**Abstract.** Earth's climate during the Maastrichtian (latest Cretaceous) was punctuated by brief warming and cooling episodes, accompanied by perturbations of the global carbon cycle. Superimposed on a long-term cooling trend, the middle Maastrichtian is characterized by deep-sea warming and relatively high values of stable carbon-isotope ratios, followed by strong climatic variability towards the end of the Cretaceous. A lack of knowledge on the timing of climatic change inhibits our understanding of underlying causal mechanisms. We present an integrated stratigraphy from Site U1403, providing an expanded deep ocean record from the North Atlantic (IODP Expedition 342, Newfoundland Margin). Distinct sedimentary cyclicity suggests that orbital forcing played a major role on depositional processes, which is confirmed by statistical analyses of high resolution elemental data obtained by X-ray fluorescence (XRF) scanning. Astronomical calibration reveals that the investigated interval encompasses seven 405-kyr cycles (Ma<sub>4051</sub> to Ma<sub>4057</sub>) and spans 2.8 Myr directly preceding the Cretaceous/Paleocene (K/Pg) boundary. A high-resolution carbon-isotope record from bulk carbonates allows to identify global trends in the late Maastrichtian carbon cycle. Low-amplitude variations (up to 0.4 ‰), typical for open ocean settings, are compared to the hemipelagic Zumaia section (N-Spain), with a well-established independent cyclostratigraphic framework. Whereas the pre-K/Pg oscillations and the negative values of the Mid-Maastrichtian Event (MME) can be readily discerned in both records, patterns diverge around 67.5 Ma, with Site U1403 more reliably reflecting global climate change. Our new carbon isotope record and the established cyclostratigraphy from Site U1403 may serve as a future reference for detailed studies of late Maastrichtian events in the North Atlantic.

## 1 Introduction

Following the high temperatures of the mid-Cretaceous greenhouse (e.g., Wilson et al., 2002; Forster et al., 2007; Bornemann et al., 2008; Friedrich et al., 2008), the latest Cretaceous is characterized by long-term climate cooling culminating in the late Campanian to Maastrichtian (e.g., Clarke and Jenkyns, 1999; Huber et al., 2002; Friedrich et al., 2012). Superimposed on this long-term trend are several short-term cooling pulses with the most pronounced episode occurring across the Campanian-Maastrichtian boundary (the so-called Campanian-Maastrichtian Boundary Event, CMBE). The CMBE is characterized by distinct changes in stable oxygen and carbon isotope records, indicating deep-water cooling and changing rates of organic carbon burial (e.g., Barrera et al., 1997; Frank and Arthur, 1999; Barrera and Savin, 1999; Friedrich et al., 2004, 2009; Frank et al., 2005; Friedrich and Hemleben, 2007; Voigt et al., 2012; Jung et al., 2013). Shortly after the CMBE, the Mid-Maastrichtian Event (MME; MacLeod et al., 1996) marks a time of deep-sea warming (Jung et al., 2013) and the acme occurrence of inoceramid bivalves in numerous open-ocean sites (e.g., MacLeod 1994; MacLeod et al., 1996).

Although the CMBE and MME have been studied extensively (Jung et al., 2013, and references therein), the causal mechanisms triggering the events are still poorly understood due to poor constraints on timing. The low temporal resolution of Maastrichtian biozones and pronounced biotic provincialism complicate correlation further. This provincialism is related to the latest Cretaceous climate cooling which resulted in the formation of three main provinces (Tethyan, Boreal and Austral; e.g., Huber and Watkins, 1992; Premoli Silva and Sliter, 1994; Burnett, 1998; Lees, 2002; Lees and Bown, 2005). To overcome the limitations of insufficient age models and biotic provincialism, high-resolution carbon isotope curves have recently been used for detailed stratigraphic correlation of Maastrichtian sections representing a variety of depositional settings (e.g., Voigt et al., 2010,

2012; Batenburg et al., 2012; Jung et al., 2012; Thibault et al., 2012a, b). Successful correlation of carbon isotope curves from the European shelf seas with datasets derived from deep-sea sediments in the tropical Pacific Ocean proved the usefulness and accuracy of this approach (Voigt et al., 2010, 2012). Furthermore, an astronomical age scale has been established for the Maastrichtian (Batenburg et al., 2012, 2014) that allows the reconstruction of the spatial and temporal extent of Maastrichtian events.

Here, we present a new, high-resolution carbon isotope dataset from bulk sediments of Integrated Ocean Drilling Program (IODP) Site U1403 that records carbon-cycle fluctuations in the late Maastrichtian North Atlantic off Newfoundland. Site U1403 provides an exceptional record of rhythmic and continuous sedimentation and provides the northernmost high-resolution deep-ocean record to date. Our findings show a good match between the carbon isotope dataset of Site U1403 with the high-resolution chemostratigraphic framework of the Zumaia section (northern Spain; Batenburg et al., 2012, 2014). Furthermore, an orbital timescale for the Upper Maastrichtian interval of Site U1403 based on high-resolution X-ray fluorescence (XRF) core scanning data independently supports the presented carbon isotope stratigraphy through the identification of hierarchical Milankovitch cycles. It correlates well to the available orbital age model for Zumaia (Batenburg et al., 2014).

## 2 Geological setting

Integrated Ocean Drilling Program Site U1403 (39°56.60'N, 51°48.20'W) is positioned at the foot of the J Anomaly Ridge off Newfoundland (Fig. 1). It was drilled in 2012 during IODP Expedition 342 in a present-day water depth of 4949 m and is the deepest site that was drilled along the Newfoundland sediment drifts depth transect (Expedition 342 Scientists, 2012).

Maastrichtian-aged sediments at Site U1403 are nannofossil chalks that show subtle, decimeter-scale rhythmic color variations between pale yellow to very pale brown (lithological Unit Vb of Site U1403; see Expedition 342 Scientists (2012) for a detailed description of lithostratigraphic units). Calcium carbonate content of Maastrichtian sediments ranges from 35 to 80 wt% (Norris et al., 2014), suggesting that Site U1403 was above the CCD during the Late Cretaceous.

## 3 Materials and Methods

### 3.1 Stable isotopes

Site U1403 has been sampled at a resolution of ~10 cm for stable carbon- and oxygen-isotope analyses on bulk carbonates (for detailed description of cores and recovery see Expedition 342 Scientists, 2012). A total of 253 samples were taken from cores 26 to 28 of Hole A and cores 28 to 32 of Hole B, spanning 247.68–296.23 m core composite depth below sea floor (CCSF; Fig. 2) After being dried and grounded, bulk samples were alternatingly analyzed using either a Finnigan MAT 253 coupled online to a Gasbench II at Goethe-University Frankfurt (Germany) or a Finnigan Delta V Advantage coupled with Gasbench II at Kanazawa-University (Japan; for details see Moriya et al., 2012). All isotope values are reported in ‰ relative to the Vienna Pee Dee belemnite standard (VPDB). For both systems, the analytical precision of replicates of standard measurements was better than 0.06 and 0.08 ‰ for carbon and oxygen, respectively. Measuring the same samples on both machines gave no difference outside the analytical error.

### 3.2 XRF scanning

The Maastrichtian interval of Site U1403 was analyzed by XRF scanning (X-Ray Fluorescence) on the surface of the core archive-halves in the Marum XRF Core Scanner Lab, University of Bremen, Germany. The AVAATECH instrument, serial no.11, with an Oxford Instruments 100W Neptune Rh X-Ray tube and a  
 5 Canberra X-PIPS Silicon Drift Detector (SDD, Model SXD 15C-150-500) was set to a step-size of 15 mm, a slit down-core of 10 mm, and a slit cross-core of 12 mm. A first run was applied with 10kV, 1.0 mA, for 20 s, and a second run at 50 kV, 0.2 mA, for 20 s. The data were processed with WIN AXIL batch software using a 10kV\_C1-Rh model and a 50kV model, respectively. Outliers, likely resulting from uneven core surfaces or micro cracks, were removed and not shown in Figure 3.

### 10 3.3 Time series analyses and astronomical calibration

To reduce noise, the natural logarithm of Fe over Ca was selected for further analyses ( $\ln \text{Fe/Ca}$ ), following the approach of Weltje and Tjallingii (2008), as well as the shipboard magnetic susceptibility data (WRMSL-MS, Expedition 342 scientists, 2012). The data were evenly sampled and periodicities larger than 5 m and 1 Myr were removed as these periodicities are too long to be reliably detected in this dataset. A wavelet application for  
 15 Matlab (Grinsted et al. 2004) was applied on the records in the depth and time domain.

In the elemental records, particularly in those of Si and Fe, as well as  $\ln \text{Fe/Ca}$ , a sharp peak occurs between 265.60 and 265.85 m CCSF. Also, high variability is observed in the interval directly beneath the K/Pg boundary. The data records were cut at these levels and spectral analyses with Redfit 3.8 (Schulz & Mudelsee 2002) were performed on both the partial records as well as on the complete data series (Figure 5). Based on the  
 20 detected spectral peaks (see Sect. 4), band-pass filters were applied using AnalySeries (Paillard et al. 1996). The filters were centered at 4.5 m (whole record), 4.3 m (upper partial record) and 3.3 m (lower partial record) for  $\ln \text{Fe/Ca}$ , and at 4.4 m for magnetic susceptibility (whole record), with a bandwidth of approximately one third of the center frequency (Figure 4, see caption for filter details).

Consecutive minima in the  $\ln \text{Fe/Ca}$  record that occur near minima in the band-pass filters (Figure 4) were  
 25 calibrated to successive minima in the 405-kyr component of eccentricity from the new La2011 (nominal) solution (Laskar et al., 2011), based on a 405-kyr band-pass filter with a bandwidth of 300–623 kyr.

## 4 Results and discussion

### 4.1 XRF scanning results and splice correction of Site U1403

Based on the XRF scanning results, a small correction of the shipboard splice is suggested by shifting the tie-point in Hole A, Core 27, Section 6, at 23.50 cm down-core by 25 cm, from originally 259.63 m CCSF to 259.88  
 30 m CCSF and adjusting all consecutive tie-points accordingly (Tab. 1). All depths beyond 259.63 m mentioned in the manuscript are on the revised CCSF scale. The 25 cm shift leads to a better matching of peaks in, among others, the Fe records of Holes A and B with high signal-to-noise-ratio in this interval but is also in agreement with the magnetic susceptibility and color reflectance data from Site U1403 which are more variable (Expedition  
 35 342 Scientists, 2012).

The elemental records of the different elements (supplementary information and data on [www.pangaea.de](http://www.pangaea.de)) can be divided in two groups. The elements Al, Si, K, Ti, Mn, Fe, and Zr are anticorrelated to carbonate-phase elements Ca and Sr (Fig. 3). The element Ba (reported as total Ba analyzed) displays different behavior characterized by intervals with high-frequency sharp peaks and relatively stable background values (Fig. 3). The elemental records show a sharp peak between 265.60 and 265.82 m CCSF, indicated by blue shading in Figure 4. This peak coincides with a marked change in the visual appearance of the cores, with closely spaced dark bands occurring below 265.60 m CCSF, and wider bands of lighter color occurring above (core images in left panel of Fig. 4). These bands occur in groups or bundles throughout the studied interval.

#### 4.2 Time series analyses and cyclostratigraphy

The magnetic susceptibility and elemental records show variability on different spatial scales, such as a marked ~20 cm variability in the two meters below the K/Pg boundary and a ~1 m variability between 255 and 259 m CCSF. The  $\ln \text{Fe/Ca}$  and magnetic susceptibility datasets display many spectral peaks when the complete records are analyzed (top panels Figure 4). Main periodicities in the  $\ln \text{Fe/Ca}$  record, above 99% confidence are at 4.5 m, 21-22 cm and around 17 cm. Other prominent peaks, above 90% confidence, occur at 1.6 m, 1.1 m, 63 cm, 46 cm, 36 cm and 27 cm. For magnetic susceptibility, the main periodicities are at 4.4 m, 1.1 m, 54-60 cm, 35 cm, 26-28 cm, 22 cm, 20 cm and around 17 cm.

The partial records resulting from cutting the records at 249.56 m, 265.60 m and 265.85 m CCSF provide cleaner spectra (Fig. 5). The periodicities above 99% confidence in the upper partial record of  $\ln \text{Fe/Ca}$  are at 44 cm, 36 cm, 26 cm, 21-22 cm and 16-17 cm, and above 90 % confidence periodicities of 4.2 m and 1.0 m are detected. For the upper partial record of magnetic susceptibility, main periodicities occur at 25-29 cm, 22 cm, 20 cm and 16-18 cm, and other periodicities at 2.1 m, 95 cm, 43 cm and 36 cm. The lower partial record of  $\ln \text{Fe/Ca}$  has main periodicities at 22 cm and 15 cm, and other prominent periodicities at 3.3 m and 17 cm. The lower partial record of magnetic susceptibility shows dominant periodicities around 20-22 cm, and other prominent periodicities at 3 m, 53-64 cm and 35 cm. For completeness, also the spectral analyses of the records only cut at 249.56 are displayed (Figure 5, lower panels).

The strong periodicities in the upper part of the  $\ln \text{Fe/Ca}$  and magnetic susceptibility records, at 4.2 m, at 1 m, at 44 and 36 cm and at 21-22 cm, have a ratio near that of the main periodicities of the orbital parameters of eccentricity-modulated precession and obliquity (20:5:2:1, formed by the ratio of the 405 kyr, 100 kyr, 41 kyr and 22 kyr components). The same holds true for the lower part of the record, with periodicities at 3.3 and 3.0 m, 64 cm, 22 cm and 15 cm, albeit less clear due to the shorter length of the partial record. The shift in periodicities is likely caused by an increase in sedimentation rate at 265.60 m CCSF, which is supported by the changes in the spacing of dark bands (Fig. 4).

During overall maxima of Fe and minima of Ca and corresponding maxima of  $\ln \text{Fe/Ca}$ , the respective elemental intensity records as well as the  $\ln \text{Fe/Ca}$  record display maximal variability (Fig. 4). This pattern likely reflects the sedimentary response to eccentricity-modulated precession, with high variability caused by large amplitude of the precessional forcing during eccentricity maxima. The observed rhythmic pattern displays the combined influence of variations in three main driving factors: carbonate productivity; dilution of carbonate content by siliciclastic terrigenous input; and the potential effect of local dissolution. Maxima in Fe counts coincide with minima in Ca counts (high  $\ln \text{Fe/Ca}$ ) and can be interpreted to reflect increasing terrigenous input, decreased carbonate production and/or increased dissolution or a combination of all. We hypothesize that our data reflect

highest terrigenous input and/or lowest carbonate production in times of maximal eccentricity. Increased terrigenous input during eccentricity maxima may indicate more runoff potentially caused by an intensified hydrological cycle whereas the increase in variability reflects the increasing influence of precessional forcing on the hydrological regime. In this scenario, minima of Ca would primarily reflect dilution by terrigenous material.

5 The dark bands directly observed below the K/Pg boundary (see core pictures in Fig. 4) may reflect local short-lived dissolution events that led to additional Fe enrichment and Ca depletion.

Based on the above-mentioned sedimentary response to eccentricity-modulated precession, minima in the  $\ln \text{Fe/Ca}$  record that occur near minima in the 4.5 m, 4.4 m and 3.3 m band-pass filters are assigned the ages of minima in the 405-kyr component of eccentricity from the La2011 solution (Laskar et al, 2011) (Tab. 2). This interpretation is supported by the occurrence of increased amplitude of 36-46 cm periodicities at five such levels, which likely corresponds to more prominent obliquity forcing during 405-kyr eccentricity minima. Astronomic calibration uses the K/Pg boundary as starting point with an age of 66.04 Ma based on new bentonite ages from coals near the K/Pg boundary of 66.04 Ma (Renne et al., 2013). After assigning ages to the consecutive 405-kyr minima, the main periodicities of the calibrated  $\ln \text{Fe/Ca}$  record are at 404, 143, 24 and 22 kyr (above 99% confidence), with other periodicities (above 90% confidence) at 96, 85, 51 and 38 kyr. For the calibrated magnetic susceptibility record, main periodicities are at 417, 85, 46, 34, 24 and 19 kyr, with other periodicities at 143 and 97 kyr (Fig. 6). These periodicities broadly correspond to the periodicities of obliquity and eccentricity-modulated precession, and display a regular behavior throughout the record (wavelet panels, Fig. 6).

10 The investigated interval of Site U1403 encompasses seven 405-kyr cycles ( $\text{Ma}_{4051}$  to  $\text{Ma}_{4057}$ , Husson et al., 2011 following the nomenclature of Westerhold et al., 2008; Fig. 6) in total and spans 2.8 Myr (68.8 to 66.04 Ma). This highlights the potential of Site U1403 to serve as a latest Maastrichtian reference section in the Atlantic Ocean. It provides the possibility to investigate the timing and duration of underlying causes and trigger mechanisms of climatic and oceanographic events and fluctuations like the MME or the K/Pg boundary as well as the time interval in-between. Especially, Site U1403 is located within the pathway of a potential Northern Component water mass which is suggested to have been a source of deep water in the North Atlantic Ocean (e.g., MacLeod et al., 2011; Robinson and Vance, 2012; Voigt et al., 2013).

15  
20  
25

#### 4.3 Stable oxygen isotope signal

Carbonates of the studied nannofossil oozes consist mainly of coccoliths and benthic and planktic foraminifera (Expedition 342 Scientists, 2012). Bulk oxygen isotope values therefore predominantly represent a surface-water signal. The  $\delta^{18}\text{O}$ -composition of bulk carbonate can be significantly altered by diagenetic processes like low-temperature exchange with pore fluids or burial diagenesis (e.g., Marshall, 1992; Schrag et al., 1995). Therefore, we refrain from calculating absolute temperatures based on oxygen isotope values. Variations in bulk oxygen isotope records, however, are often considered to reflect relative changes in temperature (e.g., Jenkyns et al., 1994; Voigt and Wiese, 2000; Friedrich et al., 2003; Kuhnt et al., 2011).

30 The bulk carbonate oxygen isotope record from Site U1403 is characterized by relatively stable values between 253 and 275 m CCSF which vary between 0 and -0.6 ‰ (Fig. 2). Above 253 m CCSF,  $\delta^{18}\text{O}$  values decrease slightly, followed by a pronounced negative excursion between 249 and 248 m CCSF with minimum values of -1.5 ‰ within nannofossil zone UC20d (Fig. 2). This decrease in oxygen isotope values suggests a significant increase in surface-water temperatures directly preceding the K/Pg boundary, as has been described in previous studies (e.g., Barrera, 1994; Li and Keller, 1998).

35  
40

#### 4.4 Carbon isotope stratigraphy and comparison to the Zumaia record

Carbon isotope values of carbonates are less prone to diagenetic alterations than oxygen isotope values (e.g., Anderson and Arthur, 1983; Marshall, 1992) and are a reliable recorder of changes in the global carbon cycle (e.g., Weissert et al., 2008). Especially for pelagic carbonate successions the method of carbon isotope stratigraphy has been successfully applied for stratigraphic correlation on a global scale and across different depositional settings (e.g., Voigt et al., 2010, 2012; Batenburg et al., 2012; Jung et al., 2012; Thibault et al., 2012a, b).

The bulk carbon isotope record of Site U1403 shows variability on long and short timescales. While  $\delta^{13}\text{C}$  values increase in the lower half of the record (275 to 260 m CCSF, Fig. 2) to maximum values of 3.15 ‰, they decrease towards the top of the studied interval, resulting in minimum values of 2.3 ‰.

The pattern of  $\delta^{13}\text{C}$  values found in Site U1403 can be compared to the trends in bulk carbonate  $\delta^{13}\text{C}$  values from the Zumaia section in northern Spain (Batenburg et al., 2012), which has an independent astrochronology (Fig. 7). For the Zumaia succession, rhythmic lithological alternations form the basis of a cyclostratigraphic framework, tested by statistical analyses of high-resolution magnetic susceptibility and color reflectance data. A 405-kyr band-pass filter of magnetic susceptibility is displayed at the right hand side of Figure 7. Compared to the carbon isotope data of Site U1403, the Zumaia record shows variations with a larger amplitude (up to 1 ‰; Fig. 7). This reflects the influence of regional processes such as weathering, runoff and productivity, which may have changed the carbon inventory of the relatively restricted Basque-Cantabric basin, and caused short-term variations superimposed on long-term global trends. The relatively low amplitude variations of bulk carbon isotope values from Site U1403 (up to 0.4 ‰; Figs 2, 7) are typical for open ocean settings like the Tethys (Voigt et al., 2012; Sprovieri et al., 2013), the tropical Pacific (Sites 305 and 1210; Voigt et al., 2010; Jung et al., 2012) or the Indian Ocean (Site 762; Thibault et al., 2012a).

Both carbon isotope records show an overall decreasing trend through the late Maastrichtian. Markedly negative values near the base of the U1403 record coincide with the Mid-Maastrichtian Event at 68.6 Ma. Distinct oscillations can be observed in both records over a million-year interval prior to the K/Pg boundary. In between these coeval shifts, the Zumaia record displays a negative shift around 67.5 Ma, which may be related to a relative drop in sea level (Batenburg et al., 2012). The behavior of the carbon isotope record of Site U1403 is likely more representative of changes in the global carbon cycle. This interpretation is supported by a comparison of available nannofossil marker species. At Site U1403, shipboard calcareous nannofossil biostratigraphy indicates zones UC20b to UC20d (Norris et al., 2014). Boundaries between these zones are at ~66.68 Ma (base *Ceratolithoides kamptneri*) and ~66.47 Ma (base *Micula prinsii*) if the herein established age model is applied. These estimated ages are somewhat older than compared to the same events at Zumaia (Batenburg et al., 2014). However, diachroneity has been noted in *M. prinsii*, with later Boreal appearances (see Gradstein et al., 2012, notes). At ODP Site 762C, Thibault et al. (2012a) reported Base *M. prinsii* towards the base of 29r (66.39 Ma) and Thibault et al. (2015) report a range of *M. prinsii* ages from 66.2–67 Ma, but mostly towards the younger end of the range, which is generally in good agreement with the estimated age of this study. Although Site U1403 and the Zumaia section represent completely different depositional settings, the carbon isotope curves display similar broad trends when presented on independent age models. Differences between the curves can be used to identify global versus regional controls on recorded  $\delta^{13}\text{C}$ . This highlights the usefulness of

carbon isotopes for stratigraphic purposes in the latest Cretaceous and their potential to unravel the underlying causes and trigger mechanisms of paleoclimatic and paleoceanographic events.

## 5 Conclusions

Based on our high-resolution XRF core scanning data, we identify a small correction of the shipboard splice and establish an orbital chronology for the late Maastrichtian interval of Site U1403. The investigated interval encompasses seven 405-kyr cycles (Ma<sub>4051</sub> to Ma<sub>4057</sub>), spanning 2.8 Myr from 68.8 to 66.0 Ma. Our new high-resolution stable carbon isotope record from Site U1403 (IODP Expedition 342, Newfoundland Margin) shows distinct variations, including the Mid-Maastrichtian Event and the oscillations prior to the K/Pg boundary. These trends can be correlated to carbon isotope records elsewhere, e.g. the Zumaia section in northern Spain. Comparison of carbon isotope stratigraphies from open-ocean and shelf settings not only provides a dating tool, but also adds insights in regional versus global drivers of the Earth's carbon cycle. Amplitudes of the carbon isotope variations at Zumaia are significantly higher than at U1403, indicating a strong influence of regional processes in the narrow Basque-Cantabric basin on the carbon isotope signal. The U1403 record displays typical open ocean values when compared to other records. In the future, Site U1403 might serve as a potential reference section for paleoclimatic and paleoceanographic events and fluctuations during the latest Cretaceous.

**Acknowledgements.** This research used samples provided by the Integrated Ocean Drilling Program (IODP), which is sponsored by the U.S. National Science Foundation and participating countries under management of Joint Oceanographic Institutions, Inc. This research used data acquired at the XRF Core Scanner Lab at the MARUM – Center for Marine Environmental Sciences, University of Bremen, Germany. Sven Hofmann is thanked for laboratory assistance. Dominik Leonhardt helped with processing of sediment samples. Funding for this study was provided by the DFG to O.F. (Emmy Noether research group “Meso- and Cenozoic paleoceanography”; grant FR2544/2-1 and grant FR2544/5) and to S.V. (DFG grant VO 687/14-1).

**Table 2:** Tie-points for reconstructing the age model and resulting linear sedimentation rates.

Depth mcd (CCSF-A)	Age (Ma)	Sed. Rate (cm/kyr)
247.700	66.04	
251.040	66.374	1.00
254.960	66.782	0.96
259.205	67.192	1.04
263.695	67.585	1.14
268.365	67.986	1.16
271.680	68.383	0.84
274.635	68.787	0.73
275.000	68.837	0.73

**Figure 1:** Paleogeographic reconstruction for the Maastrichtian (70 Ma reconstruction based on [www.odsn.de](http://www.odsn.de); Hay et al., 1999) showing locations of sites discussed (Site U1403, this study, black star; Zumaia section, white star).

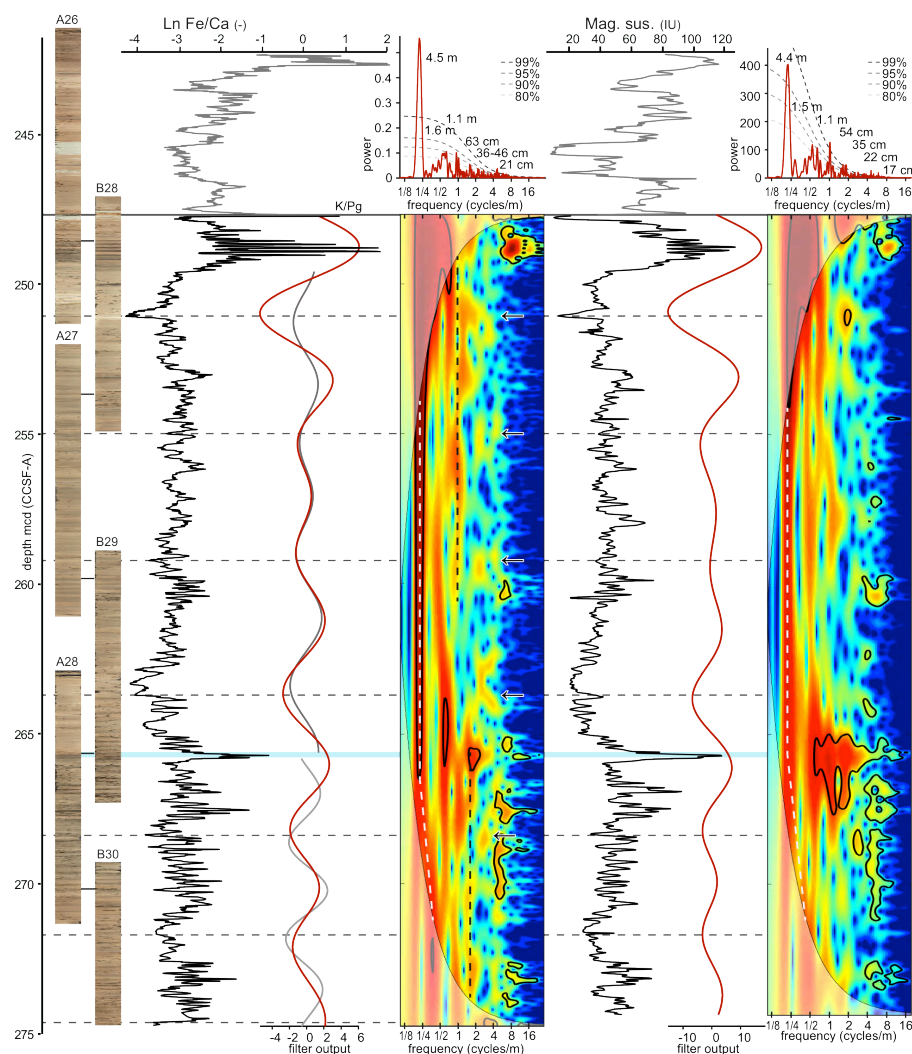

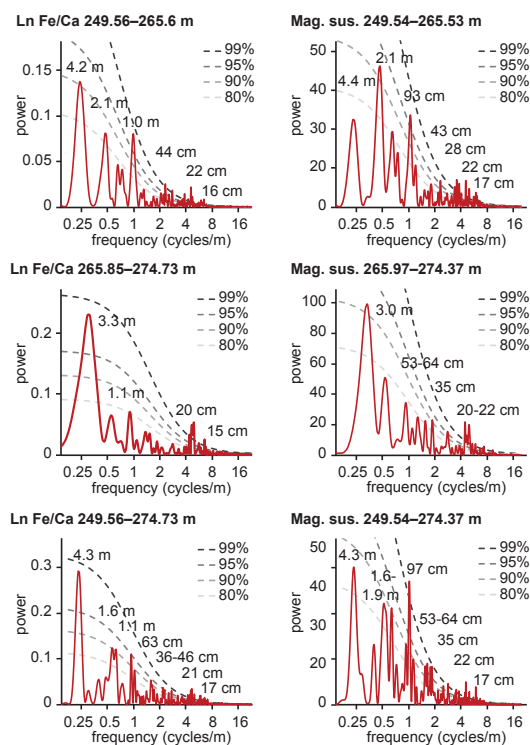

**Figure 2:** Bulk-carbonate carbon and oxygen isotope data from IODP Site U1403 (IODP Expedition 342) against CCSF and relative to shipboard calcareous nannofossil biostratigraphy (Norris et al., 2014).

**Figure 3:** High-resolution XRF scanning silica, calcium, iron and barium elemental intensities from IODP Site U1403 (IODP Expedition 342) against CCSF and relative to shipboard calcareous nannofossil biostratigraphy (Norris et al., 2014).

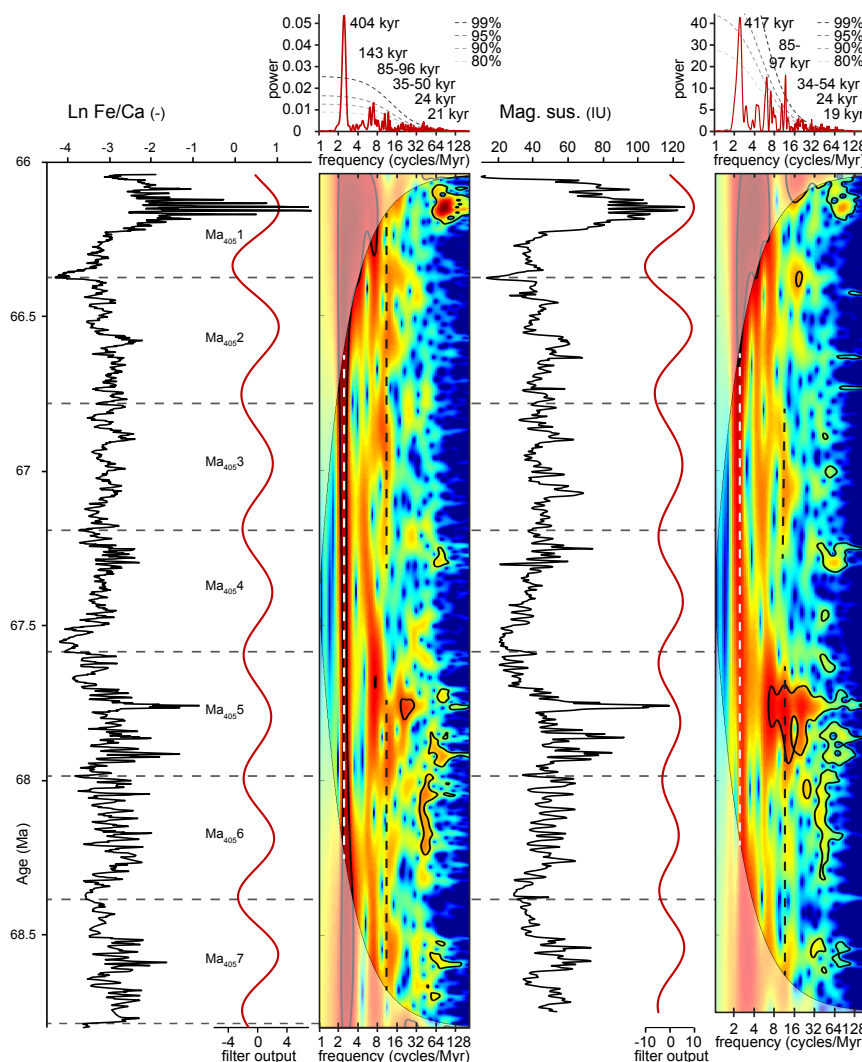

**Figure 4:** Time series analyses of the natural logarithm of the ratio of Fe and Ca counts ( $\ln \text{Fe/Ca}$ ), obtained by XRF scanning of the Maastrichtian interval of U1403, and the magnetic susceptibility (shipboard data, instrument units). From left to right: joined core photographs with splice tiepoints (black bars),  $\ln \text{Fe/Ca}$  (left) and magnetic susceptibility (right) in the depth domain, flanked by band-pass filters, wavelet analyses and Redfit power spectra. For  $\ln \text{Fe/Ca}$ , the band-pass filters over the whole record is indicated in red and centered at 4.5 m (bandwidth 3.4–6.8 m). The band-pass filters over the partial records are centered at 4.2 m (bandwidth 3.1–6.3 m) for the upper part (dark grey) and 3.3 m (bandwidth 2.5–5.0 m) for the lower part (light grey). For magnetic susceptibility, the band-pass filter over the whole record, in dark red, is centered at 4.4 m (bandwidth 3.3–6.7 m). Blue shading indicates the interval between 265.60 and 265.85 CCSF, where the records are cut. Black arrows within the wavelet analyses panel of  $\ln \text{Fe/Ca}$  indicate periodic amplitude amplifications in the frequency band of 36–46 cm. Dark grey dashed lines indicate the stratigraphic positions of minima in the  $\ln \text{Fe/Ca}$  record that occur within minima in the band-pass filters, and are used as tie-points for the age model (Table 2).

**Figure 5:** Redfit power spectra of the partial records of Ln Fe/Ca (left) and magnetic susceptibility (right). Top panel: the upper interval between the peak at 265.6 m and the variability below the K/Pg boundary, starting at 249.56 m; middle panel: the lower interval from the peak at 265.85 m downwards; bottom panel: the interval from the main variability below the K/Pg, starting at 249.56 m, downwards.

15

**Figure 6:** Time series analyses of the  $\ln \text{Fe/Ca}$  and magnetic susceptibility records calibrated to the 405-kyr component of eccentricity. Left: the  $\ln \text{Fe/Ca}$  record in the time domain, flanked by a band-pass filter centered at 404 kyr (bandwidth 302–612 kyr), and wavelet analyses, topped by a Redfit power spectrum. The curved grayscale lines indicate the 99%, 95%, 90% and 80% confidence levels, from the uppermost to the lowermost, respectively. Right: idem for the magnetic susceptibility record, with a band-pass filter centered at 417 kyr (bandwidth 313–627 kyr). Dark grey dashed lines indicate the positions of minima in the  $\ln \text{Fe/Ca}$  record that are used as tie-points in the age model.  $\text{Ma}_{405}$  numbers indicate the 405-kyr cycle from the K/Pg boundary back in time.

**Figure 7:** Correlation of carbon isotope values from IODP Site U1403 with the  $\delta^{13}\text{C}$  record of the Zumaia section (Batenburg et al., 2012). Both records plotted against the age models derived from the independently established cyclostratigraphic interpretations (this study and Batenburg et al., 2014). Black stippled lines indicate correlation points of the K/Pg boundary and the MME.
