximity to the ice core site.
298 Aerosol deposited at Tunu therefore represents a mixture of source regions, but are likely dominated by
299 the NW Greenland, Baffin Bay coastal region.

300 3.5 MSA - Sea Ice correlations

301 Locations which showed a sea ice concentration (SIC) variability greater than 10% (the average
302 estimated range of uncertainty in the satellite measurements) and have a significant correlation to MSA
303 (t-test, $p < 0.05$) are displayed in Fig. 6 and 7. A greater weight must be placed on the post-1979 sea ice

304 concentration maps (Fig. 6b, Fig. 7b) as these were derived from passive microwave satellite data and,
305 where available, operational ice chart data. The likely air-mass source regions, as defined by the results
306 of the air-mass back trajectories, are indicated by the black bordered regions in Figs. 6 and 7. Within
307 these areas there is generally a negative correlation between SIC and MSA, particularly in the spring
308 months. The large areas of positive correlation along the east coast and in the western Barents Sea are
309 striking, however, these areas are outside of the defined air-mass source region and thus are unlikely to
310 be contributing to the ice core aerosol records. The positive correlation is likely an artefact of the
311 negative autocorrelation between sea ice conditions in this region and the SE coast source region (Fig.
312 S5).

313 Over the period 1900–2010 C.E. highly significant correlation (t-test, $p < 0.001$) is found between the
314 annual ice core MSA and the amount of open water in the ice pack (OWIP, representing the area of the
315 marginal sea ice zone, Fig. 6a, Fig. 7a) in these aerosol source areas. For both ice cores the source region
316 OWIP is stable until ~1970, when it begins to decline; a trend followed by the MSA. Over the shorter,
317 satellite era (1979–2010), both the Summit-2010 and Tunu sites show strongest correlation between
318 annual MSA and OWIP in March – when the break-up of the winter sea ice begins ($r = 0.33$, $p < 0.1$; r
319 $= 0.37$, $p < 0.05$, Fig. 7b, Fig. 8b). The significance of the Tunu correlation over this period can be
320 dramatically increased ($r = 0.58$; $p < 0.001$), if the closer, secondary source region (NE Greenland) is
321 assumed to also influence the site (not shown).

322 3.6 MSA and bromine relationship

323 In an era where climate is driven by only natural forcings, chemical species that share a common source
324 should show broadly consistent variability. This is evident in the preindustrial section of both ice core
325 records where the relationship between MSA and Br (monitored as Br/MSA) remains constant over the
326 entire period (Fig. 4) despite individual records going through step function changes. Using a 25 year
327 running average on all records, the correlation between MSA and Br over the preindustrial period was
328 calculated as: Summit-2010: $r = 0.282$ ($p = 0.0008$); Tunu: $r = 0.298$ ($p = 0.0004$), $n = 138$. After ~1930,
329 relative increases in Br concentrations cause the Br/MSA ratio to increase above the stable preindustrial
330 levels by more than 160%, reaching a peak in ~2000 C.E. at both sites.

331 Bromine in excess of what is expected from a purely sea ice source (exBr) was calculated by comparison
332 to the other sea ice proxy, MSA. A linear regression of Br versus MSA was performed with the
333 preindustrial data to establish the relationship between the two proxies during an era free of
334 anthropogenic forcing. This relationship was then extrapolated into the period after 1850 C.E. in order
335 to estimate the amount of bromine sourced only from sea-ice sources during the industrial era. The MSA

336 record was smoothed with a 264 point Stineman function before being used in the extrapolation to
337 reduce the noise in the resultant record whilst maintaining the low frequency trends. exBr is thus the
338 difference between the total bromine measured and the calculated, natural sea ice bromine (in contrast
339 to Br_{exc} defined by Spolaor (2016) as the amount of bromine in excess of the Br/Na seawater ratio).

340 An estimate of the amount of bromine measured in excess of what is expected from a purely sea ice
341 source (exBr) is shown in Fig. 8. By definition, exBr is constant during the preindustrial period, but
342 during the industrial period exBr peaks, reaching a broad maximum between 1980-2000 C.E. of ~ 2 nM
343 and 5nM at Summit and Tunu, respectively.

344 **4 Discussion**

345 The significant correlation between variability of marginal sea ice zone (OWIP) area within the
346 identified source regions and the MSA records suggests that MSA records can be used as a proxy for
347 modern sea ice conditions in these areas. Assuming that no major changes in atmospheric circulation
348 patterns occurred to change the source regions for the marine aerosols between the preindustrial and
349 industrial periods, our identification of MSA as a sea ice proxy (specifically a marginal sea ice zone
350 proxy) may be valid for time periods both before and after 1850 at each ice core site. One major Northern
351 Hemisphere climate phenomena is the North Atlantic Oscillation (NAO). NAO proxy records
352 developed in Greenland ice core records (Appenzeller et al., 1998) suggest that although the NAO has
353 shown variability over the past 200 years, its effect is damped in Northern Greenland (Appenzeller et
354 al., 1998; Weißbach et al., 2015).

355 The MSA records reveal that after 1820 a gradual decline in sea ice occurred along the southern
356 Greenland coast (reflected in the Summit-2010 core) and that this decline in sea ice did not extend
357 significantly to the most northern Greenland coastline (reflected in the minimal change in Tunu MSA
358 during this period). It is not unexpected that the Summit-2010 record would show the most dramatic
359 changes in sea ice since we have demonstrated that the Summit sea ice proxy (MSA) is sourced from
360 the south-east Greenland coast – an area sensitive to climate changes as it is primarily covered by young,
361 fragile sea ice. The timing of the sea ice decline is coincident with the end of the Little Ice Age, identified
362 from $\delta^{18}O$ ice core records as spanning the period 1420-1850 A.D. in Greenland (Weißbach et al., 2015).
363 The dramatic dip in sea ice reflected in both the Tunu MSA and Br records at 1830 A.D. (and also seen
364 less dramatically in Summit) also appears in the multi-proxy reconstruction of sea ice extent in the
365 Western Nordic Seas performed by Macias Fauria et. al. (2010). This may be evidence of a sea ice
366 decline event isolated to the east Greenland coast as the ice core records do not replicate the dramatic,
367 early 20th century fluctuations observed in the latter part of the Western Nordic Seas reconstruction.

368 From the ice core records it appears that the greatest decline in Greenland sea ice began in the mid 20th
369 century, dropping to levels that are unprecedented in the last 200 years. This decline is observed along
370 the entirety of the Greenland coast. Sea ice declined first around the southern coast (from 1930 A.D.,
371 reflected in Summit-2010) followed 54 years later by the more northern coastline (reflected in the Tunu
372 record, see infection timings in Table S1). This sea ice decline is coincident with the sustained increase
373 in greenhouse gases which has been identified as the major climate forcing and driver of increased
374 global temperatures during the 20th century (Mann et al., 1998) and follows the same general trend in
375 Arctic wide sea ice extent observed by Kinnard (2008).

376 Bromine has also been suggested as a possible proxy for sea ice conditions, however the timing of the
377 largest bromine aerosol flux, in summer, does not coincide with the largest growth or extent of new sea
378 ice. Sea ice begins to increase only at the end of summer as the fractures in the ice cover are re-laminated
379 and the ice edge begins to advance southward (see Fig. 3f).

380 So what is the summer-time source of bromine? What is the cause of the increase in spring-time bromine
381 explosion events in the industrial era? (see Fig. 3, lower panel) and why does the bromine record deviate
382 from the sea ice proxy record (MSA) around the same time? Possible sources of bromine and the factors
383 which may effect the resultant bromine flux are discussed below.

384 **4.1 Alternate sources of bromine**

385 **4.1.1 Combustion of coal**

386 Bromine is present in coal (Bowen, 1979; Sturges and Harrison, 1986) and coal burning is therefore a
387 potential source of increased bromine deposition on the Greenland ice sheet over the period 1860-1940
388 (McConnell and Edwards, 2008). McConnell et al. (2008; 2007) demonstrated that pollution from the
389 Northern American coal burning era was deposited all over Greenland leaving as its fingerprint large
390 amounts of black carbon and toxic heavy metals. Sturges (1986) measured the relative concentrations
391 of Br and Pb in particulates emitted from the stacks of coal fired power stations and found a molar ratio
392 (Br:Pb) ranging between 0.36-0.67:1. Figure 8 illustrates that at both Summit and Tunu the exPb (lead
393 not from dust sources) preserved in the ice cores over the coal burning era was less than 1nM. This
394 concentration implies that the upper limit to the amount of bromine deposited from coal combustion
395 would be 0.67nM (assuming no loss of bromine from the particulates during transportation). This is an
396 insignificant amount compared to the total Br signal preserved in the ice at this time. Coal combustion
397 is not the major cause of the elevated industrial Br concentration.

398 4.1.2 Leaded Gasoline

399 The largest historical, anthropogenic source of bromine is thought to be the combustion of leaded
400 gasoline. Large quantities of 1,2, diethyl bromide (DEB) were added to leaded fuel as a scavenger for
401 Pb preventing lead oxide deposition by converting it to volatile lead bromide salts as well as CH_3Br
402 (Oudijk, 2010;Nriagu, 1990;Berg et al., 1983). In 1925 gasoline had a Br:Pb molar ratio of 2:1 in a
403 formulation which is now called “aviation fluid”. The Br:Pb molar ratio was reduced to 1:1 in the 1940s
404 except in places such as the Soviet Union which continued to use “aviation fluid” for motor gasoline
405 (Thomas et al., 1997). Although the consumption of leaded gasoline has been well documented,
406 particularly in North America, the estimates of the emissions of bromine compounds from the
407 combustion process are still unclear. Estimates of the amount of DEB that is converted into gaseous
408 CH_3Br range from 0.1% to 25% (Bertram and Kolowich, 2000) and direct measurements of exhaust
409 fumes across NW England found a Br:Pb ratio of between (0.65-0.8):1 in the airborne particulates
410 (Sturges and Harrison, 1986).

411 The ratio of Br:Pb in the gasoline formulae can therefore be used only as an upper limit to predict the
412 Br:Pb ratio in gasoline combustion aerosols transported to the ice core sites. Figure 8 shows a
413 comparison between exBr and exPb measured in each ice core. Also illustrated is the upper limit of the
414 amount of bromine expected from gasoline sources assuming the 2:1 Br:Pb ratio for aviation gasoline
415 over the whole leaded gasoline era (blue) and just between 1925 and 1940 (green; representing source
416 regions outside the Soviet Union). World-wide leaded gasoline emissions were estimated to have peaked
417 in 1970 (Thomas et al., 1997)—an assumption that is supported by the observed timing of the exPb
418 maximum observed in both ice cores. Whilst it is likely that leaded fuel contributed to the increased
419 bromine observed between 1925 and 1970, it is clear that it was not the only contributor to the exBr
420 record, particularly after 1970 when the exBr record continues to rise despite a worldwide decline in
421 leaded fuel consumption. The disparity between the exPb and exBr records suggesting the driving force
422 for the enhanced emission of Br was still active and increasing after 1970.

423 4.1.3 Seasonal salinity changes

424 Younger sea ice surfaces such as frost flowers, new and 1st year sea ice have a higher salinity and thus
425 have higher bromine concentrations than older sea ice surfaces (Hunke et al., 2011). The salinity of sea
426 ice is at its maximum at the start of the winter season after which surface salinity slowly diminishes due
427 to gravitational draining (Hunke et al., 2011). As summer approaches, ice continues to undergo
428 desalination due to melting of surface snow which percolates through the ice (Hunke et al., 2011).
429 Satellite observations that the BrO flux from the sea ice declines over summer (despite increasing

insolation) is likely due to the combined reduction in young sea ice area and in ice salinity. Ocean surface salinity decreases in the summer due to the increased meteoric water flux and melting of desalinated sea ice. Salinity increases are therefore unlikely to be the cause of the exBr flux observed in the ice core records and the observed summer maximum in bromine.

4.1.4 Organic bromine species

Gaseous bromocarbons can be a source of inorganic bromine to the snow pack when they react with $\cdot\text{OH}$ or to a lesser extent with $\cdot\text{NO}_x$ or by photolysis (Kerkweg et al., 2008; WMO, 1995) to form the less reactive, species HBr , BrNO_3 and HOBr . These species can then be washed out of the atmosphere and deposited on the snow surface due to their high solubility (Fan and Jacob, 1992; Sander et al., 1999; Yung et al., 1980).

The predominant source of gaseous bromine in the atmosphere is methyl bromide, CH_3Br (WMO, 2002). The major modern sources of CH_3Br are fumigation, biomass burning, leaded fuel combustion, coastal marshes, wetlands, rapeseed and the oceans (WMO, 2002). The ocean is also a major sink for CH_3Br , the temperature sensitive dissolution occurring through hydrolysis and chloride ion substitution to form bromide (WMO, 1995). ~30% of CH_3Br was from industrial emissions at the time of the global peak in the CH_3Br mixing ratio (1996-1998) (Montzka and Reimann, 2010). The timing of the massive increases in inorganic bromine seen at both ice cores sites coincides with the timing of maximum anthropogenic emissions of CH_3Br . However, the estimated 2.7 ppt increase in global tropospheric CH_3Br above preindustrial levels equates to only ~ 3.7 ppt (0.05nM) Br incorporated into the snow pack (assuming 100% conversion efficiency of CH_3Br in soluble Br species). This level is far less than the 2-5 nM increase in exBr observed in the ice cores during the industrial period.

Bromoform (CHBr_3) is emitted from vegetation such as marine phytoplankton and seaweed. It has the largest globe flux of all the bromocarbons (estimated at almost 5 times that of CH_3Br (Kerkweg et al., 2008). However, it is very short-lived (atmospheric lifetime of ~ 17 days (Ordóñez et al., 2012) and thus is confined to the marine boundary layer. Inorganic bromine formed from the destruction of CHBr_3 would therefore be representative of only local sources of organic bromine. The biological seasonal cycle maximises the production of CHBr_3 in summer and concentrations are greatly reduced but not negligible in winter (tidal forcing also influences bromocarbon emission by allowing coastal algae to dry-out (Kerkweg et al., 2008). The summer maximum in inorganic bromine at Summit (Fig. 3a) suggests that a biogenic source of bromine is dominant. However to-date biogenic sources have been considered insignificant in the Arctic marine boundary layer compared with the inorganic bromine source from sea salts (Simpson et al., 2007). These results suggest that a biogenic system should be

162 reconsidered as a major source of the natural inorganic bromine flux to the polar regions.

163 **4.2 Cause of the spring-time increase in bromine flux**

164 **4.2.1 Bromine explosion events**

165 Spring is the time of ‘bromine explosion’ events above sea ice. Sea salt aerosols passing through these
166 BrO plumes can become enriched with bromine by adsorbing the gaseous species (Fan and Jacob, 1992;
167 Langendörfer et al., 1999; Lehrer et al., 1997; Moldanová and Ljungström, 2001; Sander et al., 2003).
168 Nghiem (2012) showed that these bromine rich air masses can then be elevated above the planetary
169 boundary layer and transported hundreds of kilometres inland. Increasing the frequency and duration of
170 the bromine explosion events would therefore likely increase the amount of bromine delivered to the
171 ice core sites during spring without influencing the total aerosol flux.

172 Spring-time field studies at Ny Ålesund, Svalbard have shown positive correlation between atmospheric
173 filterable bromine species and elevated levels of sulphate and nitrate (Langendörfer et al., 1999; Lehrer
174 et al., 1997) suggesting that acidic, anthropogenic pollution may be the driver of the observed increases
175 in annual bromine enrichment during the industrial period.

176 **4.2.2 Acidity effects on debromination**

177 In remote, relatively clean environments such as the Arctic, even small increases in acidity are thought
178 to affect the cycling of bromine in the snow pack (Finlayson-Pitts, 2003; Pratt et al., 2013; Sander et al.,
179 1999). In the laboratory, increasing the acidity of frozen (Abbatt et al., 2010) and liquid salt solutions
180 (Frinak and Abbatt, 2006; George and Anastasio, 2007) increased the yield of gas-phase Br_2 whilst at
181 the same increasing the *solubility* of other bromine species, such as HBr . The uptake efficiency of HBr
182 by acidic sulphate aerosols, for example, is estimated at 80% compared to 30% for sea salt aerosols
183 (Parrella et al., 2012). Interestingly, Abbatt (1995) demonstrated that HBr is more than 100 times more
184 soluble in super-cooled sulphuric acid solutions than HCl . This may explain the cause of bromine
185 enrichment in the aerosol measured in the ice cores relative to the more abundant chlorine (Fig. S2).
186 The results of both the laboratory and field studies suggest that increasing snow/ice acidity in the Arctic
187 will likely enhance spring-time bromine explosion events above the sea ice whilst the increase in
188 solubility allows the termination products of the explosion to be transported away from the sites on the
189 surface of acidic aerosols. Increasing spring-time bromine aerosol concentrations would increase the
190 average annual bromine concentrations deposited on the ice sheet and could explain the exBr records
191 observed in both ice cores.

492 Figure 9 illustrates that of the two dominant acidic species preserved in the ice, HNO_3 (represented by
493 nitrate) shows the highest correlation to total bromine over sub-decadal time scales at both ice core sites.
494 Records were detrended with an 11 year running average before comparison to isolate the high
495 frequency components of each record. The bromine – sulfuric acid (represented by sulfate) correlation
496 is not significant. This is primarily because there is no bromine response to the dominant volcanic
497 sulphate spikes throughout the record. The large spikes in sulfate concentrations did not cause a
498 depletion of bromine in the snowpack (Figure 9). This result might be expected if the increased acidity
499 caused more bromine to volatilize. These results suggest that HNO_3 is the most influential of the MBL
500 acidic species in the processing and transport of Br on aerosols in the MBL.

501 4.2.3 NO_x and links to bromine

502 The snow and atmospheric chemistries of bromine and nitrate (NO_3^-) are tightly linked. NO_3^- is one of
503 the main sources of the •OH radical. The •OH radical can oxidize bromide salts and cause the release
504 of gas-phase bromine species (Abbatt et al., 2010; Chu and Anastasio, 2005; George and Anastasio,
505 2007; Jacobi et al., 2014). Morin (2008) observed that the majority of nitrate that is deposited to the
506 snow surface is of the form $BrNO_3$ in the coastal Arctic boundary layer. $BrNO_3$ forms by gas-phase
507 reaction of BrO and NO_2 . $BrNO_3$ is quickly adsorbed back onto the snow and aerosol surfaces due to
508 its high solubility. The heterogeneous hydrolysis of $BrNO_3$ to again release bromine species back into
509 the gas-phase has also been observed (Parrella et al., 2012) and can occur both during sunlight hours as
510 well as in the dark (Sander et al., 1999). NO_x are intertwined with Br as it cycles between the gas and
511 condensed phases.

512 The seasonality of the NO_3^- signal preserved in the ice cores is coherent with Br, showing a summer-
513 time maximum (Fig. 3a,d). The slight shift in timing of the industrial nitrate seasonal maximum towards
514 spring is replicated in the seasonal bromine signal preserved in the ice (Figure 3). The high correlation
515 between the preindustrial (1750-1850) NO_3^- and Br records (Fig. 9) supports this observation of co-
516 transport and sink of Br and NO_3^- into the snow pack, though the natural sources of each are distinctly
517 different.

518 In the industrial era the low frequency temporal profile of the bromine (Fig. 2) and nitrate records (Fig.
519 4) differ dramatically, apparently questioning the tight relationship observed before 1850. However, the
520 positive correlation between the nitrate and the Br/MSA records is striking at both sites. The large
521 relative increase in bromine (compared with MSA) during the era of high NO_x pollution may point to a
522 non-sea ice source of bromine linked to nitrate emissions.

523 Bromine and NO_x species shared a common source in the 20th century through the combustion of leaded

524 gasoline (Sect. 4.1.2). As discussed above, we observe that leaded fuel pollution reaching the Arctic
525 began to decline after 1970 in-line with reduced global consumption, but the amount of bromine in-
526 excess of natural sources (exBr, Fig. 8) continued to increase – following the trends in NO_x pollution
527 (Fig. 4). The continued increase in NO_x despite the decline in leaded fuel combustion is attributed
528 primarily to biomass burning, soil emissions and unleaded fossil fuel combustion (Lamarque et al.,
529 2013). As the leaded fuel source of bromine began to decline, organic bromine pollutants continued to
530 increase, as was discussed in Sect. 4.1.4. This can only account for a small fraction of the observed Br.
531 The continued correlation between nitrate and exBr despite the decoupling of nitrate and bromine
532 anthropogenic sources after 1970, suggests that nitrate pollution is likely influencing the processing of
533 local, natural sources of bromine in the polar MBL, in effect increasing the mobility of the bromine and
534 thus its flux onto the ice sheet.

535 **4.2.4 Consequences of nitrate driven increased bromine mobility in the Arctic**

536 Plumes of BrO emitted from sea ice regions have been linked to mercury deposition events which lead
537 to an increase in the bioavailability of toxic mercury species in polar waters (Parrella et al., 2012).
538 Increased spring-time mobilization of bromine from the sea ice induced by anthropogenic nitrate could
539 therefore increase the frequency and duration of these events and thus the mercury toxicity of the oceans.
540 Increased atmospheric bromine concentrations would also increase the frequency of ozone depletion
541 events (Simpson et al., 2007) thereby altering the oxidative chemistry of the polar MBL.

542 Whilst several studies have begun to explore bromine records from ice cores as a proxy for past sea ice
543 conditions, the results of this study demonstrate that in an era of massive increases in atmospheric acidity
544 the natural relationship between bromine and sea ice conditions can become distorted, precluding it
545 from being an effective modern-day Arctic sea ice proxy.

546

547 **5 Conclusion**

548 In this study we have shown that high resolution MSA measurements preserved in ice cores can be used
549 as a proxy for sea ice conditions (specifically the size of the marginal sea ice zone) along specific
550 sections of the Greenland coast. The MSA records show that sea ice began to decline at the end of the
551 LIA and again, more dramatically during the Industrial period. Also, unsurprisingly, the changes in sea
552 ice conditions in the northern sites have been less dramatic than along the southern coastline.
553 Comparison between the 260 year records of bromine and MSA presented in this study allow us to show
554 that in the preindustrial era bromine concentrations preserved in the Greenland ice sheet are also likely
555 linked to the local sea ice conditions. With the decline of sea ice in the modern era and the dramatic

556 increase in acidic pollutants reaching the Arctic the sea ice-bromine connection is distorted, precluding
557 it from being an effective, direct sea ice proxy during the industrial era. The introduction of NO_x
558 pollution in particular, into the clean Arctic environment promotes mobilization of bromine from the
559 sea ice, which in turn increases the bromine enrichment of the sea salt aerosols, forcing more bromine
560 inland (particularly in spring) than would occur naturally. Whilst Northern Hemisphere pollution may
561 prevent bromine from being an effective modern-day sea ice proxy in the Arctic, in Antarctica the
562 anthropogenic flux of nitrate species is thought to be small in comparison with natural sources (Wolff,
563 2013), leaving room for the possibility that bromine may still be an effective proxy for local Antarctic
564 sea ice conditions.

311 **Figure 1.** Locations of ice cores used in this study. Summit-2010: (72°20'N 38°17'24"W), Tunu: (78°
312 2' 5.5"N, 33° 52' 48"W)

313

314

315

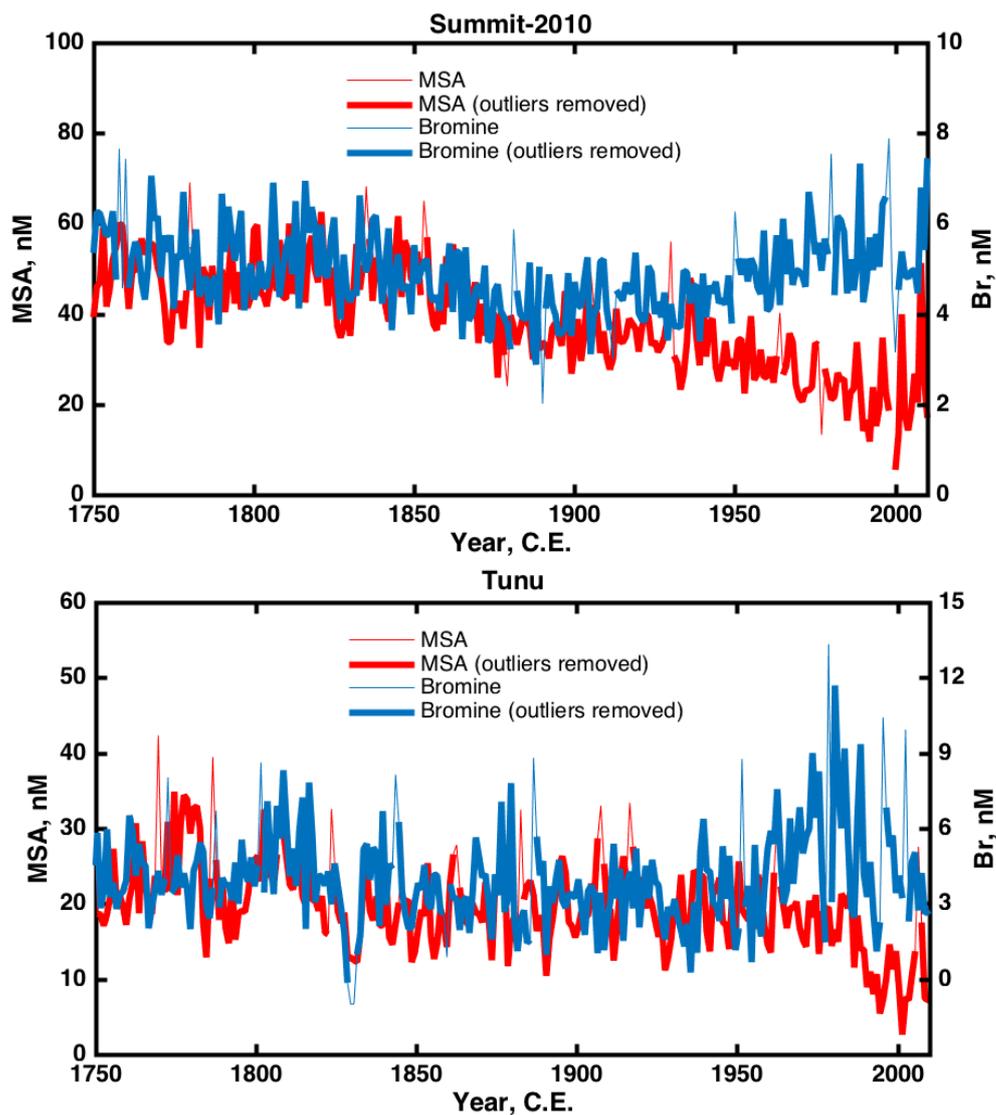

316

317

318

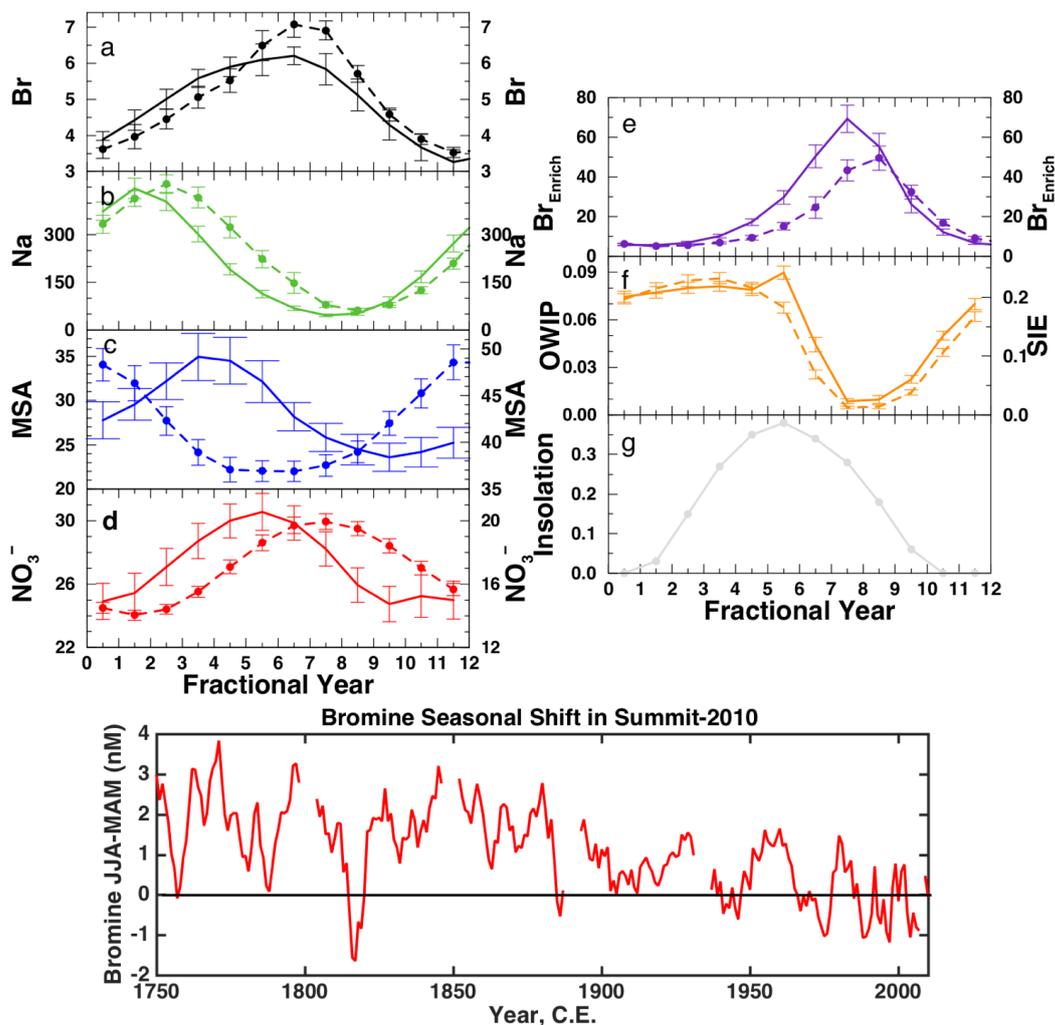

319

320

321

322 **Figure 2.** Annual record of bromine (thin blue) and MSA (thin red). Annual record of bromine (thick
323 blue) and MSA (thick red) with outlying spikes removed using a 25 year running average filter described
324 by Sigl et al. (2013). All records were fit with a 3 step linear regression and the results of the fits which
325 identify the timing of inflection points are summarized in Table S1.

326

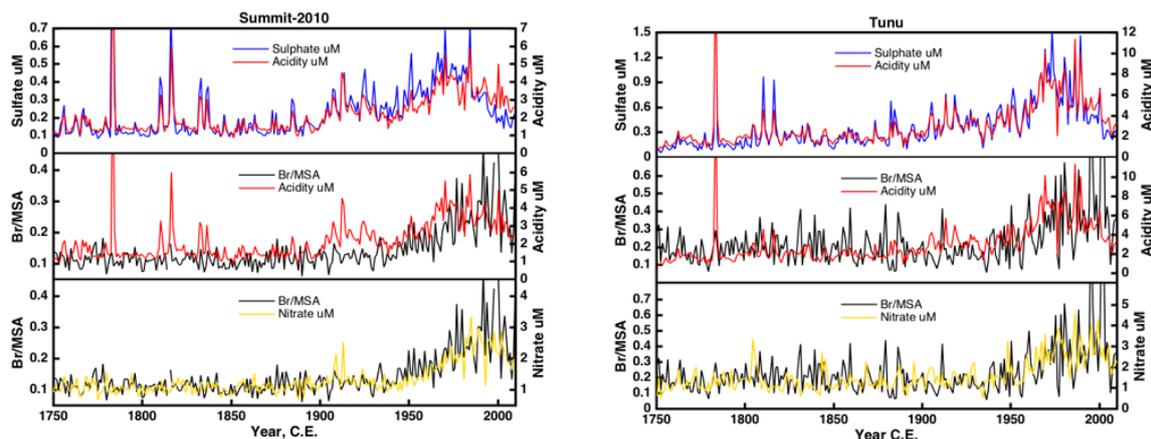

327 **Figure 3.** Upper plots: Average seasonal cycle of species in the Summit-2010 ice core. The left-hand Y
 328 axes are associated with the solid lines, and the right-hand Y axes associated with the dashed lines.
 329 Dashed lines (a-e): Average seasonal cycle from depths 43.5 – 87.3 m (years 1742-1900). Solid lines
 330 (a-e): Average seasonal cycle from 0-43.5 m (years 1900-2010). Error bars indicate the standard error
 331 of the monthly value. (a) Total bromine, (b) total sodium, (c) MSA, (d) nitrate. Units for (a-d) are nM.
 332 Note that the seasonal cycle in bromine appears to broaden in the 1900-2010 period (see lower panel).
 333 Note also that the MSA maximum shifts from spring in the shallowest part of the ice core (solid line) to
 334 winter in the deepest part of the ice core (dashed line) due to post-depositional effects (see Fig. S3). (e)
 335 Average seasonal cycle in bromine enrichment (relative to sea salt sodium, see Eq. (4)). (f-right) The
 336 sea ice extent (SIE) within an area of the East Greenland coast [70°– 63° N, 15°– 45° W] that shows

337 highest correlations to MSA (see Fig. 6), (f – left) Area of open water within the sea ice pack (OWIP)
338 for the area defined by SIE. (g) Solar insolation at 12 GMT at the latitude of Summit
339 (eosweb.larc.nasa.gov). Lower plot: Broadening of bromine seasonal cycle in the Summit-2010 ice core.
340 The difference between the summer and spring bromine signal (JJA-MAM) was monitored over the
341 length of the entire ice core. In the preindustrial era (pre-1850) bromine peaks in summer; realised as
342 positive values of JJA-MAM. After 1900 there is a marked broadening of the seasonal signal towards
343 spring and by ~1970 the seasonal signal maximum is routinely shared between summer and spring
344 realised as an averaged JJA-MAM of approximately zero.
345

346

347

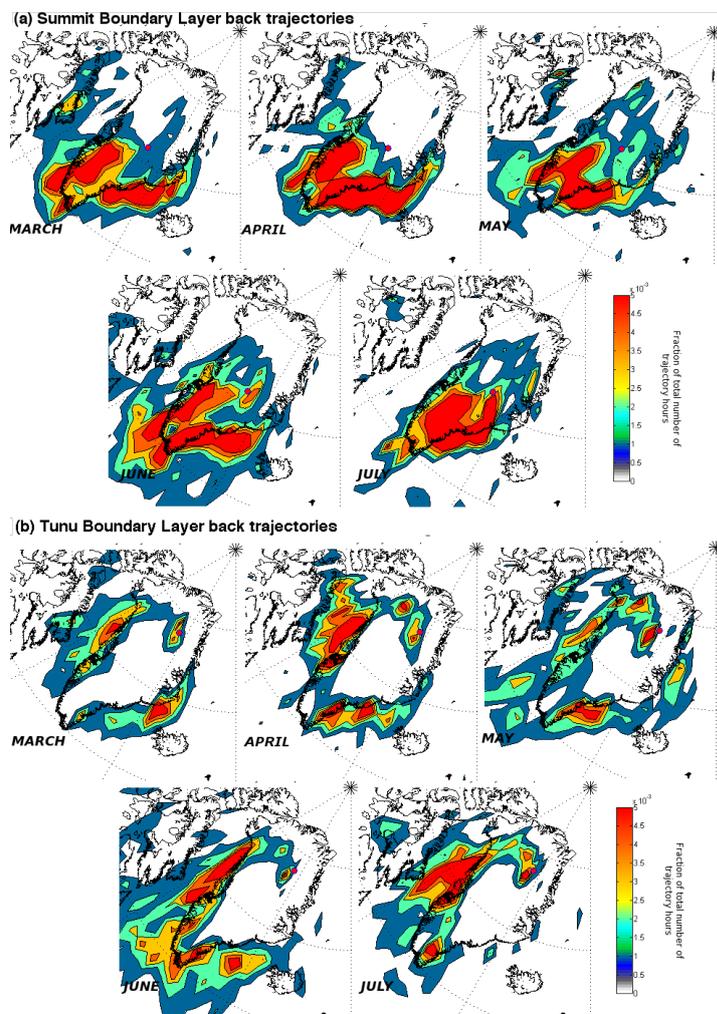

348 **Figure 4.** Comparison between the measured total sulfur (shown as sulfate) and acidity records from
349 each ice core (top panels). The acidity record is dominated by the influence of the sulfur species until
350 the early 21st century when the NO_x pollution remains elevated whilst anthropogenic sulfur sources are
351 depleted resulting in a slight relative elevation of the total acidity relative to total sulfur concentrations.
352 The large spikes in the acidity and sulfur records are identified as volcanic events. The ice core records
353 cover the period of the 1783 Laki eruption as well as the Unknown 1909 eruption and Tambora eruption
354 (Indonesia) in 1815 (Sigl et al., 2013). Comparison between Br/MSA and total acidity (center panels)
355 and nitrate (NO_3^- , bottom panels) measured in the ice cores. The Br/MSA ratio follows the total acidity
356 record closely except where the record is dominated by the sulphur component (e.g. early 1900s). Of
357 the two major acidic species the Br/MSA follows the nitrate most closely at both ice core sites.

358

359

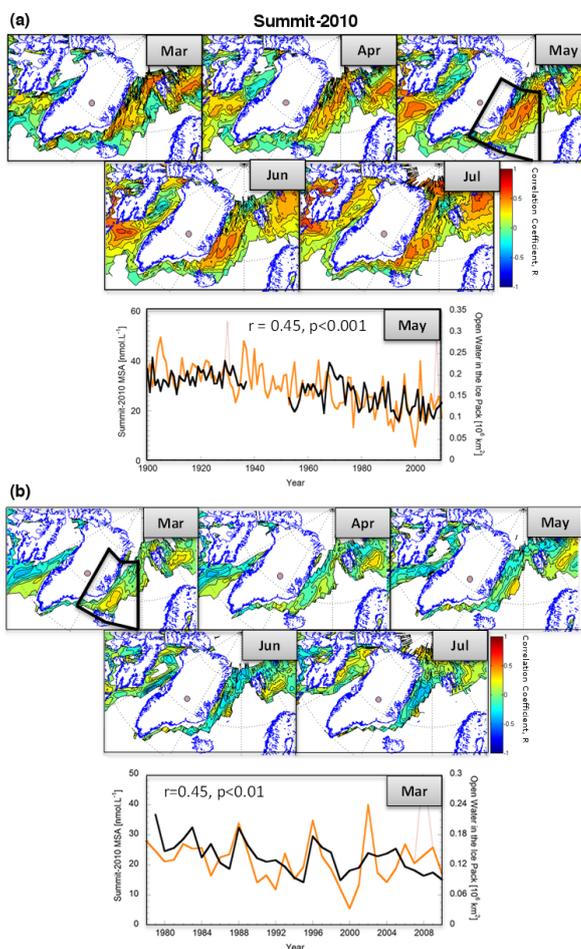

360

361

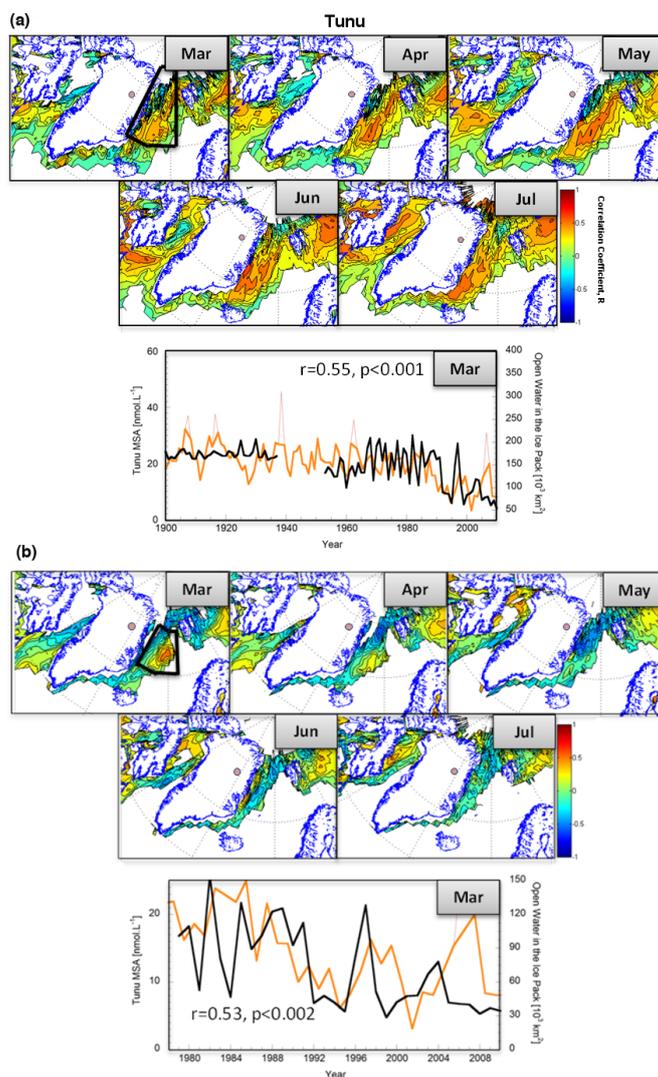

362

363 **Figure 5.** Air mass back trajectories from the (a) Summit-2010 and (b) Tunu ice core sites over the
364 period 2005-2013 C.E. Maps display the fraction of the total number of trajectory hours (ranging
365 between 21400-25500 hr month⁻¹) spent at altitudes under 500 m. Back trajectories were allowed to
366 travel for 10 hr. New trajectories were started every 12 hours. Map grid resolution is 2°x 2°. Ice core
367 locations are shown by a pink circle. Maps show that air masses consistently arrive at Summit from the
368 SE Greenland coast with a smaller contribution from the SW coast. Air masses consistently arrive at
369 Tunu from the western Greenland coast with a smaller contribution from the SE and NE coast. The air
370 mass originating from the NE coast is most dominant in May and comparison with the total vertical
371 column profile (Fig. S4) shows it is confined to lower altitudes unlike those from the west coast.

372

373 **Figure 6.** Correlation maps of monthly sea ice concentration (SIC) derived from the Summit-2010 ice
374 core. (a) HadISST1 ICE dataset from 1900-2012 C.E. correlated with annual records of MSA. Outliers
375 were removed from the MSA records before the correlations were performed. Month labels indicate
376 month of SIC compared with the annual MSA value. Only locations that showed a SIC variability
377 greater than 10% and have a significant correlation (t-test, $p < 0.05$) are displayed. The area of sea ice
378 that is the likely source of MSA (as indicated by the air-mass trajectories) are outlined in black [70°–
379 63° N, 15°–45° W]. Graphed is the area of open water in the sea ice in this region (OWIP, black)
380 overlaid on the annual MSA record (red, outliers removed - orange). (b) As for the upper panel but
381 focused on the satellite period 1979-2012 C.E. Summit MSA shows a significant, positive correlation
382 with the amount of OWIP during spring within the integrated region.

383

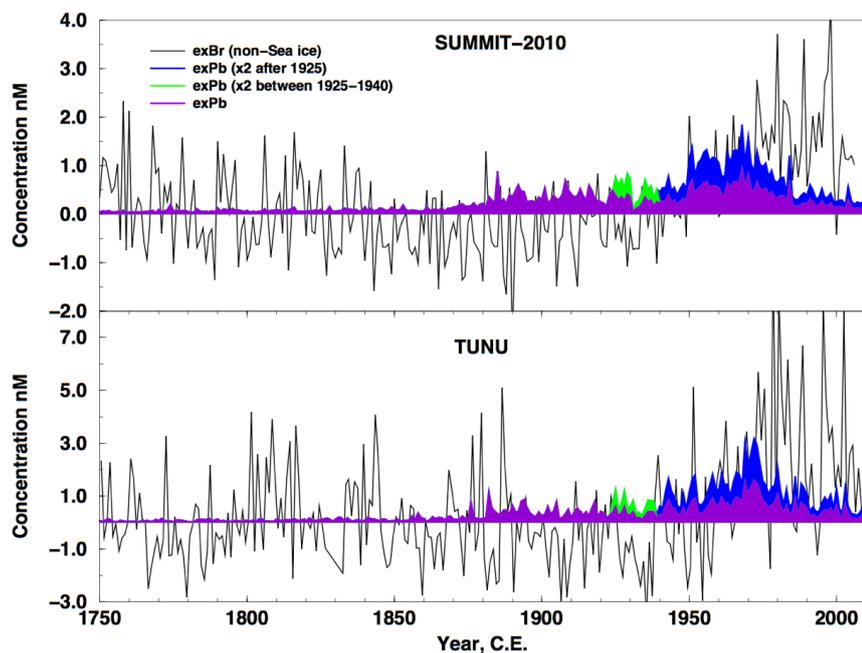

384 **Figure 7.** Correlation maps of monthly sea ice concentration (SIC) derived from the Tunu ice core. (a)
 385 HadISST1 ICE dataset from 1900-2012 C.E. correlated with annual records of MSA. Outliers were
 386 removed from the MSA records before the correlations were performed. Month labels indicate the
 387 month of SIC compared with the annual MSA value. Only locations that showed a SIC variability
 388 greater than 10% and have a significant correlation (t-test, $p < 0.05$) are displayed. The area of sea ice
 389 that is the likely source of MSA (as indicated by the air-mass trajectories) are outlined in black [80° –
 390 73° N, 20° – 0° W]. Graphed is the area of open water in the sea ice in this region (OWIP, black) overlaid
 391 on the annual MSA record (red, outliers removed - orange). Like in the Summit-20101 ice core, Tunu

392 MSA also shows a significant, positive correlation with the amount of OWIP during spring but the
393 correlation is highest when MSA is compared to the annual OWIP in the source region. (b) As for the
394 upper panel but focused on the satellite period 1979-2012 C.E. Again MSA shows a significant, positive
395 correlation with the amount of OWIP during spring at both sites. During the satellite period the
396 correlation between OWIP and MSA concentrations at Tunu is greatly increased when a second, closer
397 region is also included in the integration [80° – 73° N, 20° – 0° W].
398

399

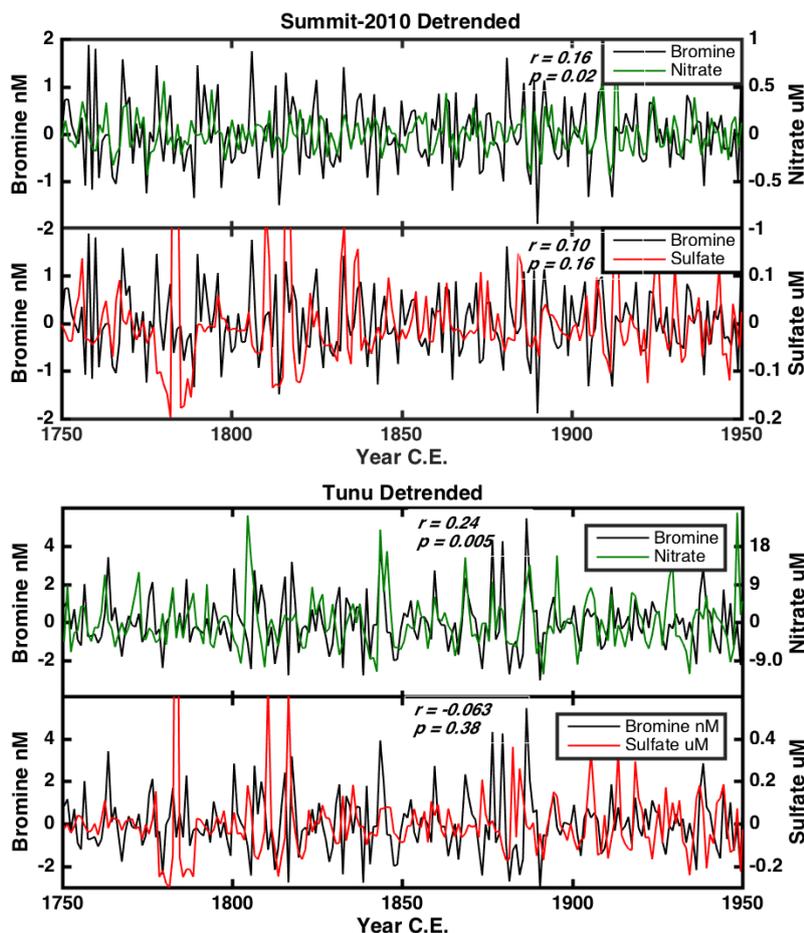

300

301 **Figure 8.** Comparison between measurements of excess lead (exPb, purple shading) and bromine in
302 excess of what is expected from the preindustrial (1750-1880) Br/MSA relationship (exBr, black).
303 Between 1925-1940 world-wide leaded gasoline sources contained a Pb:Br molar ratio of 1:2 (aviation
304 fuel). After 1940 only Russia continued to use the 1:2 ratio in their leaded fuel whilst the rest of the
305 world changed to a 1:1 ratio. The green shading shows an estimate of bromine from leaded fuel
306 combustion over the 1925-1940 period (relative to the exPb concentrations). The blue shading shows
307 the upper limit to the amount of bromine (relative to exPb) that could be derived from leaded fuel
308 combustion by assuming Pb:Br ratio of 1:2 after 1940. After 1970, when world consumption of leaded
309 gasoline began to fall, exBr concentrations continued to rise at both ice core sites far above the
310 concentrations that could be explained by leaded gasoline sources.

311

312

313

14

15

16 **Figure 9.** High frequency comparison between the annual bromine, nitrate and sulfate records measured
17 in the ice cores. Each series has been detrended with an 11 year running average before comparison to
18 remove the low frequency changes in each record. The correlation is highest between bromine and
19 nitrate at both sites. The r-value for bromine versus nitrate at Summit increases in significance ($r =$
20 $0.24, p = 0.001$) when the entire period (1750-2010) is considered. At both sites there is a close
21 relationship between the variability in the nitrate and bromine due to their intimate relationship during
22 emission from the sea ice, transport and deposition onto the snow pack. The correlation between sulfate
23 (or indeed bulk acidity) and bromine is not significant significant over any of the time periods shown at
24 either site. Particularly evident is the non-response of the bromine signal to the sulfur rich volcanic
25 events as described in Sect.4.2.2.
