Abstract. We present the neodymium isotopic composition (ϵNd) of mixed planktonic foraminifera species from a sediment core collected at 622 m water depth in the Balearic Sea, as well as ϵNd of scleractinian cold-water corals (CWC; *Madrepora oculata*, *Lophelia pertusa*) retrieved at 280–414 m water depth in the Alboran Sea and the south Sardinian continental margin. The aim is to constrain hydrological variations at intermediate depths in the western Mediterranean Sea during the last 20 kyr. Planktonic (*Globigerina bulloides*) and benthic (*Cibicidoides pachyderma*) foraminifera were also analyzed for stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotopes. The foraminiferal and coral ϵNd values from the Balearic and Alboran Sea are comparable over the last ~13 kyr, with mean values of -8.94 ± 0.26 (1σ ; $n=24$) and -8.91 ± 0.18 (1σ ; $n=25$), respectively. Before 13 ka BP, the foraminiferal ϵNd values are slightly lower (-9.28 ± 0.15) and tend to reflect a higher mixing between intermediate and deep waters, which is characterized by more unradiogenic ϵNd values. The slight ϵNd increase after 13 ka BP is associated to a decoupling in the benthic foraminiferal $\delta^{13}\text{C}$ composition between intermediate and deeper depths, which started at ~16 ka BP. This suggests an earlier stratification of the water masses and a subsequent reduced contribution of unradiogenic ϵNd from deep waters. The CWC from the Sardinia Channel show a much larger scattering of ϵNd values, from -8.66 ± 0.30 to -5.99 ± 0.50 , and a lower average (-7.31 ± 0.73 ; $n=19$) compared to the CWC and foraminifera from the Alboran and Balearic Sea, indicative of intermediate waters sourced from the Levantine basin. At the time of sapropel S1 deposition (10.2 to 6.4 ka), the ϵNd values of the Sardinian CWC become more unradiogenic (-8.38 ± 0.47 ; $n=3$ at ~8.7 ka BP), suggesting a significant contribution of intermediate waters originated from the western basin. Accordingly, we propose that western

47 Mediterranean intermediate waters replaced the Levantine Intermediate Water (LIW), which was strongly
48 reduced during the mid-sapropel (~8.7 ka BP). This observation supports a notable change of Mediterranean
49 circulation pattern centered on sapropel S1 that needs further investigations to be confirmed.

50

51 **1. Introduction**

52 The Mediterranean Sea is a mid-latitude semi-enclosed basin, characterized by evaporation exceeding
53 precipitation and river runoff, where the inflow of fresh and relatively warm surface Atlantic water is
54 transformed into saltier and cooler (i.e. denser) intermediate and deep waters. Several studies have demonstrated
55 that the Mediterranean thermohaline circulation was highly sensitive to both the rapid climatic changes
56 propagated into the basin from high latitudes of the Northern Hemisphere (Cacho et al., 1999, 2000, 2002;
57 Moreno et al., 2002, 2005; Paterne et al., 1999; Martrat et al., 2004; Sierro et al., 2005; Frigola et al., 2007,
58 2008) and orbitally-forced modifications of the eastern Mediterranean freshwater budget mainly driven by
59 monsoonal river runoff from the south (Rohling et al., 2002; 2004; Bahr et al., 2015). A link between the
60 intensification of the Mediterranean Outflow Water (MOW) and the intensity of the Atlantic Meridional
61 Overturning Circulation (AMOC) was proposed (Cacho et al., 1999, 2000, 2001; Bigg and Wadley, 2001; Sierro
62 et al., 2005; Voelker et al., 2006) and recently supported by new geochemical data in sediments of the Gulf of
63 Cádiz (Bahr et al., 2015). In particular, it has been suggested that the intensity of the MOW and, more generally,
64 the variations of the thermohaline circulation of the Mediterranean Sea could play a significant role in triggering
65 a switch from a weakened to an enhanced state of the AMOC through the injection of saline Mediterranean
66 waters in the intermediate North Atlantic at times of weak AMOC (Rogerson et al., 2006; Voelker et al., 2006;
67 Khélifi et al., 2009). The Mediterranean intermediate waters, notably the Levantine Intermediate Water (LIW),
68 which represent today up to 80 % in volume of the MOW (Kinder and Parilla, 1987) are considered an important
69 driver of MOW-derived salt into the North Atlantic. Furthermore, the LIW also plays a key role in controlling
70 the deep-sea ventilation of the Mediterranean basin, being strongly involved in the formation of deep waters in
71 the Aegean Sea, Adriatic Sea, Tyrrhenian Sea and Gulf of Lions (Millot and Taupier-Letage, 2005). It is
72 hypothesized that a reduction of intermediate and deep-water formation as a consequence of surface hydrological
73 changes in the eastern Mediterranean basin acted as a precondition for the sapropel S1 deposition by limiting the
74 oxygen supply to the bottom waters (De Lange et al., 2008; Rohling et al., 2015; Tachikawa et al., 2015).
75 Therefore, it is crucial to gain a more complete understanding of the variability of the Mediterranean
76 intermediate circulation in the past and its impact on the MOW outflow and, in general, on the Mediterranean
77 thermohaline circulation.

78 Previous studies have mainly focused on the glacial variability of the deep-water circulation in the western
79 Mediterranean basin (Cacho et al., 2000, 2006; Sierro et al., 2005; Frigola et al., 2007, 2008). During the Last
80 Glacial Maximum (LGM), strong deep-water convection took place in the Gulf of Lions, producing cold, well-
81 ventilated western Mediterranean Deep Water (WMDW) (Cacho et al., 2000, 2006; Sierro et al., 2005), while
82 the MOW flowed at greater depth in the Gulf of Cádiz (Rogerson et al., 2005; Schönfeld and Zahn, 2000). With
83 the onset of the Termination 1 (T1) at about 15 ka, the WMDW production declined until the transition to the
84 Holocene due to the rising sea level, with a relatively weak mode during the Heinrich Stadial 1 (HS1) and the
85 Younger Dryas (YD) (Sierro et al., 2005; Frigola et al., 2008), that led to the deposition of the Organic Rich
86 Layer 1 (ORL1; 14.5-8.2 ka BP; Cacho et al., 2002).

87 Because of the disappearance during the Early Holocene of specific epibenthic foraminiferal species, such as
88 *Cibicoides* spp., which are commonly used for paleohydrological reconstructions, information about the
89 Holocene variability of the deep-water circulation in the western Mediterranean are relatively scarce and are
90 mainly based on grain size analysis and sediment geochemistry (e.g. Frigola et al., 2007). These authors have
91 identified four distinct phases representing different deep-water overturning conditions in the western
92 Mediterranean basin during the Holocene, as well as centennial- to millennial-scale abrupt events of overturning
93 reinforcement.

94 Faunal and stable isotope records from benthic foraminifera located at intermediate depths in the eastern basin
95 reveal uninterrupted well-ventilated LIW during the last glacial period and deglaciation (Kuhnt et al., 2008;
96 Schmiedl et al., 2010). Similarly, a grain-size record obtained from a sediment core collected within the LIW
97 depth range (~500 m water depth) at the east Corsica margin also documents enhanced bottom currents during
98 the glacial period and for specific time intervals during the deglaciation, such as HS1 and YD (Toucanne et al.,
99 2012). The Early Holocene is characterized by a collapse of the LIW (Kuhnt et al., 2008; Schmiedl et al., 2010;
100 Toucanne et al., 2012) synchronous with the sapropel S1 deposition (10.2 – 6.4 cal ka BP; Mercone et al., 2000).
101 Proxies for deep-water conditions reveal the occurrence of episodes of deep-water overturning reinforcement in
102 the eastern Mediterranean basin at 8.2 ka BP (Rohling et al., 1997, 2015; Kuhnt et al., 2007; Abu-Zied et al.,
103 2008, Siani et al., 2013; Tachikawa et al., 2015), responsible for the interruption of the sapropel S1 in the eastern
104 Mediterranean basin (Mercone et al., 2001; Rohling et al., 2015).

105 Additional insights into Mediterranean circulation changes may be obtained using radiogenic isotopes, such as
106 neodymium, that represent reliable tracers for constraining water-mass mixing and sources (Goldstein and
107 Hemming, 2003, and references therein). It has recently been shown that the neodymium (Nd) isotopic
108 composition, expressed as $\epsilon\text{Nd} = \left(\frac{(^{143}\text{Nd}/^{144}\text{Nd})_{\text{sample}}}{(^{143}\text{Nd}/^{144}\text{Nd})_{\text{CHUR}}} - 1 \right) \times 10000$ (CHUR: Chondritic
109 Uniform Reservoir [Jacobsen and Wasserburg, 1980]) of living and fossil scleractinian CWC faithfully traces
110 intermediate and deep-water mass provenance and mixing of the ocean (e.g. van de Flierdt et al., 2010; Colin et
111 al., 2010; López Correa et al., 2012; Monterro-Serrano et al., 2011, 2013; Copard et al., 2012). Differently from
112 the CWC, the ϵNd composition of fossil planktonic foraminifera is not related to the ambient seawater at
113 calcification depths but reflects the bottom and/or pore water ϵNd , due to the presence of authigenic Fe-Mn
114 coatings precipitated on their carbonate shell (Roberts et al., 2010; Elmore et al., 2011; Piotrowski et al., 2012;
115 Tachikawa et al., 2014; Wu et al., 2015). Therefore, the ϵNd composition of planktonic foraminiferal tests can be
116 used as a useful tracer of deep-water circulation changes in the past, although the effect of pore water on
117 foraminiferal ϵNd values could potentially complicate the interpretation (Tachikawa et al., 2014).

118 In the Mediterranean Sea, modern seawater ϵNd values display a large range from ~-11 to ~-5, and a clear
119 vertical and longitudinal gradient, with more radiogenic values encountered in the eastern basin and typically at
120 intermediate and deeper depths (Spivack and Wasserburg 1988; Henry et al., 1994; Tachikawa et al., 2004;
121 Vance et al., 2004). Considering this large ϵNd contrast, ϵNd recorded in fossil CWC and planktonic
122 foraminifera from the Mediterranean offers great potential to trace intermediate and deep-water mass exchange
123 between the two basins, especially during periods devoid of key epibenthic foraminifera, such as the sapropel S1
124 or ORL1 events.

125 Here, the ϵNd of planktonic foraminifera from a sediment core collected in the Balearic Sea and CWC samples
126 from the Alboran Sea and the Sardinia Channel was investigated to establish past changes of the seawater ϵNd at

127 intermediate depths and constrain hydrological variations of the LIW during the last ~20 kyr. The ϵNd values
128 have been combined with stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotope measurements of benthic (*Cibicidoides*
129 *pachyderma*) and planktonic (*Globigerina bulloides*) foraminifera and sea-surface temperature estimates by
130 modern analogue technique (MAT). Results reveal significant ϵNd variations at intermediate depths in the
131 western basin interpreted as a drastic reduction of the hydrological exchanges between the western and eastern
132 Mediterranean Sea and the subsequent higher proportion of intermediate water produced in the Gulf of Lions
133 during the time interval corresponding to the sapropel S1 deposition.

134

135

136 2. Seawater ϵNd distribution in the Mediterranean Sea

137 The Atlantic Water (AW) enters the Mediterranean Sea as surface inflow through the Strait of Gibraltar with an
138 unradiogenic ϵNd signature of ~ -9.7 in the strait (Tachikawa et al., 2004) and ~ -10.4 in the Alboran Sea
139 (Tachikawa et al., 2004, Spivack and Wasserburg, 1988) for depths shallower than 50 m. During its eastward
140 flowing, AW mixes with upwelled Mediterranean Intermediate Water forming the Modified Atlantic Water
141 (MAW) that spreads within the basin (Millot and Taupier-Letage, 2005) (Fig.1). The surface water ϵNd values
142 (shallower than 50 m) range from -9.8 to -8.8 in the western Mediterranean basin (Henry et al., 1994; Montagna,
143 pers. comm., 2016) and -9.3 to -4.2 in the eastern basin, with seawater off the Nile delta showing the most
144 radiogenic values (Tachikawa et al., 2004; Vance et al., 2004; Montagna, pers. comm., 2016). The surface waters
145 in the eastern Mediterranean basin become denser due to strong mixing and evaporation caused by cold and dry
146 air masses flowing over the Cyprus-Rhodes area in winter, and eventually sink leading to the formation of LIW
147 (Ovchinnikov, 1984; Lascaratos et al., 1993, 1998; Malanotte-Rizzoli et al., 1999; Pinardi and Masetti, 2000).
148 The LIW spreads throughout the entire Mediterranean basin at depths between ~ 150 - 200 m and ~ 600 - 700 m,
149 and is characterized by more radiogenic ϵNd values ranging from -7.9 to -4.8 (average value $\pm 1\sigma$: -6.6 ± 1) in
150 the eastern basin and from -10.4 to -7.58 (-8.7 ± 0.9) in the western basin (Henry et al., 1994; Tachikawa et al.,
151 2004; Vance et al., 2004; Montagna, pers. comm., 2016). The LIW acquires its ϵNd signature mainly from the
152 partial dissolution of Nile River particles (Tachikawa et al., 2004), which have an average isotopic composition
153 of -3.25 (Weldeab et al., 2002), and the mixing along its path with overlying and underlying water masses with
154 different ϵNd signatures. The LIW finally enters the Atlantic Ocean at intermediate depths through the Strait of
155 Gibraltar with an average ϵNd value of -9.2 ± 0.2 (Tachikawa et al., 2004; Montagna, pers. comm., 2016).

156 The WMDW is formed in the Gulf of Lions due to winter cooling and evaporation followed by mixing between
157 the relative fresh surface water and the saline LIW and spreads into the Balearic basin and Tyrrhenian Sea
158 between ~ 2000 m and 3000 m (Millot, 1999; Schroeder et al., 2013) (Fig. 1). The WMDW is characterized by an
159 average ϵNd value of -9.4 ± 0.9 (Henry et al., 1994; Tachikawa et al., 2004; Montagna, pers. comm., 2016).
160 Between the WMDW and the LIW (from ~ 700 to 2000 m), the Tyrrhenian Deep Water (TDW) has been found
161 (Millot et al., 2006), which is produced by the mixing between WMDW and Eastern Mediterranean Deep Water
162 (EMDW) that cascades in the Tyrrhenian Sea after entering from the Strait of Sicily (Millot, 1999, 2009;
163 Astraldi et al., 2001). The TDW has an average ϵNd value of -8.1 ± 0.5 (Montagna, pers. comm., 2016).

164

165 3. Material and methods

166 3.1. Cold-water coral and foraminifera samples

167 Forty-four CWC samples belonging to the species *Lophelia pertusa* and *Madrepora oculata* collected from the
168 Alboran Sea and the Sardinia Channel were selected for this study (Fig. 1). Nineteen fragments were collected at
169 various core depths from a coral-bearing sediment core (RECORD 23; 38°42.18' N; 08°54.75' E; Fig. 1)
170 retrieved from 414 m water depth in the "Sardinian Cold-Water Coral Province" (Taviani et al., 2015) during the
171 R/V Urania cruise "RECORD" in 2013. The core contains well-preserved fragments of *M. oculata* and *L.*
172 *pertusa* embedded in a brownish muddy to silty carbonate-rich sediment. The Sardinian CWC samples were
173 used for U-series dating and Nd isotopic composition measurements. For the southern Alboran Sea, twenty-five
174 CWC samples were collected at water depths between 280 and 442 m in the "eastern Melilla Coral Province"
175 (Fig. 1) during the R/V Poseidon cruise "POS-385" in 2009 (Hebbeln et al. 2009). Eleven samples were
176 collected at the surface of two coral mounds (New Mound and Horse Mound) and three coral ridges (Brittlestar
177 ridges I, II and III), using a box corer and a remotely operated vehicle (ROV). In addition, fourteen CWC
178 samples were collected from various core depths of three coral-bearing sediment cores (GeoB13728, 13729 and
179 13730) retrieved from the Brittlestar ridge I. Details on the location of surface samples and cores collected in the
180 southern Alboran Sea and details on the radiocarbon ages obtained from these coral samples are reported in Fink
181 et al. (2013). Like the CWC sample set from the Sardinia Channel, the dated Alboran CWC samples were also
182 used for further Nd isotopic composition analyses in this study.

183 In addition, a deep-sea sediment core (barren of any CWC fragments) was recovered southwest of the Balearic
184 Sea at 622 m water depth during the R/V Le Suroît cruise "PALEOCINAT II" in 1992 (SU92-33; 35°25.38' N;
185 0°33.86' E; Fig. 1). The core unit, which consists of 2.1 m of grey to brown carbonaceous clays, was sub-
186 sampled continuously at 5-10 cm intervals for a total number of 24 samples used for $\delta^{18}\text{O}$, $\delta^{13}\text{C}$ and ϵNd
187 analyzes.

188

189 **3.2. Analytical procedures on cold-water coral samples**

190 **3.2.1. U/Th dating**

191 The nineteen CWC samples collected from the sediment core RECORD 23 (Sardinia Channel) were analysed for
192 uranium and thorium isotopes to obtain absolute dating using a Thermo ScientificTM Neptune^{Plus} MC-ICPMS
193 installed at the Laboratoire des Sciences du Climat et de l'Environnement (LSCE, Gif-sur-Yvette, France). Prior
194 to analysis, the samples were carefully cleaned using a small diamond blade to remove any visible contamination
195 and sediment-filled cavities. The fragments were examined under a binocular microscope to ensure against the
196 presence of bioeroded zones and finally crushed into a coarse-grained powder with an agate mortar and pestle.
197 The powders (~60-100 mg) were transferred to acid cleaned Teflon beakers, ultrasonicated in MilliQ water,
198 leached with 0.1N HCl for ~ 15 s and finally rinsed twice with MilliQ water. The physically and chemically
199 cleaned samples were dissolved in 3-4 ml dilute HCl (~10%) and mixed with an internal triple spike with known
200 concentrations of ^{229}Th , ^{233}U and ^{236}U , calibrated against a Harwell Uraninite solution (HU-1) assumed to be at
201 secular equilibrium. The solutions were evaporated to dryness at 70°C, redissolved in 0.6 ml 3N HNO₃ and then
202 loaded into 500 μl columns packed with Eichrom UTEVA resin to isolate uranium and thorium from the other
203 major and trace elements of the carbonate matrix. The U and Th separation and purification followed a
204 procedure slightly modified from Douville et al. (2010). The U and Th isotopes were determined following the
205 protocol recently revisited at LSCE (Pons-Branchu et al., 2014). The $^{230}\text{Th}/\text{U}$ ages were calculated from
206 measured atomic ratios through iterative age estimation (Ludwig and Titterton, 1994), using the ^{230}Th , ^{234}U

207 and ^{238}U decay constants of Cheng et al. (2013) and Jaffey et al. (1971). Due to the low ^{232}Th concentration (< 1
208 ng/g; see Table 1), no correction was applied for the non-radiogenic ^{230}Th fraction.

209

210 3.2.2 Nd isotopic composition analyses on cold-water coral fragments

211 Sub-samples of the CWC fragments from the Sardinia Channel used for U-series dating in this study (Table 1) as
212 well as sub-samples of the twenty-five CWC fragments originating from the Alboran Sea, which were already
213 radiocarbon-dated by Fink et al. (2013) (Table 2), were used for further Nd isotopic composition analyses. The
214 fragments (350 to 600 mg) were subjected to a mechanical and chemical cleaning procedure. The visible
215 contaminations, such as Fe-Mn coatings and detrital particles, were carefully removed from the inner and
216 outermost surfaces of the coral skeletons using a small diamond blade. The physically cleaned fragments were
217 ultrasonicated for 10 min with 0.1 N ultra-clean HCl, followed by several MilliQ water rinses and finally
218 dissolved in 2.5 N ultraclean HNO_3 . Nd was separated from the carbonate matrix using Eichrom TRU and LN
219 resins, following the analytical procedure described in detail in Copard et al. (2010).

220 The $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of all purified Nd fractions were analyzed using the ThermoScientific Neptune^{Plus} Multi-
221 Collector Inductively Coupled Plasma Mass Spectrometer (MC-ICP-MS) hosted at LSCE. The mass-
222 fractionation correction was made by normalizing $^{146}\text{Nd}/^{144}\text{Nd}$ to 0.7219 and applying an exponential law.
223 During each analytical session, samples were systematically bracketed with analyses of JNdi-1 and La Jolla
224 standard solutions, which are characterised by accepted values of 0.512115 ± 0.000006 (Tanaka et al., 2000) and
225 0.511855 ± 0.000007 (Lugmair et al., 1983), respectively. Standard JNdi-1 and La Jolla solutions were analysed
226 at concentrations similar to those of the samples (5-10 ppb) and all the measurements affected by instrumental
227 bias were corrected, when necessary, using La Jolla standard. The external reproducibility (2σ) for time resolved
228 measurement, deduced from repeated analyses of La Jolla and JNdi-1 standards, ranged from 0.1 to 0.5 ϵNd
229 units for the different analytical sessions. The analytical error for each sample analysis was taken as the external
230 reproducibility of the La Jolla standard for each session. Concentrations of Nd blanks were negligible compared
231 to the amount of Nd of CWC investigated in this study.

232

233 3.3. Analyses on sediment of core SU92-33

234 3.3.1. Radiocarbon dating

235 Radiocarbon dating was measured at UMS-ARTEMIS (Pelletron 3MV) AMS (CNRS-CEA Saclay, France).
236 Seven AMS radiocarbon (^{14}C) dating were performed in core SU92-33 on well-preserved calcareous tests of the
237 planktonic foraminifera *G. bulloides* in the size fraction $>150 \mu\text{m}$ (Table 3). The age model for the core was
238 derived from the calibrated planktonic ages by applying a mean reservoir effect of ~400 years (Siani et al., 2000,
239 2001). All ^{14}C ages were converted to calendar years (cal. yr BP, BP = AD 1950) by using the INTCAL13
240 calibration data set (Reimer et al., 2013) and the CALIB 7.0 program (Stuiver and Reimer, 1993).

241

242 3.3.2. Stable isotopes

243 Stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotope measurements were performed in core SU92-33 on well-
244 preserved (clean and intact) samples of the planktonic foraminifera *G. bulloides* (250-315 μm fraction) and the
245 epibenthic foraminifera *C. pachyderma* (250-315 μm fraction) using a Finnigan MAT-253 mass spectrometer at
246 the State Key Laboratory of Marine Geology (Tongji University). Both $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values are presented

247 relative to the Pee Dee Belemnite (PDB) scale by comparison with the National Bureau of Standards (NBS) 18
248 and 19. The mean external reproducibility was checked by replicate analyses of laboratory standards and is better
249 than $\pm 0.07\%$ (1σ) for $\delta^{18}\text{O}$ and $\pm 0.04\%$ for $\delta^{13}\text{C}$.

250 3.3.3 *Nd isotope measurements on planktonic foraminifera*

251 Approximately 25 mg of mixed planktonic foraminifera species were picked from the $>63\ \mu\text{m}$ size fraction of
252 each sample already used for stable isotope measurements (Table 4). The samples were gently crushed between
253 glass slides under the microscope to ensure that all chambers were open, and ultrasonicated with MilliQ water.
254 Samples were allowed to settle between ultrasonication steps before removing the supernatant. Each sample was
255 rinsed thoroughly with MilliQ water until the solution was clear and free of clay. The cleaned samples were
256 dissolved in 1N acetic acid and finally centrifuged to ensure that all residual particles were removed, following
257 the procedure described in Roberts et al. (2010). Nd was separated following the analytical procedure reported in
258 Wu et al. (2015). For details on the measurement of Nd isotopes see the section above.

259

260 3.3.4. *Modern analogue technique (MAT)*

261 The palaeo-sea surface temperatures (SST) were estimated using the modern analogue technique (MAT)
262 (Hutson, 1980; Prell, 1985), implemented by Kallel et al. (1997) for the Mediterranean Sea. This method directly
263 measures the difference between the faunal composition of a fossil sample with a modern database, and it
264 identifies the best modern analogues for each fossil assemblage (Prell, 1985). Reliability of SST reconstructions
265 is estimated using a square chord distance test (dissimilarity coefficient), which represents the mean degree of
266 similarity between the sample and the best 10 modern analogues. When the dissimilarity coefficient is lower than
267 0.25, the reconstruction is considered to be of good quality (Overpeck et al., 1985; Kallel et al., 1997). For core
268 SU92-33, good dissimilarity coefficients are <0.2 , with an average value of ~ 0.13 (varying between 0.07 and
269 0.19; Fig. 2a). The calculated mean standard deviation of SST estimates observed in core MD90-917 are ~ 1.5
270 $^{\circ}\text{C}$ from the late glacial period to the Younger Dryas and $\sim 1.2\ ^{\circ}\text{C}$ for the Holocene.

271

272 4. Results

273 4.1. *Cold-water corals*

274 The good state of preservation for the CWC samples from the Sardinia Channel (RECORD 23; Fig. 1) is attested
275 by their initial $\delta^{234}\text{U}$ values (Table 1), which is in the range of the modern seawater value (146.8 ± 0.1 ; Andersen
276 et al., 2010). If the uncertainty of the $\delta^{234}\text{U}_i$ is taken into account, all the values fulfill the so-called “strict” ± 4
277 $\%$ reliability criterion and the U/Th ages can be considered strictly reliable. The coral ages range from
278 0.091 ± 0.011 to 10.904 ± 0.042 ka BP (Table 1), and reveal three distinct clusters of coral age distribution during
279 the Holocene representing periods of sustained coral occurrence. These periods coincide with the Early Holocene
280 encompassing a 700-years-lasting time interval from ~ 10.9 to 10.2 ka BP, the very late Early Holocene at ~ 8.7
281 ka BP, and the Late Holocene starting at ~ 1.5 ka BP (Table 1).

282 Radiocarbon ages obtained for CWC samples collected in the Alboran Sea were published by Fink et al. (2013)
283 (Table 2). They also document three periods of sustained CWC occurrence coinciding with the Bølling–Allerød
284 (B-A) interstadial (13.5 – 12.9 cal ka BP), the Early Holocene (11.2 – 9.8 cal ka BP) and the Mid- to Late Holocene
285 (5.4 – 0.3 cal ka BP).

286 The ϵNd record obtained from the CWC samples from the Alboran Sea displays a narrow range from -9.22 ± 0.30
287 to -8.59 ± 0.3 , which is comparable to the ϵNd record of the planktonic foraminifera from the Balearic Sea over
288 the last 13.5 kyr (Table 2, Fig. 3b). Most of the CWC ϵNd values are similar within error and the record does not
289 reveal any clear difference over the last ~ 13.5 kyr.

290 On the contrary, the CWC samples from the Sardinia Channel display a relatively large ϵNd range, with values
291 varying from -5.99 ± 0.50 to -7.75 ± 0.10 during the Early and Late Holocene, and values as low as -8.66 ± 0.30
292 during the the mid-sapropel S1 deposition (S1a) at ~ 8.7 ka BP (Table 1, Fig. 3c).

293

294

295 **4.2 Core SU92-33**

296 The stratigraphy of core SU92-33 was derived from the $\delta^{18}\text{O}$ variations of the planktonic foraminifera
297 *G. bulloides* (Fig. 2b). The last glacial/interglacial transition and the Holocene encompasses the upper 2.1 m of
298 the core (Fig. 2b). The $\delta^{18}\text{O}$ record of *G. bulloides* shows higher values (~ 3.5 ‰) during the late glacial
299 compared to the Holocene (from ~ 1.5 to 0.8 ‰) exhibiting a pattern similar to those observed in nearby deep-sea
300 cores from the Western Mediterranean Sea (Sierro et al., 2005; Melki et al., 2009).

301 The age model for the upper 1.2 m of the core SU92-33 was based on 7 AMS- ^{14}C age measurements and a
302 linear interpolation between these ages (Table 3, Fig. 2). For the lower portion of the core, a control point was
303 established at the onset of the last deglaciation, which is coeval in the western and central Mediterranean Sea at
304 ~ 17 cal ka BP (Sierro et al., 2005; Melki et al., 2009; Siani et al., 2001). Overall, the upper 2.1 m of core SU92-
305 33 spans the last 19 kyr, with an estimated average sedimentation rate ranging from ~ 15 cm ka^{-1} during the
306 deglaciation to ~ 10 cm ka^{-1} during the Holocene.

307 April-May SST reconstruction was derived from MAT to define the main climatic events recorded in
308 core SU92-33 during the last 19 kyr. SST vary from 8.5°C to 17.5°C with high amplitude variability over the last
309 19 kyr BP (Fig. 2a). The LGM (19-18 ka BP) is characterized by SST values centered at around 12°C . Then, a
310 progressive decrease of $\sim 4^\circ\text{C}$ between 17.8 ka and 16 ka marks the Heinrich Stadial 1 (HS1) (Fig. 2a). A
311 warming phase ($\sim 14^\circ\text{C}$) between 14.5 ka BP and 13.8 ka BP coincides with the B-A interstadial and is followed
312 by a cooling ($\sim 11^\circ\text{C}$) between 13.1 ka BP and 11.8 ka BP largely corresponding to the YD (Fig. 2a). During the
313 Holocene, SST show mainly values of $\sim 16^\circ\text{C}$, with one exception between 7 ka BP and 6 ka BP pointing to an
314 abrupt cooling of $\sim 3^\circ\text{C}$ (Fig. 2a). From the late glacial to the Holocene, SST variations show a similar pattern to
315 that previously observed in the Gulf of Lions and Tyrrhenian Sea (Kallel et al., 1997; Melki et al., 2009) as well
316 as in the Alboran Sea (Martrat et al., 2014; Rodrigo-Gámiz et al., 2014). They are globally synchronous for the
317 main climatic transitions to the well dated South Adriatic Sea core MD90-917 (Siani et al., 2004) confirming the
318 robustness of the SU92-33 age model (Fig. 2a).

319 The $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ records obtained from the benthic foraminifera *C. pachyderma* display significant variations
320 at millennial time scales (Figs. 2c and 2d). The $\delta^{18}\text{O}$ values decrease steadily from ~ 4.5 ‰ during the LGM to
321 ~ 1.5 ‰ during the Holocene, without showing any significant excursion during HS1 and the YD events (Fig.
322 2c), in agreement with results obtained from the neighbor core MD99-2343 (Sierro et al., 2005).

323 The $\delta^{13}\text{C}$ record of *C. pachyderma* shows a decreasing trend since the LGM with a low variability from ~ 1.6 ‰
324 to ~ 0.6 ‰ (Fig. 2d). The heaviest $\delta^{13}\text{C}$ values are related to the LGM (~ 1.6 ‰) while the lightest values (~ 0.6

325 ‰) characterize the Early Holocene and in particular the period corresponding to the sapropel S1 event in the
326 eastern Mediterranean basin (Fig. 2d).

327 The ϵNd values of planktonic foraminifera of core SU92-33 from the Balearic Sea vary within a relatively
328 narrow range between -9.50 ± 0.30 and -8.61 ± 0.30 , with an average value of -9.06 ± 0.28 (Table 2, Fig. 3b). The
329 record shows a slight increasing trend since the LGM, with the more unradiogenic values (average -9.28 ± 0.15 ;
330 $n=7$) being observed in the oldest part of the record (between 18 and 13.5 ka BP), whereas Holocene values are
331 generally more radiogenic (average -8.84 ± 0.22 ; $n=17$) (Fig. 3b).

332

333 **5. Discussion**

334 Overall, the CWC and foraminiferal ϵNd values measured in this study point to a pronounced dispersion at
335 intermediate depth in terms of absolute values and variability in Nd isotopes during the Holocene between the
336 Alboran and Balearic Seas and the Sardinia Channel. Furthermore, the foraminiferal ϵNd record reveals an
337 evolution towards more radiogenic values at intermediate water depth in the Balearic Sea over the last ~19 kyr
338 (Fig. 3).

339 A prerequisite to properly interpret such ϵNd differences and variations through time consists in characterizing
340 first the present-day ϵNd of the main water-mass end-members flowing in the western Mediterranean basin. It is
341 also necessary to evaluate the temporal changes in ϵNd of the end-members since the LGM, and assess the
342 potential influences of lithogenic Nd input and regional exchange between the continental margins and seawater
343 (“boundary exchange”; Lacan and Jeandel, 2001, 2005) on the ϵNd values of intermediate water masses.

344 During its westward flow, the LIW continuously mixes with surrounding waters with different ϵNd signatures
345 lying above and below. For the western Mediterranean basin, these water masses are the MAW/Western
346 Intermediate Water (WIW) and the TDW/WMDW, respectively. Accordingly, a well-defined and gradual ϵNd
347 gradient exists at intermediate depth between the eastern and western Mediterranean basins, with LIW values
348 becoming progressively more unradiogenic towards the Strait of Gibraltar, from -4.8 ± 0.2 at 227 m in the
349 Levantine basin to -10.4 ± 0.2 at 200 m in the Alboran Sea (Tachikawa et al., 2004). Such an ϵNd pattern implies
350 an effective vertical mixing with more unradiogenic water masses along the E-W LIW trajectory ruling out
351 severe isotopic modifications of the LIW due to the local exchange between the continental margins and
352 seawater. Unfortunately, no information exists on the potential temporal variability in ϵNd of the Mediterranean
353 water-mass end-members since the LGM.

354 It has been demonstrated that eolian dust input can modify the surface and sub-surface ϵNd distribution of the
355 ocean in some areas (Arsouze et al., 2009). The last glacial period was associated with an aridification of North
356 Africa (Sarnthein et al., 1981; Hooghiemstra et al., 1987; Moreno et al., 2002; Wienberg et al., 2010) and higher
357 fluxes of Saharan dust to the NE tropical Atlantic (Itambi et al., 2009) and the western Mediterranean Sea
358 characterized by unradiogenic ϵNd values (between -11 ± 0.4 and -14 ± 0.4 ; see synthesis in Scheuven et al.,
359 2013). Bout-Roumazeilles et al. (2013) documented a dominant role of eolian supply in the Siculo-Tunisian
360 Strait during the last 20 ka, with the exception of a significant riverine contribution (from the Nile River) and a
361 strong reduction of eolian input during the sapropel S1 event. Such variations in the eolian input to the
362 Mediterranean Sea are not associated to a significant change in the seawater ϵNd record obtained for the Balearic
363 Sea (core SU92-33) during the sapropel S1 event (Fig. 3). Furthermore, the ϵNd signature of the CWC from the
364 Sardinia Channel (core RECORD 23) shifts to more unradiogenic values (-8.66 ± 0.30) during the sapropel S1

365 event, which is opposite to what expected if it was related to a strong reduction of eolian sediment input. In a
366 recent study, Rodrigo-Gámiz et al. (2015) have documented variations in the terrigenous provenance from a
367 sediment record in the Alboran Sea (core 293G; 36°10.414'N, 2°45.280'W, 1840 m water depth) since the
368 LGM. Radiogenic isotopes (Sr, Nd, Pb) point to changes from North African dominated sources during the
369 glacial period to European dominated source during the Holocene. Nevertheless, the major Sr-Nd-Pb excursions
370 documented by Rodrigo-Gámiz et al. (2015) and dated at ca. 11.5, 10.2, 8.9-8.7, 5.6, 2.2 and 1.1. ka cal BP do
371 not seem to affect the ϵNd values of our foraminifera and coral records.

372 Taken together, these results suggest that changes of eolian dust input since the LGM were not responsible for
373 the observed ϵNd variability at intermediate water depths.

374 Consequently, assuming that the Nd isotopic budget of the western Mediterranean Sea has not been strongly
375 modified since the LGM, the reconstructed variations of the E-W gradient of ϵNd values in the western
376 Mediterranean Sea for the past and notably during the sapropel S1 event (Fig. 3) are indicative of a major
377 reorganization of intermediate water circulation.

378

379 **5.1 Hydrological changes in the Alboran and Balearic Seas since the LGM**

380 The range in ϵNd for the CWC from the Alboran Sea (from -9.22 ± 0.30 to $-8.8.59\pm 0.30$; Table 2) is very close to
381 the one obtained for the planktonic foraminifera from the Balearic Sea (from -9.50 ± 0.30 to -8.61 ± 0.30 ; Table 4,
382 Fig. 3c), suggesting that both sites are influenced by the same intermediate water masses at least for the last 13.5
383 kyr BP. Today, LIW occupies a depth range between ~ 200 and ~ 700 m in the western Mediterranean basin
384 (Millot, 1999; Sparnocchia et al., 1999). More specifically, the salinity maximum corresponding to the core of
385 LIW is found at around 400 m in the Alboran Sea (Millot, 2009) and up to 550 m in the Balearic Sea (López-
386 Jurado et al., 2008). The youngest CWC sample collected in the Alboran Sea with a rather "recent" age of 0.34
387 cal ka BP (Fink et al. 2013) displays an ϵNd value of -8.59 ± 0.30 (Table 2) that is similar to the present-day value
388 of the LIW at the same site (-8.3 ± 0.2) (Dubois-Dauphin et al., submitted) and is significantly different from the
389 WMDW ϵNd signature in the Alboran Sea (-10.7 ± 0.2 , 1270 m water depth; Tachikawa et al., 2004). Considering
390 the intermediate depth range of the studied CWC and foraminifera samples, we can reasonably assume that
391 samples from both sites, in the Balearic Sea (622 m water depth) and in the Alboran Sea (280 to 442 m water
392 depth), record ϵNd variations of the LIW. The ϵNd record obtained from planktonic foraminifera generally
393 displays more unradiogenic and homogenous values before ~ 13 cal ka BP (range from -9.46 to -9.12) compared
394 to the most recent part of the record (range from -9.50 to -8.61), with the highest value of -8.61 ± 0.3 in the Early
395 and Late Holocene.

396 The SST record displays values centered at around 12°C during the LGM with a subsequent rapid SST decrease
397 towards 9°C , highlighting the onset of the HS1 (Fig. 2a). These values are well comparable to recent high-
398 resolution SST data obtained in the Alboran Sea (Martrat et al., 2014; Rodrigo-Gámiz et al., 2014).

399 The $\delta^{18}\text{O}$ record obtained on *G. bulloides* indicates an abrupt 1‰ excursion towards lighter values centered at
400 about 16 cal ka BP (Table 4), synchronous with the HS1 (Fig. 2b), which is similar to the $\delta^{18}\text{O}$ shift reported by
401 Sierra et al. (2005) for a core collected at 2391 m water depth NE of the Balearic Islands (MD99-2343; Fig. 1).
402 As the Heinrich events over the last glacial period are characterized by colder and fresher surface water in the
403 Alboran Sea (Cacho et al., 1999; Pérez-Folgado et al., 2003; Martrat et al., 2004, 2014; Rodrigo-Gámiz et al.,
404 2014) and dry climate on land over the western Mediterranean Sea (Allen et al., 1999; Combourieu-Nebout et

405 al., 2002; Sanchez Goni et al., 2002; Bartov et al., 2003), lighter $\delta^{18}\text{O}$ values of planktonic *G. bulloides* are
406 thought to be the result of the inflow of freshwater derived from the melting of icebergs in the Atlantic Ocean
407 into the Mediterranean Sea (Sierro et al., 2005; Rogerson et al., 2008).

408 During this time interval, the $\delta^{13}\text{C}$ record of *C. pachyderma* from the Balearic Sea (core SU92-33) displays a
409 decreasing $\delta^{13}\text{C}$ trend after ~16 cal ka BP (from 1.4 ‰ to 0.9 ‰; Table 4; Fig. 4a). Moreover, the $\delta^{13}\text{C}$ record
410 obtained on benthic foraminifera *C. pachyderma* from the deep Balearic Sea (core MD99-2343) reveals similar
411 $\delta^{13}\text{C}$ values before ~16 cal ka BP suggesting well-mixed and ventilated water masses during the LGM and the
412 onset of the deglaciation (Sierro et al., 2005).

413 The slightly lower foraminiferal ϵNd values before ~13 cal ka BP could reflect a stronger influence of water
414 masses deriving from the Gulf of Lions as WMDW (ϵNd : -9.4 ± 0.9 ; Henry et al., 1994; Tachikawa et al., 2004;
415 Montagna, pers. comm., 2016). This is in agreement with ϵNd results obtained by Jiménez-Espejo et al. (2015)
416 from planktonic foraminifera collected from deep-water sites (1989 m and 2382 m) in the Alboran Sea (Fig. 4c).
417 Jiménez-Espejo et al. (2015) documented lower ϵNd values (ranging from -10.14 ± 0.27 to -9.58 ± 0.22) during the
418 LGM, suggesting an intense deep-water formation. This is also associated to an enhanced activity of the deeper
419 branch of the MOW in the Gulf of Cádiz (Rogerson et al., 2005; Voelker et al., 2006) linked to the active
420 production of the WMDW in the Gulf of Lions during the LGM (Jiménez-Espejo et al., 2015).

421 The end of the HS1 (14.7 cal ka BP) is concurrent with the onset of the B-A warm interval characterized by
422 increased SST up to 14°C in the Balearic Sea (SU92-33; Fig. 3a), also identified for various sites in the
423 Mediterranean Sea (Cacho et al., 1999; Martrat et al., 2004, 2014; Essallami et al., 2007; Rodrigo-Gámiz et al.,
424 2014). The B-A interval is associated with the so-called melt-water pulse 1A (e.g. Weaver et al., 2003) occurring
425 at around 14.5 cal ka BP. This led to a rapid sea-level rise of about 20 m in less than 500 years and large
426 freshwater discharges in the Atlantic Ocean due to the melting of continental ice sheets (Deschamps et al., 2012),
427 resulting in an enhanced Atlantic inflow across the Strait of Gibraltar. Synchronously, cosmogenic dating of
428 Alpine glacier retreat throughout the western Mediterranean hinterland suggests maximum retreat rates (Ivy-
429 Ochs et al., 2007; Kelly et al., 2006). Overall, these events are responsible for freshening Mediterranean waters
430 and reduced surface water density, and hence, weakened ventilation of intermediate (Toucanne et al., 2012) and
431 deep-water masses (Cacho et al., 2000; Sierro et al., 2005). Similarly, lower benthic $\delta^{13}\text{C}$ values obtained for the
432 Balearic Sea (Fig. 4a) point to less ventilated intermediate water relative to the late glacial. In addition, a
433 decoupling in the benthic $\delta^{13}\text{C}$ values is observed between deep (MD99-2343) and intermediate (core SU92-33)
434 waters after ~16 cal ka BP (Sierro et al. 2005), suggesting an enhanced stratification of the waters masses (Fig.
435 4a). At this time, the shallowest ϵNd record from the deep Alboran Sea (core 300G) shifted towards more
436 radiogenic values, while the deepest one (core 304G) remained close to the LGM values (Jimenez-Espejo et al.,
437 2015) (Fig. 4c). Furthermore, results from the UP10 fraction (particles > 10 μm) of the MD99-2343 sediment
438 core (Fig. 4d) indicate a declining bottom-current velocity at 15 ka BP (Frigola et al., 2008). Rogerson et al.
439 (2008) have hypothesized that during deglacial periods the sinking depth of dense waters produced in the Gulf of
440 Lions was shallower resulting in new intermediate water (WIW) rather than new deep-water (WMDW) as
441 observed today during mild winters (Millot, 1999; Schott et al., 1996). Therefore, intermediate depths of the
442 Balearic Sea could have been isolated from the deep-water with the onset of the T1 (at ~15 ka BP). The reduced
443 convection in the deep western Mediterranean Sea together with the shoaling of the nutricline (Rogerson et al.,
444 2008) led to the deposition of the ORL 1 (14.5 to 8.2 ka B.P; Cacho et al., 2002) and dysoxic conditions below

445 2000 m in agreement with the absence of epibenthic foraminifera such as *C. pachyderma* after 11 cal ka BP in
446 MD99-2343 (Sierro et al., 2005) (Fig. 4a).

447 After 13.5 ka BP, planktonic foraminifera ϵNd values from the Balearic Sea (core SU92-33) become more
448 radiogenic and are in the range of CWC ϵNd values from the Alboran Sea (Fig. 4b). These values may reveal a
449 stronger influence of the LIW in the Balearic Sea during the Younger Dryas, as also supported by the sortable
450 silt record from the Tyrrhenian Sea (Toucanne et al., 2012) (Fig. 4e). Deeper depths of the Alboran Sea also
451 record a stronger influence of the LIW with an ϵNd value of -9.1 ± 0.4 (Jimenez-Espejo et al., 2015). In addition,
452 a concomitant activation of the upper MOW branch, as reconstructed from higher values of Zr/Al ratio in
453 sediments of the Gulf of Cádiz, can be related to the enhanced LIW flow in the western Mediterranean Sea (Fig.
454 4f) (Bahr et al., 2015).

455 The time of sapropel S1 deposition (10.2 – 6.4 ka) is characterized by a weakening or a shutdown of
456 intermediate- and deep-water formation in the eastern Mediterranean basin (Rossignol-Strick et al., 1982; Cramp
457 and O’Sullivan, 1999; Emeis et al., 2000; Rohling et al., 2015). At this time, planktonic foraminifera ϵNd values
458 from intermediate water depths in the Balearic Sea (core SU92-33) remain high (between -9.15 ± 0.3 and
459 -8.61 ± 0.3) (Fig. 4b). On the other hand, the deeper Alboran Sea provides a value of -9.8 ± 0.3 pointing to a
460 stronger contribution of WMDW (Jimenez-Espejo et al., 2015), coeval with the recovery of deep-water activity
461 from core MD99-2343 (Frigola et al., 2008).

462

463 **5.2 Hydrological changes in the Sardinia Channel during the Holocene**

464 The present-day hydrographic structure of the Sardinia Channel is characterized by four water masses, with the
465 surface, intermediate and deep-water masses being represented by MAW, LIW and TDW/WMDW, respectively
466 (Astraldi et al., 2002a; Millot and Taupier-Lepage, 2005). In addition, the WIW, flowing between the MAW and
467 the LIW, has also been observed along the Channel (Sammari et al., 1999). The core of the LIW is located at
468 400-450 m water depth in the Tyrrhenian Sea (Hopkins, 1988; Astraldi et al., 2002b), which is the depth range of
469 CWC samples from the Sardinia Channel (RECORD 23; 414 m) (Taviani et al., 2015). The youngest CWC
470 sample dated at ~ 0.1 ka BP has an ϵNd value of -7.70 ± 0.10 (Table 1, Fig. 5), which is similar within error to the
471 value obtained from a seawater sample collected at 451 m close to the coral sampling location (-8.0 ± 0.4 ;
472 Montagna, pers. comm., 2016).

473 The CWC dating from the Sardinia Channel shows three distinct periods of sustained coral occurrence in this
474 area during the Holocene, with each displaying a large variability in ϵNd values. CWC from the Early Holocene
475 (10.9-10.2 ka BP) and the Late Holocene (<1.5 ka BP) exhibit similar ranges of ϵNd values (ranging from
476 -5.99 ± 0.50 to -7.75 ± 0.20 ; Table 1, Fig 5c). Such variations are within the present-day ϵNd range being
477 characteristic for intermediate waters in the eastern Mediterranean Sea (-6.6 ± 1.0 ; Tachikawa et al., 2004; Vance
478 et al., 2004). However, the CWC ϵNd values are more radiogenic than those observed at mid-depth in the
479 present-day western basin (ranging from -10.4 ± 0.2 to -7.58 ± 0.47 ; Henry et al., 1994; Tachikawa et al., 2004;
480 Montagna, pers. comm., 2016), suggesting a stronger LIW component in the Sardinia Channel during the Early
481 and Late Holocene. The Sardinian CWC ϵNd variability also reflects the sensitivity of the LIW to changes in the
482 eastern basin such as rapid variability of the Nile River flood discharge (Revel et al., 2014; 2015; Weldeab et al.,
483 2014) or a modification through time in the proportion between the LIW and the Cretan Intermediate Water
484 (CIW). Today, the intermediate water outflowing from the Strait of Sicily is composed by ~ 66 to 75 % of LIW

485 and 33 to 25 % of CIW (Manca et al., 2006; Millot, 2014). As the CIW is formed in the Aegean Sea, this
486 intermediate water mass is generally more radiogenic than LIW (Tachikawa et al., 2004; Montagna, pers.
487 comm., 2016). Following this hypothesis, a modification of the mixing proportion between the CIW and the
488 LIW may potentially explain values as radiogenic as about -6 in the Sardinia Channel during the Early and Late
489 Holocene (Fig. 5c). However, a stronger LIW and/or a CIW contribution cannot be responsible for ϵNd values as
490 low as -8.66 ± 0.30 observed during the sapropel S1 event at 8.7 ka BP (Table 1, Fig. 5c). Considering that such
491 unradiogenic value is not observed at intermediate depth in the modern eastern Mediterranean basin, the most
492 plausible hypothesis suggested here is that the CWC were influenced by a higher contribution of intermediate
493 water from the western basin.

494

495 *5.3 Hydrological implications for the intermediate water masses of the western Mediterranean Sea*

496 The ϵNd records of the Balearic Sea, Alboran Sea and Sardinia Channel document a temporal variability of the
497 east-west gradient in the western Mediterranean basin during the Holocene. The magnitude of the gradient
498 ranges from ~ 1.5 to ~ 3 ϵ units during the Early and Late Holocene and it is strongly reduced at 8.7 ka BP,
499 coinciding with the sapropel S1 event affecting the eastern Mediterranean basin (Fig. 5). Such variations could
500 be the result of a modification of the Nd isotopic composition of intermediate water masses due to changes of the
501 LIW production through time and a higher contribution of the western-sourced intermediate water towards the
502 Sardinia Channel coinciding with the sapropel S1 event.

503 The LIW acquires its radiogenic ϵNd in the Mediterranean Levantine basin mainly from Nd exchange between
504 seawater and lithogenic particles originating mainly from Nile River (Tachikawa et al., 2004). A higher sediment
505 supply from the Nile River starting at ~ 15 ka BP was documented by a shift to more radiogenic ϵNd values of
506 the terrigenous fraction obtained from a sediment core having been influenced by the Nile River discharge
507 (Revel et al., 2015) (Fig. 5e). Others studies pointed to a gradual enhanced Nile River runoff as soon as 14.8 ka
508 BP and a peak of Nile discharge from 9.7 to 8.4 ka recorded by large increase in sedimentation rate from 9.7 to
509 8.4 ka (>120 cm/ka) (Revel et al., 2015; Weldeab et al., 2014; Castaneda et al., 2016). Similarly, enhanced Nile
510 discharge at ~ 9.5 cal kyr B.P was inferred based on $\delta^{18}\text{O}$ in planktonic foraminifera from a sediment core in the
511 southeast Levantine Basin (PS009PC ($32^\circ 07.7' \text{N}$, $34^\circ 24.4' \text{E}$; 552 m water depth) (Hennekam et al., 2014). This
512 increasing contribution of the Nile River to the eastern Mediterranean basin has been related to the African
513 Humid Period (14.8–5.5 ka BP; Shanahan et al., 2015), which in turn was linked to the precessional increase in
514 Northern Hemisphere insolation during low eccentricity (deMenocal et al., 2000; Barker et al., 2004; Garcin et
515 al., 2009). An increasing amount of radiogenic sediments dominated by the Blue/Atbara Nile River contribution
516 (Revel et al., 2014) could have modified the ϵNd of surface water towards more radiogenic values (Revel, pers.
517 comm., 2016). Indeed, planktonic foraminifera ϵNd values as high as ~ -3 have been documented in the eastern
518 Levantine Basin (ODP site 967; $34^\circ 04.27' \text{N}$, $32^\circ 43.53' \text{E}$; 2553 m water depth) during the sapropel S1 event as a
519 result of enhanced Nile flooding (Scrivner et al., 2004). The radiogenic signature was likely transferred to
520 intermediate depth as a consequence of the LIW formation in the Rhodes Gyre, and it might have been
521 propagated westwards towards the Sardinia Channel.

522 Therefore, considering the more unradiogenic value of the CWC samples from the Sardinia Channel during the
523 sapropel S1a event, it is very unlikely that eastern-sourced water flowed at intermediate depth towards the
524 Sardinia Channel. A possible explanation could be the replacement of the radiogenic LIW that was no longer

525 produced in the eastern basin (Rohling, 1994) by less radiogenic western intermediate water (possibly WIW).
526 Such a scenario could even support previous hypotheses that invoke a potential circulation reversal in the eastern
527 Mediterranean from anti-estuarine to estuarine during sapropel formation (Huang and Stanley, 1972; Calvert,
528 1983; Sarmiento et al., 1988; Buckley and Johnson, 1988; Thunell and Williams, 1989). An alternative
529 hypothesis would be that reduced surface water densities in the eastern Mediterranean during sapropel S1
530 resulted in the LIW sinking to shallower depths than at present. As a result of this shoaling, CWC from the
531 Sardinia Channel would have been bathed by underlying Western Intermediate Water during the sapropel S1a
532 event.

533

534 **6. Conclusions**

535 The foraminiferal ϵNd record from intermediate depths in the Balearic Sea reveals a relatively narrow range of
536 ϵNd values varying between -9.50 and -8.61 since the LGM (~20 ka). Between 18 and 13.5 cal ka BP, the more
537 unradiogenic ϵNd values support a vigorous deep overturning in the Gulf of Lions while $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values
538 indicate a stratification of the water masses after 16 cal ka BP. The stratification together with a decrease of the
539 deep-water intensity led to more radiogenic values after ~13 cal ka BP. The foraminiferal ϵNd record, supported
540 by ϵNd values from CWC in the Alboran Sea, shows only minor changes in neodymium isotopes from 13.5 cal
541 ka BP to 0.34 cal ka BP, suggesting that the westernmost part of the western Mediterranean basin is not very
542 sensitive to hydrological variations of the LIW.

543 On the contrary, CWC located at the depth of the LIW in the Sardinia Channel exhibit large ϵNd variations
544 (between -7.75 ± 0.10 and -5.99 ± 0.50) during the Holocene, suggesting either the role of the Nile River in
545 changing the ϵNd of the LIW in the eastern Mediterranean basin or a variable LIW/CIW mixing of the water
546 outflowing from the Strait of Sicily. At the time of the sapropel S1 event at ~8.7 ka BP, CWC display a shift
547 toward lower values (-8.66 ± 0.30), similar to those obtained at intermediate depths in the westernmost part of the
548 western basin. This suggests that western-sourced intermediate water likely filled mid-depth of the southern
549 Sardinia, replacing LIW that was no longer produced (or heavily reduced) in the eastern basin. These results
550 could potentially support a reversal of the Mediterranean circulation, although this assumption needs further
551 investigation to be confirmed.

552

553 **Acknowledgements**

554 The research leading to this study has received funding from the French National Research Agency
555 “Investissement d’Avenir” (n°ANR-10-LABX-0018), the HAMOC project ANR-13-BS06-0003, the
556 MISTRALS/PALEOMEX/COFIMED and ENVIMED/Boron Isotope and Trace Elements project. This work
557 contributes to the RITMARE project. We thank Hiske Fink for selecting and kindly providing the cold-water
558 corals samples from the Alboran Sea. We further thank François Thil and Louise Bordier for their support with
559 Nd isotopic composition analyses. Paolo Montagna is grateful for financial support from the Short Term
560 Mobility Program (CNR). Thanks are also extended to the captains, crews, chief scientists, and scientific parties
561 of research cruises RECORD (R/V Urania), POS-385 (R/V Poseidon) and PALEOCINAT II (R/V Le Suroît).

972 **Table captions**

973

974 **Table 1.** U-series ages and ϵNd values obtained for cold-water coral samples collected from sediment core RECORD 23
975 (Sardinia Channel).

976

977 **Table 2.** ϵNd values obtained for cold-water corals from the southern Alboran Sea. The AMS ^{14}C ages published by Fink et
978 al. (2013) are also reported as Median probability age (ka BP).

979

980 **Table 3.** AMS ^{14}C ages of samples of the planktonic foraminifer *G. bulloides* from ‘off-mound’ sediment core SU92-33. The
981 AMS ^{14}C ages were corrected for ^{13}C and a mean reservoir age of 400 yrs, and were converted into calendar years using the
982 INTCAL13 calibration data set (Reimer et al., 2013) and the CALIB 7.0 program (Struiver et al., 2005).

983

984 **Table 4.** Multiproxy data obtained for the upper 2.1 m of sediment core SU92-33 (Balearic Sea). Stable oxygen and carbon
985 isotopes were measured on benthic (*C. pachyderma*) and planktonic (*G. bulloides*) foraminifera; ϵNd values were obtained on
986 mixed planktonic foraminifera samples. The age results from a combination of 7 AMS- ^{14}C age measurements for the upper
987 1.2 m of the core and by a linear interpolation between these ages as well as the $\delta^{18}\text{O}$ variations of the planktonic
988 foraminifera *G. bulloides*.

989

990 **Figure captions**

991

992 **Figure 1.** Map of the western Mediterranean Sea showing the locations of samples investigated in this study. Yellow dot
993 indicates the sampling location of the sediment core from the Balearic Sea (SU92-33); yellow stars indicate the locations of
994 the CWC-bearing cores from the Sardinia Channel (RECORD 23) and the southern Alboran Sea (for further details on the
995 CWC from the Alboran Sea refer also to Fink et al., 2013). The cores discussed in this paper (Gulf of Cádiz: IODP site
996 U1387, Balearic Sea: MD09-2343, northern Tyrrhenian Sea: MD01-2472, Adriatic Sea: MD90-917) are indicated by black
997 dots, and seawater stations are marked by open squares. Arrows represent the main oceanographic currents. The black line
998 shows the general trajectory of the Modified Atlantic Water (MAW) flowing at the surface from the Atlantic Ocean toward
999 the western and eastern Mediterranean. The orange line represents the Levantine Intermediate Water (LIW) originating from
1000 the eastern basin. The black dashed line shows the trajectory of the Western Mediterranean Deep Water (WMDW) flowing
1001 from the Gulf of Lions toward the Strait of Gibraltar.

1002

1003 **Figure 2.** (a) Sea Surface Temperature (SST) records of cores SU92-33 (red line) and MD90-917 (green line; Siani et al.,
1004 2004), (b) $\delta^{18}\text{O}$ record obtained on planktonic foraminifer *G. bulloides* for core SU92-33, (c) $\delta^{18}\text{O}$ record obtained on benthic
1005 foraminifer *C. pachyderma* for core SU92-33, (d) $\delta^{13}\text{C}$ record obtained on benthic foraminifer *C. pachyderma* for core SU92-
1006 33. LGM: Last Glacial Maximum; HS1: Heinrich Stadial 1; B-A: Bølling-Allerød; YD: Younger Dryas. Black triangles
1007 indicate AMS ^{14}C age control points.

1008

1009 **Figure 3.** (a) Sea Surface Temperature (SST) record of core SU92-33 (red line), (b) ϵNd records obtained on mixed
1010 planktonic foraminifers from core SU92-33 (open circles) and from cold-water coral fragments collected in the Alboran Sea
1011 (red squares), (c) ϵNd values of cold-water corals from core RECORD 23 (Sardinia Channel).

1012

1013 **Figure 4.** (a) $\delta^{13}\text{C}$ records obtained on benthic foraminifer *C. pachyderma* for cores SU92-33 (red line) and MD99-2343
1014 (blue line; Sierro et al., 2005). (b) ϵNd records obtained on mixed planktonic foraminifers from core SU92-33 (open circles)
1015 and from cold-water coral fragments collected in the Alboran Sea (red squares). Modern ϵNd values for LIW (orange dashed
1016 line) and WMDW (blue dashed line) are also reported for comparison. (c) ϵNd values obtained for planktonic foraminifera
1017 with Fe-Mn coatings at sites 300G (36°21.532' N, 1°47.507' W; 1860 m; open dots) and 304G (36°19.873' N, 1°31.631' W;
1018 2382 m; black dots) in Alboran Sea (Jimenez-Espejo et al., 2015). (d) UP10 fraction (>10 μm) from core MD99-2343
1019 (Frigola et al., 2008). (e) Sortable silt mean grain-size of core MD01-2472 (Toucanne et al., 2012). (f) Ln Zr/Al ratio at IODP
1020 site U1387 (36°48.3' N 7°43.1' W; 559 m) (Bahr et al., 2015).

1021
1022 **Figure 5.** (a) $\delta^{18}\text{O}$ record obtained on planktonic foraminifer *G. bulloides* for core SU92-33, (b) $\delta^{13}\text{C}$ records obtained on
1023 benthic foraminifer *C. pachyderma* for core SU92-33, (c) ϵNd values of cold-water corals from core RECORD 23 (Sardinia
1024 Channel), (d) ϵNd values records obtained on mixed planktonic foraminifera from core SU92-33 (open circles) and from
1025 cold-water coral fragments collected in the Alboran Sea (red squares), (e) ϵNd values obtained on terrigenous fraction of
1026 MS27PT located close the Nile River mouth in the eastern Mediterranean basin (Revel et al., 2015).
