**Abstract.** The ocean's ability to store large quantities of carbon, combined with the millennial longevity over which this reservoir is overturned, has implicated the ocean as a key driver of glacial-interglacial climates. However, the combination of processes that cause an accumulation of carbon within the ocean during glacial periods is still under debate. Here we present simulations of the Last Glacial Maximum (LGM) using the CSIRO Mk3L-COAL Earth System Model to test the contribution of physical and biogeochemical processes to ocean carbon storage. For the LGM simulation, we find a significant global cooling of the surface ocean (3.2 °C) and the expansion of both minimum and maximum sea ice cover broadly consistent with proxy reconstructions. The glacial ocean stores an additional 267 Pg C in the deep ocean relative to the Pre-Industrial (PI) simulation due to stronger Antarctic Bottom Water formation. However, 889 Pg C is lost from the upper ocean via equilibration with a lower atmospheric CO<sub>2</sub> concentration and a global decrease in export production, causing a net loss of carbon relative to the PI ocean. The LGM deep ocean also experiences an oxygenation (>100 mmol O<sub>2</sub> m<sup>-3</sup>) and deepening of the calcite saturation horizon (exceeds the ocean bottom) at odds with proxy reconstructions. With modifications to key biogeochemical processes, which include an increased export of organic matter due to a simulated release from iron limitation, a deepening of remineralisation and decreased inorganic carbon export driven by cooler temperatures, we find that the carbon content of the glacial ocean can be sufficiently increased (317 Pg C) to explain the reduction in atmospheric and terrestrial carbon at the LGM (194 ± 2 and 330 ± 400 Pg C, respectively). Assuming an LGM-PI difference of 95 ppm pCO<sub>2</sub>, we find that 55 ppm can be attributed to the biological pump, 28 ppm to circulation changes, and the remaining 12 ppm to solubility. The biogeochemical modifications also improve model-proxy agreement in export production, carbonate chemistry and dissolved oxygen fields. Thus, we find strong evidence that variations in the oceanic biological pump exert a primary control on the climate.

Keywords: CO<sub>2</sub>, biological pump, palaeoclimate modelling, Pleistocene, ocean biogeochemistry

## 1 Introduction

The late Pleistocene is characterised by a sawtooth-like cycling between cool glacial and warm interglacial states (Emiliani, 1966; Shackleton, 1967). Global temperatures and atmospheric CO<sub>2</sub> are strongly correlated across these climate cycles with approximately 80-100 ppm of change corresponding to global-mean temperature variations of 3-4 °C (Grootes and Stuiver, 1997; Jouzel et al., 1987; Parrenin et al., 2013; Petit et al., 1999). This correlation was extended to causation by evidence that increases in atmospheric CO<sub>2</sub> preceded decreases in global ice mass during glacial terminations (Sowers et al., 1991; Broecker and Henderson, 1998). The large potential of the ocean to store carbon, coupled with evidence that the terrestrial reservoir was diminished under glacial conditions (Shackleton, 1977), has implicated the ocean as the prime candidate for driving glacial-interglacial changes in atmospheric CO<sub>2</sub> (Broecker, 1982; Skinner et al., 2015; Wilson et al., 2015). However, identifying the combination of mechanisms that drove a flux of carbon into the ocean during glacial periods remains a fundamental and largely unresolved problem.

If we first consider only physical changes, a net influx of CO<sub>2</sub> caused by cooling is a feature of the glacial ocean. However, the increase in solubility attributed to cooling is partially offset by increased salinity due to a lower sea level (Siddall et al., 2003), so that the contribution of solubility changes is estimated at ~13 ppm of the total 80-100 ppm CO<sub>2</sub> drawdown (Sigman and Boyle, 2000; Kohfeld and Ridgwell, 2009). Therefore, other physical changes associated with a glacial climate, notably changes to the large-scale circulation and sea ice fields (Stephens and Keeling, 2000), may make a considerable contribution to carbon sequestration. Proxy evidence (Curry and Oppo, 2005; Duplessy et al., 1988; McManus et al., 2004; Oliver et al., 2010; Skinner et al., 2010) and model experiments (Brovkin et al., 2007; Hain et al., 2010; Menviel et al., 2012; Watson and Naveira Garabato, 2006) of the glacial climate have shown that a greater proportion of the deep ocean was dominated by southern source waters (see Adkins, 2013, for a review). The existence of this glacial-type circulation has been connected to an expanded sea ice field (Ferrari et al., 2014). An expansion of southern source waters throughout the deep ocean and an expanded sea ice field are now considered to be primary candidates for carbon sequestration during glacial climates (Adkins, 2013).

However, the most promising explanations of the glacial decline in atmospheric CO<sub>2</sub> involve changes to ocean productivity in concert with reorganisations of the global overturning circulation (Hain et al., 2010; Gottschalk et al., 2016). An increased glacial productivity, first proposed by Broecker (1982) and explored by Archer et al. (2000) by increasing the global nutrient inventory, is now an established feature of the sub-Antarctic zone due to enhanced aeolian deposition of iron (Martinez-Garcia et al., 2014). The Southern Ocean exerts a strong control on atmospheric CO<sub>2</sub> through its direct connection deep waters (Marinov et al., 2006), and enhanced productivity in this zone is thus a prime candidate for explaining a fraction of the glacial-interglacial CO<sub>2</sub> difference.

In numerous other regions, however, productivity appears to have been reduced during glacial climates. The affected regions

include waters south of the Antarctic Polar Front (Francois et al., 1997; Jaccard et al., 2013), the North Pacific (Crusius et al., 2004; Jaccard et al., 2005; Kohfeld and Chase, 2011; Ortiz et al., 2004), tropical Indian Ocean (Singh et al., 2011) and the Equatorial Pacific (Costa et al., 2016; Herguera, 2000; Loubere et al., 2007). A weaker export production in these regions would have offset a strengthened biological pump in the sub-Antarctic, thereby weakening the ability of the ocean to store carbon during glacial conditions. Whether the strengthening of the biological pump in the glacial sub-Antarctic was sufficient to increase the carbon content of the ocean despite losses in productivity in other regions therefore requires further testing.

This has led some authors to look for alternative biogeochemical mechanisms. A notable example is the application of temperature-dependent remineralisation to global fluxes of organics into the interior ocean. The positive relationship between microbial metabolism and temperature has been known for some time (Eppley, 1972), but it was only recently that this relationship was applied to a glacial setting. By prescribing a global cooling of 5 °C, Matsumoto (2007) reduced atmospheric CO<sub>2</sub> by ~35 ppm. Further research has shown that even a slight deepening in the remineralisation profile can cause large changes in oceanic carbon content by reducing surface ocean inorganic carbon concentrations, which in turn strengthens the air-sea influx of carbon (Menviel et al., 2012).

Another biogeochemical mechanism that is proposed to increase oceanic carbon storage is an altered calcium carbonate to organic carbon (CaCO<sub>3</sub>:C<sub>org</sub>) export production ratio (Sigman et al., 1998; Archer et al., 2000). A global decrease in the CaCO<sub>3</sub>:C<sub>org</sub> ratio would enhance carbon storage by reducing the pCO<sub>2</sub> of surface waters (see Sigman and Boyle, 2000, for a review). A decrease in CaCO<sub>3</sub> production could be caused by cooling (Stoll et al., 2002) and/or an increase in silicate delivery to the lower latitude oceans that simulated organic carbon production (Matsumoto et al., 2002).

Numerous physical and biogeochemical changes have been associated with a glacial ocean and all have been identified in some respect as important drivers of glacial-interglacial climate cycles. Now, recent insights into the distributions of dissolved oxygen (Jaccard et al., 2014) and carbonate species (Yu et al., 2014) at the Last Glacial Maximum (LGM; ~21,000 years BCE) provide new constraints to identify which combination of physical and biogeochemical changes could have realistically sequestered carbon within the ocean at this time. Here, we use an Earth System Model with attached biogeochemistry, CSIRO Mk3L-COAL, to test current theories against these new insights. Using our simulated LGM ocean state, we quantify the contribution of physical and biogeochemical changes to the estimated increased of 520 ± 400 Pg of carbon within the oceanic reservoir at the LGM (Ciais et al., 2011), and demonstrate the importance of marine biogeochemistry to global climate.

## 2 Model and experiments

The model simulations were performed using the CSIRO Mk3L climate system model version 1.2 (Phipps et al., 2011, 2012), which includes components that describe the atmosphere, land, sea ice and ocean. The horizontal resolution of the atmosphere,

land and sea ice models are  $5.6^{\circ} \times 3.2^{\circ}$  in the longitudinal and latitudinal dimensions, respectively, with 18 vertical levels. The ocean model has a horizontal resolution of  $2.8^{\circ} \times 1.6^{\circ}$  with 21 vertical levels. For this study, we conduct simulations using both the full climate system model and the stand-alone ocean model.

5 Two fully coupled model experiments were undertaken to simulate the Pre-Industrial (Cpl-PI) and Last Glacial Maximum (Cpl-LGM) climates. The Cpl-PI climate was obtained by forcing the model with an atmospheric  $\text{CO}_2$  concentration of 280 ppm and by prescribing 1950 CE values for the orbital parameters. This experiment was integrated for a total of 10,000 years (Phipps et al., 2013). The Cpl-LGM simulation followed the protocol developed by Phase III of the Palaeoclimate Modelling Intercomparison Project (PMIP3), with the exception that no changes were made to terrestrial topography, oceanic bathymetry  
10 or the positions of the coastlines. The closure of important oceanic connections due to sea level loss, such as the Bering Strait, was not considered. The atmospheric  $\text{CO}_2$  equivalent concentration was set to 167 ppm, providing a radiative forcing equivalent to the specified reductions in the atmospheric concentrations of  $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{N}_2\text{O}$  from 280 ppm/760 ppb/270 ppb for pre-industrial simulations to 185 ppm/350 ppb/200 ppb for LGM simulations. The orbital parameters were set to values for 21,000 years BP. The Cpl-LGM simulation was initialised from the state of the Cpl-PI simulation at the end of model year 100.  
15 The model was then integrated for a total of 3,900 model years, until it had reached quasi-equilibrium. Over this integration the ocean experienced an increase in salinity by 0.5 psu due to increased evaporation, which reflected the coupling between a cooler, drier atmosphere and the ocean.

With the climate state provided by the Cpl-LGM experiment, nine additional ocean biogeochemical simulations were made  
20 with different physical and biogeochemical conditions to explore the effect on the carbon cycle (Table 1). These experiments utilised Mk3L-COAL (Carbon-Ocean-Atmosphere-Land), an enhanced version of the Mk3L climate system model which includes biogeochemical modules embedded within the ocean, atmosphere and terrestrial models. All experiments were forced by key boundary conditions (wind stresses, temperature, salinity, incident radiation, sea ice), which were obtained as monthly averages over the final 50 years of the fully coupled model experiments. The heat and freshwater fluxes into the ocean were  
25 determined by relaxing the SST and SSS towards the prescribed fields using a 20 day timescale. An additional 0.5 psu was added to the salinity field of the LGM experiments to ensure that the ocean was 1 psu more saline than the PI. For a description of the ocean biogeochemistry the reader is directed towards Appendix A of Matear and Lenton (2014) and the experiments of Duteil et al. (2012).

30 First, five experiments were conducted to explore how the physics of a glacial ocean affected carbon content. Two experiments, O-PI and O-LGM, were completed under standard PI and LGM conditions. These standard experiments were compared with three additional experiments that together were used to discern how changes in solubility, sea ice and circulation between the PI and LGM climates affected carbon. One of these experiments, O-PI $_{\text{CO}_2}^{\text{LGM}}$ , involved a standard PI simulation with prescribed atmospheric  $p\text{CO}_2$  concentrations of the LGM (185 ppm). This allowed direct comparison between experiments O-  
35 LGM and O-PI $_{\text{CO}_2}^{\text{LGM}}$  to determine how global physical changes affected carbon storage. To separate the effects of an expanded

sea ice field, solubility changes, and circulation changes at the LGM, another two PI experiments, O-PI<sub>ice</sub><sup>LGM</sup> and O-PI<sub>sol</sub><sup>LGM</sup>, were completed. These experiments were forced by PI physics, such that a PI circulation was present, but the biogeochemical model responded to the sea ice field and sea surface conditions (temperature and salinity) of the LGM, respectively, under an atmospheric  $p\text{CO}_2$  of 185 ppm. An atmosphere  $p\text{CO}_2$  of 185 ppm was chosen for direct comparison with experiment O-PI<sub>CO<sub>2</sub></sub><sup>LGM</sup>.

5

Second, four experiments, O-LGM<sub>poc</sub><sup>BGC</sup>, O-LGM<sub>rem</sub><sup>BGC</sup>, O-LGM<sub>pic</sub><sup>BGC</sup> and O-LGM<sub>all</sub><sup>BGC</sup>, represented LGM experiments in which the equations controlling biogeochemical cycling were altered. It should be made clear that these experiments did not explicitly simulate the biogeochemical changes caused by an altered climate in any mechanistic sense. However, the prescription of the following changes allowed us to undertake a theoretical investigation into their capacity to sequester carbon at the LGM. The 10 experiments were as follows:

**O-LGM<sub>poc</sub><sup>BGC</sup>.** The scaling factor ( $S_{npp}^O$ ) was increased by a factor of 10 (Eq. (1)) to increase the export of Particulate Organic Carbon (POC) from the surface ocean, and therefore strengthen the biological carbon pump. Increasing POC export in the LGM ocean was motivated by an enhanced delivery of iron to the surface ocean via aeolian dust at the LGM (Martin, 1990; 15 Martinez-Garcia et al., 2014).

$$POC = S_{npp}^O \cdot V_{max} \cdot \min\left(\frac{[PO_4]}{[PO_4] + P_k}, F(I)\right) \quad (1)$$

where,

$V_{max}$  = The temperature-dependent maximum growth of phytoplankton (Eppley, 1972)

$P_k$  = The half-saturation constant for nutrient-limited growth, set to 0.1 mmol PO<sub>4</sub> m<sup>-3</sup>

20

$F(I)$  = The productivity versus irradiance equation for determining light-limited growth (Clementson et al., 1998)

**O-LGM<sub>rem</sub><sup>BGC</sup>.** The POC remineralisation depth was increased by changing the power law exponent ( $b$ ) in Equation (2) from -0.9 to -0.7, which replicated a bulk shift of POC from the upper to the deep ocean. The motivation for increasing the amount of POC that reaches deeper levels is the expectation that a cooler ocean would reduce the rate of bacterial remineralisation of POC in the upper ocean (Rivkin and Legendre, 2001; Matsumoto, 2007). This change increased the simulated POC that 25 reaches the 1,000 m depth level from 12.5 % to 20 %.

$$Remin(z) = \min\left(1, \left(\frac{z}{100}\right)^b\right) \quad (2)$$

**O-LGM<sub>pic</sub><sup>BGC</sup>.** Export production of Particulate Inorganic Carbon (PIC) was turned off by setting the rain ratio ( $R_{PIC}$ ) of PIC:POC to zero in Equation (3). The motivation for reducing PIC export in the glacial ocean is related to the positive linear relationship between calcification and temperature (Stoll et al., 2002), and an increased silicate supply to lower latitudes that 30 potentially favoured non-calcifying producers (Matsumoto et al., 2002).

$$PIC = POC \cdot R_{PIC} \quad (3)$$

**O-LGM<sub>all</sub><sup>BGC</sup>**. All three modifications to ocean biogeochemistry were employed. All ocean-only simulations were integrated for 10,000 years to ensure that the ocean carbon cycle reached a steady state.

To assess whether the behaviour of the biogeochemical tracers within the coupled model differed from those in the ocean-only model, we ran the coupled model with online ocean biogeochemistry for a further 1,000 years using the steady-state biogeochemical fields from the ocean-only experiments. This assessment was made using both the PI and LGM climates. For key diagnostics, such as the meridional overturning circulation, ocean carbon content and global export production, the behaviour of the ocean-only simulation differed by less than 1 % from the coupled simulations. Given the computational speed of the ocean-only model, these experiments provide an ideal platform to test the sensitivity of the ocean biogeochemical fields to the parameterisations used in the biogeochemical model.

### 3 Results and discussion

In the following, we first discuss the simulated physical changes to the ocean observed between the Cpl-PI and Cpl-LGM simulations. Second, we discuss how the ocean biogeochemical fields differed between the O-PI and O-LGM simulations, which were forced with the output of the coupled simulations. Finally, we explore how modifying biogeochemical parameterisations alters the biogeochemistry, including changes to carbon storage, export production, carbonate chemistry and dissolved oxygen.

#### 3.1 LGM climate: physical fields

##### 3.1.1 Sea surface temperature (SST)

The simulated change in SST between the Cpl-PI and the Cpl-LGM simulations shows a similar magnitude and spatial structure to proxy reconstructions and prior modelling studies, with greatest cooling in the equatorial oceans, high latitudes and eastern boundary currents, and the least cooling in the subtropics and western boundary current regions (Fig. 1; Table 2). The global SST mean of the Cpl-LGM was 3.2 °C cooler than the Cpl-PI. This change falls within the range of estimates (~2-4 °C) produced by other climate models (Alder and Hostetler, 2015; Annan and Hargreaves, 2013; Braconnot et al., 2007), but sits towards the cooler limits of previous multiproxy SST reconstructions that estimate a change of  $2 \pm 1.8$  °C (Ballantyne et al., 2005; Waelbroeck et al., 2009). However, a recent reanalysis of the proxy data presented by Waelbroeck et al. (2009) showed past estimates may have underestimated cooling by as much as 50 % (Ho and Laepple, 2015). This finding reconciles some disagreement between climate models and palaeoproxies, and places our simulated cooling of 3.2 °C well within the bounds of uncertainty in reconstructions.

Regionally, the greatest cooling took place in the high latitudes and in the Equatorial Pacific, where temperatures were in excess

of 4 °C cooler than the Cpl-PI climate. Meanwhile, the Western Pacific Warm Pool, subtropical gyres and western boundary currents cooled less (0.5-3.0 °C). Again, proxy (Waelbroeck et al., 2009) and climate modelling (Annan and Hargreaves, 2013) are consistent with both the magnitude and spatial pattern of cooling. A notable example of model-data agreement is in the Pacific sector of the Southern Ocean, where SSTs were up to and in excess of 4 °C cooler at the LGM (Benz et al., 2016).

5 Enhanced cooling in the high latitudes and in the eastern boundary currents generated strong zonal and meridional temperature gradients relative to Cpl-PI SST. There is a consistent regional pattern to SST cooling in the LGM emerging from proxy and model simulations (Annan and Hargreaves, 2013; Braconnot et al., 2007) that is broadly consistent with our simulated cooling.

Where there is still large uncertainty in SST change at the LGM is in the tropical ocean (see Annan and Hargreaves, 2015, for a review). The Cpl-LGM cooling of 3.3 °C across the tropical ocean (15° S - 15° N) is greater than other simulations (Annan and Hargreaves, 2013; Braconnot et al., 2007), but falls well within the -5.1 to -2.17 °C estimated by Ho and Laepple (2015). Regionally, climate models (Otto-Bliesner et al., 2009) and proxies (Waelbroeck et al., 2009) agree that cooling in the tropical Atlantic Ocean probably exceeded cooling in the tropical Pacific and Indian Oceans by roughly 1 °C. In contrast, the tropical Pacific Ocean cooled by 2 °C more than the Tropical Atlantic and Indian Oceans in the Cpl-LGM simulation. Although SSTs in the east equatorial Pacific have been reported as 1.5-3.0 °C cooler than the PI (Dubois et al., 2014; Kucera et al., 2005), the simulated cooling over much of the tropical Pacific appears excessive compared to previous simulations (Braconnot et al., 2007).

### 3.1.2 Sea ice extent

20 The Cpl-PI sea ice extent is consistent with estimates made using satellite measurements during the 1979-1987 period (Gloersen et al., 1993, Table 2). These measurements represent the first global estimates of sea ice coverage, and although there is evidence that sea ice has declined by 20 % since the 1950's (Curran et al., 2003), the strong agreement between the Cpl-PI sea ice fields and the observations of Gloersen et al. (1993) provide a good benchmark for assessing LGM sea ice changes.

25 Associated with cooler SSTs, sea ice coverage (fractional sea ice area  $\geq 15$  %) was greatly expanded in the Cpl-LGM for both hemispheres relative to the Cpl-PI (Fig. 2, Table 2). In the Southern Hemisphere, total sea ice coverage increased by  $\sim 120$  % and  $\sim 225$  % at its seasonal maximum and minimum, respectively, relative to the Cpl-PI. In the Northern Hemisphere, total sea ice coverage increased by  $\sim 145$  % and  $\sim 105$  % at its seasonal maximum and minimum, respectively, relative to the Cpl-PI. These increases correspond to equatorward expansions of the sea ice field of between 5-10° around the Southern Ocean, and in excess of 15° in both the North Atlantic and Pacific Oceans.

The simulated expansion of sea ice around much of the Southern Ocean agrees well with proxy reconstructions. Maximum sea ice extent reached as far north as 47° S in both the Atlantic and Indian sectors (Gersonde et al., 2005) and as far north as 55° S in the Pacific sector of the Southern Ocean (Benz et al., 2016; Gersonde et al., 2005, Fig. 2). The magnitude of growth in the

Atlantic and Indian sectors has been tested and largely supported by subsequent studies (Collins et al., 2012; Xiao et al., 2016), and is consistent with our Cpl-LGM sea ice field. In the Pacific sector, however, the simulated maximum sea ice edge extends well equatorward of the  $55^{\circ}$  S boundary that has been defined by Benz et al. (2016) (Fig. 2). By comparing the coverage of sea ice in the Southern Hemisphere of the Cpl-LGM ( $\sim 46 \times 10^6$  km<sup>2</sup>) with that estimated by Gersonde et al. (2005) ( $\sim 39 \times 10^6$  km<sup>2</sup>), we can attribute the simulated excess of sea ice in the glacial Southern Ocean to a possible overestimate in the Pacific sector.

The Cpl-LGM sea ice was broadly consistent with reconstructions in the North Atlantic, with the exception that too much ice covered the Nordic Seas. The central and eastern parts of the subpolar North Atlantic, including the Nordic Seas, are thought to have been at least seasonally ice-free (Pflaumann et al., 2003; De Vernal et al., 2005). The Cpl-LGM sea ice field showed strong, year-round cover in these regions. However, good model-proxy agreement was produced in other parts of the North Atlantic. Perennial sea ice cover was present in the Greenland Sea and Fram Strait during the LGM (Müller et al., 2009; Telesiński et al., 2014). There is also evidence that winter sea ice reached south of Iceland to fill much of the Labrador Sea (Pflaumann et al., 2003) and extended along the eastern Canadian margin (De Vernal et al., 2005). These features were produced in the Cpl-LGM simulation.

In the North Pacific, the Cpl-LGM sea ice field expanded across a large area. Proxy reconstructions indicate the presence of strong cover in the Okhotsk Sea (Sakamoto et al., 2005; Nürnberg and Tiedemann, 2004), the Japan Sea (Ikehara, 2003) and the western Bering Sea (Riethdorf et al., 2013) during the LGM, with seasonally ice-free conditions in the central west (Jaccard et al., 2005). Thus, like the North Atlantic, sea ice presence was likely more extensive in the western margins of the North Pacific, and this pattern is replicated by other climate models (Fig. 2). In the Cpl-LGM simulation, more intense sea ice cover developed in the west, but year-round cover also developed over the central North Pacific and contrasts directly with the findings of Jaccard et al. (2005), who argued for ice-free conditions during the summer. Thus, our simulated sea ice extent in the North Pacific may be an exaggeration.

25

### 3.1.3 Meridional overturning circulation

The changes observed in the surface ocean within the Cpl-LGM climate were accompanied by changes in the global meridional overturning circulation (Fig. 3; Table 2). The rate of Antarctic Bottom Water (AABW) formation in the Southern Ocean doubled between the Cpl-PI and Cpl-LGM experiments, increasing from 10.3 to 20.2 Sv. An increase in surface density of  $0.9$  kg m<sup>-3</sup> between  $60^{\circ}$  S to  $40^{\circ}$  S drove this intensification, and also strengthened transport by the Antarctic Circumpolar Current (ACC) from 140 to 309 Sv. Meanwhile, the Atlantic Meridional Overturning Circulation (AMOC) weakened from 15.6 to 11.4 Sv. The weakened glacial AMOC was also associated with a shoaling of its lower boundary from approximately 3,000 to 1,500 metres. As a result, much of the Atlantic Ocean below 1,500 metres was dominated by AABW as part of the lower overturning cell.

These changes in the lower and upper overturning cells were conducive to the development of a global overturning circulation dominated by a denser AABW and a shallower AMOC. These results are supported by numerous palaeonutrient tracers showing an increased presence of southern source waters within the deep North Atlantic Ocean during glacial periods (Curry and Oppo, 2005; Duplessy et al., 1988; Keigwin, 2004; Marchitto and Broecker, 2006; Oliver et al., 2010; Skinner et al., 2010). The prevailing interpretation of the palaeonutrient tracers is that the maximum depth of the AMOC was displaced above about 2,000 metres, and that this shoaling facilitated the development of a saltier, more stratified glacial deep ocean (Adkins, 2013). Ferrari et al. (2014) have linked these changes to the expansion of sea ice in the Southern Ocean, which caused a greater proportion of Circumpolar Deep Water to rise into a zone of negative buoyancy flux and thereby produce greater quantities of denser AABW.

However, contradictory changes in the glacial overturning circulation have been simulated in other climate system models. The rates of AABW formation tend to increase under LGM conditions (Otto-Bliesner et al., 2007), but responses of the AMOC among models are highly variable. In earlier experiments as part of the PMIP2 project, the AMOC response ranged between 40 % above and below the PI rate of overturning (Weber et al., 2007). Our weakened ( $\sim 35\%$ ) and shallower ( $\sim 50\%$ ) glacial AMOC is therefore consistent with the lower bounds of these simulations, as are our rates of AABW formation (Table 2). More recent LGM simulations as part of the PMIP3 project, however, developed stronger and deeper glacial AMOCs (Muglia and Schmittner, 2015). Furthermore, a recent reconstruction of Southern Ocean circulation indicates that extreme intensifications of AABW formation and ACC transport at the LGM are unlikely (Lynch-Stieglitz et al., 2016). Consequently, these results challenge our simulated changes in meridional overturning, as well as the prevailing interpretation of palaeonutrient evidence.

Despite inconsistencies between climate model simulations, palaeonutrient reconstructions continue to support the existence of a shallower AMOC overlying southern source waters during glacial periods. Variations in the isotopic signature of Neodymium, for instance, indicate that AABW was more dominant in the deep ocean during the LGM, and that its mixing with a glacial form of NADW was more intense (Howe et al., 2016). These and other authors (Burckel et al., 2016) find further support for the presence of a shallower AMOC above 2,500 metres. Moreover, simulated distributions of carbon isotopes across a range of idealised circulations have shown that a shallower AMOC is necessary to ensure good model-proxy agreement at the LGM (Menviel et al., 2016). Importantly, our Cpl-LGM simulation developed an increased presence of AABW throughout the global deep ocean and the development of a shallower AMOC.

30

### **3.2 LGM climate: biogeochemical fields**

The physical changes in the ocean between the Cpl-PI and the Cpl-LGM, as described above, caused significant changes in ocean biogeochemistry within the ocean-only simulations (Table 3). To assist in the discussion of the large-scale biogeochemical changes we divide the upper and the deep ocean based on the 2,000 m depth. This approach also allows for more clearly

distinguishing between changes to the global overturning circulation, air-sea exchange and biological processes on the biogeochemical fields.

### 3.2.1 Carbon

5 For experiment O-LGM, the carbon content of the ocean was 622 Pg C less than the O-PI experiment (Fig. 4; Table 3). The net loss of carbon reflected the combined effect of physical changes to the ocean, which include an increase in solubility due to cooling, an expanded sea ice field, an altered overturning circulation, and the tendency for outgassing caused by a lower  $p\text{CO}_2$ . The physical changes were sufficient in combination to increase carbon in the deep ocean by 267 Pg C. However, lowering the atmospheric  $p\text{CO}_2$  to 185 ppm drove a large amount of carbon out of the ocean, causing a loss of 889 Pg C from waters  
10 in the upper 2,000 metres. The combined effect of our simulated LGM physical state could therefore not overcome the global equilibration with a lower atmospheric  $p\text{CO}_2$  concentration.

The increase in carbon content in the glacial deep ocean did suggest that despite the net loss caused by outgassing, the glacial ocean was indeed conducive to storing carbon. The loss of carbon from the ocean of experiment O-PI $_{\text{CO}_2}^{\text{LGM}}$  demonstrated this  
15 (Fig. 4; Table 3). The ocean carbon content of O-PI $_{\text{CO}_2}^{\text{LGM}}$  evolved to be 1,290 Pg less than the O-PI experiment, which placed the O-LGM carbon content as 668 Pg greater than O-PI $_{\text{CO}_2}^{\text{LGM}}$ . This confirmed that the glacial ocean had a greater ability to store carbon than the PI ocean.

To investigate this further, the individual contributions of glacial solubility, sea ice and circulation to carbon sequestration  
20 were determined by comparing the idealised experiments of O-PI $_{\text{ice}}^{\text{LGM}}$  and O-PI $_{\text{sol}}^{\text{LGM}}$  to O-PI $_{\text{CO}_2}^{\text{LGM}}$ . Under a PI circulation and a  $p\text{CO}_2$  of 185 ppm, solubility changes associated with the LGM increased the total carbon content of the ocean by 349 Pg C. Meanwhile, sea ice expansion reduced carbon content by 160 Pg. The gains and losses of carbon in each experiment, respectively, occurred in the high latitudes (Fig. 4). Carbon increased markedly in the Arctic and North Atlantic Ocean due to cooling, while decreases in export production caused by sea ice expansion reduced carbon content of the sub-Arctic Pacific,  
25 Labrador Sea and across the Southern Ocean. Circulation changes associated with the glacial climate redistributed carbon from the upper to the deep ocean, and was therefore responsible for the increase in deep ocean carbon in O-LGM. The isolated effect of the glacial circulation was the addition of 479 Pg C, which was calculated by solving for the difference between the combined effect of solubility and sea ice (189 Pg C) and the gain between the O-LGM and O-PI $_{\text{CO}_2}^{\text{LGM}}$  experiments (668 Pg C).

30 Therefore, we primarily implicate circulation and secondarily solubility changes as the physical drivers of oceanic carbon storage at the LGM, while presenting sea ice expansion as a mechanism for reducing ocean carbon storage. Regarding solubility, previous work has constrained the effect of glacial solubility on atmospheric carbon to approximately 15 ppm (Kohfeld and Ridgwell, 2009; Sigman and Boyle, 2000). By taking the 1,290 Pg C difference between the O-PI and O-PI $_{\text{CO}_2}^{\text{LGM}}$  experiments and assuming an *a priori* addition of 520 Pg C in a glacial ocean (Ciais et al., 2011), we can attribute approximately 18 ppm to

our simulated solubility changes (Table 4). Our results are therefore roughly consistent with other estimates. Clearly though, the tendency for carbon to be released to the atmosphere would have been reduced by storing more carbon in the deep ocean. We therefore note that circulation changes and cooling would have had a complementary effect on carbon sequestration, and magnified their individual effects.

5

Regarding sea ice, a prevailing view is that sea ice expansion would enhance oceanic carbon storage by limiting air-sea gas exchange (Stephens and Keeling, 2000). This theory largely focuses on the restriction of outgassing from carbon-rich deep waters that upwell in the Southern Ocean. However, this neglects responses in the Northern Hemisphere and in the biological pump. In a seminal paper, Marinov et al. (2006) showed that export production and circulation in the Antarctic zone has a strong effect on atmospheric CO<sub>2</sub>. We found that light limitation of highly productive regions in both hemispheres caused by increased sea ice cover led to a global loss of 160 Pg C, equivalent to 8 ppm pCO<sub>2</sub>. Similar responses have been simulated in other models that consider the impact of sea ice on biological production and do not consider temperature and salinity changes associated with sea ice growth (Kurahashi-Nakamura et al., 2007; Sun and Matsumoto, 2010).

10  
15 Our results demonstrated that although the storage of carbon was enhanced in the glacial ocean (668 Pg C) due to physical changes, namely due to the overturning circulation, they could not overcome the loss of carbon (1,290 Pg C) caused by equilibration with a lower atmospheric pCO<sub>2</sub>.

### 3.2.2 Nutrients and export production

20 Like carbon, phosphate (PO<sub>4</sub>) concentrations in experiment O-LGM were redistributed from the upper to the deep ocean (Fig. 5). This change was driven by a strengthened AABW formation and is consistent with proxy reconstructions. Cadmium and δ<sup>13</sup>C measurements from the Atlantic Ocean show increased nutrient concentrations in the deep ocean, but reduced levels above 2,000 m at the LGM (Boyle, 1992; Gebbie, 2014; Marchitto and Broecker, 2006; Tagliabue et al., 2009).

25 A direct consequence of the redistribution of PO<sub>4</sub> was the reduction in the production of particulate organic matter across many regions of the O-LGM ocean (Fig. 5). With the exception of the South Pacific and isolated areas in the subtropics, export production in the O-LGM experiment decreased relative to the O-PI experiment, so that global export production was 56 % of O-PI. The global reduction was also illustrated by a decrease in regenerated carbon (*C<sub>org</sub>*), which indicated that the biological carbon pump was weakened (Table 3). The reduction in export production and regenerated carbon for the O-LGM experiment is significant when compared with other studies that argue for a more efficient glacial biological pump than that of the Holocene (Galbraith and Jaccard, 2015; Schmittner and Somes, 2016). The weakened efficiency of our simulated biological pump can be attributed, in part, to a large decrease in export production from the sub-Antarctic zone. This feature is in direct conflict with palaeoproductivity proxies in the Atlantic and Indian sectors of the sub-Antarctic Ocean (Anderson et al., 2002, 2014; Chase et al., 2001; Jaccard et al., 2013; Nürnberg et al., 1997), and some parts of the Pacific sector (Bradt Miller et al., 2009; Lamy

et al., 2014). Outside of the Southern Ocean, the reduction in export production in the O-LGM experiment is largely consistent with palaeoproductivity evidence (see Introduction).

### 3.2.3 Carbonate chemistry

- 5 The loss of phosphate from the upper ocean and its increase at depth was mirrored by changes in alkalinity and salinity, so that a more alkaline and saline signature of AABW, relative to NADW, dominated the deep ocean in experiment O-LGM. Alkalinity and salinity decreased by 66 mmol Eq m<sup>-3</sup> and 0.37 psu in the surface ocean and increased by 147 mmol Eq m<sup>-3</sup> and 2.71 psu in the deep ocean (Fig. 6).
- 10 Because the majority of LGM-PI change in salinity occurred in the deep ocean, the changes in carbonate chemistry across the surface ocean were small. Little change between experiments O-PI and O-LGM was found in the aragonite saturation state ( $\Omega_{ar}$ ), which is a unitless index indicating under- and super-saturation at values below and above one (Fig. 7). Surface  $\Omega_{ar}$  between 40° S and 40° N in O-LGM ( $\Omega_{ar} = 3.8$ ) was slightly lower than that of O-PI ( $\Omega_{ar} = 4.0$ ), but increased in the high latitude oceans. Consequently, the simulated  $\Omega_{ar} = 3.25$  isoline, the value at present used to define the location of viable
- 15 coral reef conditions (Hoegh-Guldberg et al., 2007), was nearly unchanged between the O-LGM and O-PI experiments. Recent sonar and coring in the southern portion of the Great Barrier Reef (Abbey et al., 2011; Yokoyama et al., 2011) have detected the presence of drowned coral reefs that existed at the LGM as far south as reefs present today. Such observations are consistent with our O-LGM experiment and indicates that the extent of viable coral reefs was unlikely to have been significantly different at the LGM relative to today.

20

- However, the magnitude of increase in alkalinity in the glacial deep ocean, which was not accompanied by a stoichiometrically matched increase in carbon, caused unrealistic increases in the calcite saturation horizon ( $\Omega_{ca} = 1$ ). The average position of the calcite saturation horizon increased from 2666 metres in O-PI to 3208 metres in O-LGM. While this increase may seem modest, the increase exceeded the ocean floor over the majority of the ocean, so that seawater was completely saturated for
- 25 calcite outside of the eastern tropical Pacific (Fig. 8). There is good evidence that the carbonate chemistry of the LGM ocean was not appreciably different to the Late Holocene (Yu et al., 2014), and this information places our simulated changes in deep ocean  $\Omega_{ca}$  at the LGM as unrealistic.

### 3.2.4 Dissolved oxygen

- 30 Experiment O-PI produced a global average oxygen concentration of  $\sim 181$  mmol O<sub>2</sub> m<sup>-3</sup>, similar to the PI global average of about 178 mmol O<sub>2</sub> m<sup>-3</sup> (Garcia, 2005). The combination of cooler SSTs, an enhanced subduction of AABW and the reduction in export production in experiment O-LGM dramatically increased the oxygen content in both the upper and deep ocean by  $\sim 80$  and  $\sim 120$  mmol m<sup>-3</sup>, respectively, which constituted a global increase of 55 % (Fig. 9; Table 3).

The increase in dissolved oxygen in O-LGM was considerable, but agreed well with proxy reconstructions for the upper ocean. The oxygen-poor intermediate waters of the western North Pacific (Ishizaki et al., 2009; Shibahara et al., 2007), eastern North Pacific (Cannariato and Kennett, 1999; Cartapanis et al., 2011; Chang et al., 2014; Dean, 2007; Nameroff et al., 2004; 5 Pride et al., 1999; Ohkushi et al., 2013; van Geen et al., 2003), eastern South Pacific (Martinez et al., 2006; Muratli et al., 2010; Salvattecchi et al., 2016), Equatorial Pacific (Leduc et al., 2010) and Indian Ocean (Reichart et al., 1998; Suthhof et al., 2001; van der Weijden et al., 2006) were better oxygenated at the LGM relative to the PI climate. An important consequence of oxygenating the upper ocean is a reduction in the strength of denitrification in these regions. Sedimentary  $\delta^{15}\text{N}$  records suggest that global aggregate rates of water column denitrification rates over the past 200,000 years were lower during glacial 10 periods and higher during interglacial periods (Galbraith et al., 2004), and this is consistent with the simulated oxygenation of the upper ocean.

However, dissolved oxygen concentrations in the deep ocean increased to an average of  $300 \text{ mmol O}_2 \text{ m}^{-3}$  in O-LGM, and this contrasts starkly with existing palaeoclimate reconstructions. Deep waters of the Indian (Murgese et al., 2008; Sarkar et al., 15 1993; Schmiedl and Mackensen, 2006), North Atlantic (Hoogakker et al., 2014), Southern Ocean (Chase et al., 2001; Jaccard et al., 2016) and Equatorial Pacific (de la Fuente et al., 2015) were poorly ventilated at the LGM relative to the Holocene. Drawing from a global compilation of like studies, Jaccard and Galbraith (2012) and Jaccard et al. (2014) demonstrated that the deep ocean was largely deoxygenated relative to the Holocene on a global scale. While the increase in oxygen concentrations in the upper ocean aligned with the direction of change inferred from proxies, the response in the deep ocean can be 20 considered unrealistic.

### 3.3 Importance of ocean biogeochemistry for climate

The carbon content, export production field, carbonate chemistry, and deep ocean oxygen content of experiment O-LGM are 25 outstanding in their disagreement with proxy evidence. Notably,  $622 \text{ Pg C}$  was lost from experiment O-LGM relative to O-PI. The standard LGM simulation was therefore unable to explain the glacial-interglacial drawdown of atmospheric  $\text{CO}_2$ , despite the existence of a physical ocean state within realistic bounds. If we are to reconcile the biogeochemistry of the glacial ocean with that inferred from proxy evidence, we must therefore consider altering ocean biogeochemistry.

#### 30 3.3.1 Reconciling the carbon budget

Three plausible modifications to ocean biogeochemistry (see methods) were considered: (1) increased POC export production, (2) increased depth of POC remineralisation, and (3) reduced PIC export. In the following we step through the changes to carbon content caused by each modification, and the reader is directed to Table 3 for reference.

(1) **Experiment O-LGM<sub>poc</sub><sup>BGC</sup>**. Although the scaling factor controlling the export production of organic matter was increased 10-fold, the actual increase in POC export production averaged over the global ocean was more modest at roughly 30 %. Because most of the ocean became phosphate limited as greater quantities of nutrients were redistributed into the deep ocean, the increase in export production in experiment O-LGM<sub>poc</sub><sup>BGC</sup> was only felt in those regions where PO<sub>4</sub> was not limiting. The sub-Antarctic zone of the Southern Ocean experienced the greatest increase in export production (~250 %), followed by a few small regions along the Chilean margin and in the Northwest Pacific (Fig. 10). These regional responses caused the global net export production rate to increase from 4.48 to 5.96 Pg C yr<sup>-1</sup>. Although this rate of POC export production was still lower than the O-PI experiment of 8.02 Pg C yr<sup>-1</sup>, this increased carbon content by 179 Pg C.

10

(2) **Experiment O-LGM<sub>rem</sub><sup>BGC</sup>**. The shift of organic matter to depth was associated with a global reduction in POC export production of ~1.2 Pg C yr<sup>-1</sup> as remineralisation released PO<sub>4</sub> and carbon further from the photic zone. Despite the reduction in the biological pump, the bulk transfer of POC to depth generated an increase in ocean carbon storage of 167 Pg C.

15 (3) **Experiment O-LGM<sub>pic</sub><sup>BGC</sup>**. The elimination of PIC in the simulated glacial ocean increased the solubility of CO<sub>2</sub> in the surface ocean and enabled the ocean to store an additional 329 Pg C.

Independently, none of the above modifications were able to increase ocean carbon content relative to the O-PI experiment (O-LGM<sub>poc</sub><sup>BGC</sup>: -443 Pg C; O-LGM<sub>rem</sub><sup>BGC</sup>: -455 Pg C; O-LGM<sub>pic</sub><sup>BGC</sup>: -293 Pg C). However, by employing all three biogeochemical modifications in one experiment (**Experiment O-LGM<sub>all</sub><sup>BGC</sup>**), the glacial ocean was able to store an additional 939 Pg C more than experiment O-LGM and 317 Pg C more than O-PI.

This magnitude of increase places our glacial ocean state within the plausible bounds required to offset the loss of atmospheric and terrestrial carbon reported by Ciais et al. (2011) of ~520 ± 400 Pg C at the LGM (Table 4). By assuming a glacial-interglacial difference in atmospheric CO<sub>2</sub> of 95 ppm and applying this to our changes in carbon content, we attribute roughly 40 ppm to changes in ocean physics and 55 ppm to changes in the biological pump. Within the physical changes, 28 ppm is attributed to the reorganisation of the global overturning circulation, while 12 ppm can be attributed to changes in surface properties, including sea ice expansion, cooling and salinification.

### 30 3.3.2 Reconciling export production

Of the three biogeochemical modifications applied to the LGM ocean, only two had an effect on POC export, as the amount of PIC exported from the photic zone has no influence on the amount of POC export. Deepening the remineralisation of POC (O-LGM<sub>rem</sub><sup>BGC</sup>) shifted a greater fraction of regenerated PO<sub>4</sub> into the deep ocean, which resulted in a global reduction of export production. Increasing the scaling factor (O-LGM<sub>poc</sub><sup>BGC</sup>), however, caused an increase in global export production from 4.48 to

5.96 Pg C yr<sup>-1</sup>. Most of this increase occurred in the Southern Ocean, particularly the sub-Antarctic zone, and in a few isolated pockets in the Northwest Pacific and North Atlantic where excess nutrients were available (Fig. 10).

The increase in the scaling factor dominated the change in export production produced when combining all three biogeochemical modifications (O-LGM<sub>all</sub><sup>BGC</sup>). The strong increase in export production observed in the sub-Antarctic was clearly replicated within this experiment and reconciles our simulated export production field with current evidence of productivity at the LGM. In the Southern Ocean, the Atlantic and Indian sectors of the sub-Antarctic zone experienced a greater flux of organics (Anderson et al., 2002, 2014; Chase et al., 2001; Jaccard et al., 2013; Nürnberg et al., 1997). Whether this was also the case for the Pacific sector remains under debate, with some evidence for increase (Bradtmiller et al., 2009; Lamy et al., 2014) and some for no change (Bostock et al., 2013; Chase et al., 2003). Meanwhile, it is widely accepted that waters south of the Antarctic Polar Front were reduced in their productivity (Bostock et al., 2013; Chase et al., 2003; Elderfield and Rickaby, 2000; Francois et al., 1997; Frank et al., 2000; Kohfeld et al., 2005; Kumar et al., 1995; Mortlock et al., 1991; Ninnemann and Charles, 1997; Shemesh et al., 1993), likely due to increased sea ice extent (Benz et al., 2016; Gersonde et al., 2005; Jaccard et al., 2013) and stratification (Anderson et al., 2014; Jaccard et al., 2005).

In experiment O-LGM<sub>all</sub><sup>BGC</sup>, net export production remained less than the O-PI experiment by 3.16 Pg C yr<sup>-1</sup> despite the application of biogeochemical modifications. The weakened carbon transfer to the interior ocean was also observed in the regenerated carbon content of the ocean ( $C_{org}$ ), which was 646 Pg less than the O-PI experiment (Table 3). The net decline in export production observed in this study was dominated by the decline in tropical and subtropical waters. Many palaeoproductivity studies located outside of the sub-Antarctic zone have found weakened productivity at the LGM (Chang et al., 2014, 2015; Costa et al., 2016; Crusius et al., 2004; Kohfeld et al., 2005; Kohfeld and Chase, 2011; Jaccard et al., 2005; McKay et al., 2015; Ortiz et al., 2004; Riethdorf et al., 2013; Salvatelli et al., 2016; Singh et al., 2011; Thomas et al., 1995). Additionally, an enhanced utilisation of available nutrients in the sub-Antarctic zone (Martinez-Garcia et al., 2014) would reduce the nutrient content of intermediate waters formed in the Southern Ocean and would thus reduce the delivery of nutrients to lower latitudes (Sarmiento et al., 2004). This mechanism coupled with cooler temperatures caused reductions in export production across much of the mid and lower latitude oceans in experiment O-LGM<sub>all</sub><sup>BGC</sup>, which maintains the qualitative agreement between the simulated export production field and proxy observations. However, the global weakening of the biological pump in our simulations is contrary to proxy and model-based evidence for a strengthened biological pump ( $> C_{org}$ ) at the LGM (Galbraith and Jaccard, 2015; Schmittner and Somes, 2016). Hence, while we present good spatial agreement between O-LGM<sub>all</sub><sup>BGC</sup> and palaeoproductivity proxies at the LGM, which was essential to increasing the carbon content of the ocean, we note that additional increases in the export production field may be valid.

### 3.3.3 Reconciling carbonate chemistry

There is good evidence that the carbonate chemistry of the glacial deep ocean was not appreciably different to the Late Holocene (Yu et al., 2014). Because much of the ocean was saturated for calcite in the O-LGM experiment, additional processes were required to shoal the depth at which calcite becomes unsaturated ( $\Omega_{ca} = 1$ ), and thereby reconcile proxy evidence.

5 One mechanism to reduce deep ocean  $\Omega_{ca}$  would be to reduce continental inputs of alkalinity at the LGM. However, the presence of glaciers, drier atmospheric conditions and the exposure of continental shelves due to lower sea level would have increased the supply of carbonates to the ocean (Gibbs and Kump, 1994; Riebe et al., 2004), thereby increasing ocean alkalinity and further deepening the carbonate saturation horizon. This mechanism has been largely refuted as having a significant effect on the glacial-interglacial difference in the carbon budget (Brovkin et al., 2007; Foster and Vance, 2006; Jones et al., 2002), and can therefore be ignored.

10

The individual biogeochemical modifications were also insufficient to reduce  $\Omega_{ca}$  to be consistent with palaeo evidence. However, combining all three modifications in experiment O-LGM<sup>BGC<sub>all</sub></sup> reduced  $\Omega_{ca}$  significantly (Fig. 11), and produced a globally-averaged calcite saturation horizon at 2839 metres. Remarkably, our simulated PI to LGM changes in  $\Omega_{ca}$  are also consistent with palaeoproxy reconstructions in a regional sense. The calcite saturation horizon in the Pacific Ocean was deeper  
15 in experiment O-LGM<sup>BGC<sub>all</sub></sup> relative to O-PI, but was shallower in the Atlantic Ocean and within the Atlantic and Indian sectors of the sub-Antarctic zone. Similar changes are seen in the proxy record, with a deepening of less than 1,000 metres in the North Pacific and Southern Ocean at the LGM (Anderson et al., 2002; Catubig et al., 1998), and a shoaling in the Atlantic Ocean (Anderson et al., 2002).

20 An important caveat of this study, which cannot be ignored, is the exclusion of calcium carbonate ( $\text{CaCO}_3$ ) burial within ocean sediments. Because this process is not included in the model, it is highly likely that the deepening of the calcite saturation horizon that occurred in the standard LGM experiment (O-LGM) was too extreme.  $\text{CaCO}_3$  burial lowers the alkalinity of the glacial ocean, and is therefore a negative feedback mechanism that modulates changes in carbonate chemistry (see Sigman et al., 2010, for a review). If calcite saturation increases through the water column, as found in O-LGM, the burial of  $\text{CaCO}_3$   
25 would increase and subsequently mitigate the rise in whole-ocean alkalinity, which would in turn the rise in calcite saturation and the ability of the ocean to store carbon. By not taking this process into account, both the deepening of the calcite saturation horizon and the storage of carbon were overestimated in experiment O-LGM.

However, the same reasoning can be applied to the experiments with biogeochemical modifications. If the burial of  $\text{CaCO}_3$   
30 was included in these experiments, the shoaling of the calcite saturation horizon would have been somewhat mitigated by decreased  $\text{CaCO}_3$  burial that increased ocean alkalinity (Archer and Maier-Reimer, 1994). Consequently, the shoaling that was observed in these experiments was likely exaggerated, just as the deepening observed in experiment O-LGM was exaggerated.

Again, this can be applied to changes in the carbon content of the ocean, as a shallower calcite saturation horizon would have increased whole-ocean alkalinity and thereby increased carbon storage. This effect would have been particularly important for experiment O-LGM<sub>pic</sub><sup>BGC</sup>, where inorganic carbon export was eliminated. If whole-ocean alkalinity was able to respond to a decrease in CaCO<sub>3</sub> rain, this would have amplified the carbon sequestration of experiment O-LGM<sub>pic</sub><sup>BGC</sup>. Therefore, the exclusion of CaCO<sub>3</sub> burial in experiment O-LGM<sub>all</sub><sup>BGC</sup> (O-LGM) caused an exaggerated shoaling (deepening) of the calcite saturation horizon and an underestimated (overestimated) carbon content.

### 5 3.3.4 Reconciling dissolved oxygen

As discussed previously, the increase in oxygen concentrations of the upper ocean in experiment O-LGM is consistent with the current assemblage of proxy evidence. All experiments with modified biogeochemistry, including O-LGM<sub>all</sub><sup>BGC</sup>, had little effect on the upper ocean oxygen concentration (Fig. 12; Table 3), and therefore did not compromise the agreement between simulated and proxy oxygen reconstructions.

10

Modifying ocean biogeochemistry did, however, have a large effect on the oxygen concentrations of the deep ocean (Fig. 13). Increasing export production (O-LGM<sub>poc</sub><sup>BGC</sup>) and deepening the remineralisation depth (O-LGM<sub>rem</sub><sup>BGC</sup>) both reduced oxygen concentrations by 28 and 13 mmol m<sup>-3</sup>, respectively. The combination of these modifications (O-LGM<sub>all</sub><sup>BGC</sup>) amplified their individual effects, so that deep ocean oxygen was reduced by 63 mmol m<sup>-3</sup> relative to O-LGM. The increased sensitivity of deep ocean oxygen to the combination of increased export production and a deeper remineralisation depth was also observed in the increase in the quantity of regenerated nutrients ( $C_{org}$ ) that resulted (Table 3). A greater proportion of regenerated nutrients relative to preformed nutrients at the LGM has been identified as a key driver of interior ocean deoxygenation (Jaccard and Galbraith, 2012; Sigman et al., 2010), and this process was captured in experiment O-LGM<sub>all</sub><sup>BGC</sup>.

15

While the combination of biogeochemical modifications (O-LGM<sub>all</sub><sup>BGC</sup>) did reduce deep ocean oxygen towards the concentrations of the PI ocean in a number of areas (Fig. 13), by no means were global deep ocean concentrations (237 mmol m<sup>-3</sup>) lower than those of O-PI (180 mmol m<sup>-3</sup>). The simulated oxygenation of the deep ocean remains in contrast to proxy records. However, this inconsistency may be resolved by addressing some key differences in physical and biogeochemical fields that evolved in our simulations. A key physical mechanism to reduce deep ocean oxygen concentrations would include equivalent or slower formation rates of major ocean deep waters (as per Menviel et al., 2016) combined with an intensified coverage of sea ice in the region of their formation. The growth of sea ice and the formation rate of AABW were likely too strong in our LGM simulation (see sections 3.1.2 and 3.1.3), and we therefore suggest that a sluggish circulation is necessary for reducing deep ocean oxygen. Key biogeochemical mechanisms include a further increase in global export production, and/or a different spatial pattern of export production, and/or increasing the injection of organic matter to deep water via further lengthening the remineralisation profile. The weakened biological pump in our LGM simulations contrasts with other studies (Galbraith and Jaccard, 2015; Schmittner and Somes, 2016), and indicates export production may be underestimated by our simulations. The

20  
25  
30

combination of a more sluggish deep ocean circulation with an enhanced export of organics would significantly reduce the oxygen content of the deep ocean, while potentially further increasing carbon storage.

#### 4 Conclusions

In this study we have shown that simulated physical changes in the ocean state during the climate of the Last Glacial Maximum are not sufficient to explain the 80-100 ppm drawdown of atmospheric CO<sub>2</sub>. Physical changes associated with the glacial climate, including an expanded sea ice field, increased solubility and a reorganisation of the global overturning circulation, were responsible for roughly 40 ppm of CO<sub>2</sub> drawdown. The effect of circulation on carbon storage was greatest at 28 ppm, and was associated with an expansion of southern source waters throughout the deep ocean. Thus, various biogeochemical modifications were necessary to further increase carbon storage in the ocean. The biogeochemical modifications explored in this study were (1) an increase in export production consistent with greater iron fertilisation, (2) a shift of remineralisation to the deep ocean consistent with cooler temperatures, and (3) a decrease in the production of particulate inorganic carbon consistent with cooler temperatures and increased delivery of silicate to lower latitudes. Together, these modifications increased the carbon content of the ocean and, combined with physical changes, were able to account for the loss of carbon from the atmosphere and land at the Last Glacial Maximum. Furthermore, their addition improved model-proxy agreement in the fields of export production, carbonate chemistry and dissolved oxygen. This study demonstrates that fundamental changes to ocean biogeochemical function are required to explain glacial-interglacial cycles.

**Table 1.** Summary of modelling experiments performed. An O before a model name denotes that it was an ocean-only simulation.

Experiment	Model	Greenhouse Gas Forcing (CO <sub>2</sub> e) <sup>a</sup>	Orbital Parameters	Comment
Cpl-PI	Coupled	280	0 ka BP	Unmodified BGC
Cpl-LGM	Coupled	167	21 ka BP	Unmodified BGC

Experiment	Model	Atmospheric CO <sub>2</sub> (ppm)	Climate State	Comment
O-PI	Ocean	280	PI	Unmodified BGC
O-LGM	Ocean	185	LGM	Unmodified BGC
O-PI <sup>LGM</sup> <sub>CO<sub>2</sub></sub>	Ocean	185	PI	Unmodified BGC
O-PI <sup>LGM</sup> <sub>ice</sub>	Ocean	185	PI	Unmodified BGC / LGM sea ice
O-PI <sup>LGM</sup> <sub>sol</sub>	Ocean	185	PI	Unmodified BGC / LGM SST and SSS
O-LGM <sup>BGC</sup> <sub>poc</sub>	Ocean	185	LGM	10× potential export production
O-LGM <sup>BGC</sup> <sub>rem</sub>	Ocean	185	LGM	Increased depth of remineralization <sup>b</sup>
O-LGM <sup>BGC</sup> <sub>pic</sub>	Ocean	185	LGM	No particulate inorganic carbon export
O-LGM <sup>BGC</sup> <sub>all</sub>	Ocean	185	LGM	BGC modifications of O-LGM <sup>BGC</sup> <sub>poc</sub> , O-LGM <sup>BGC</sup> <sub>rem</sub> and O-LGM <sup>BGC</sup> <sub>pic</sub>

<sup>a</sup> Carbon Dioxide equivalents, corresponding to CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O from 280 ppm/760 ppb/270 ppb for PI simulations to 185 ppm/350 ppb/200 ppb for LGM simulations.

<sup>b</sup> Power law exponent for organic matter remineralization changed from  $-0.9$  to  $-0.7$ .

**Figure 1.** Annual sea surface temperature (SST) difference between (a) the coupled PI experiment, Cpl-PI, and the observations from Levitus (2001), and (b) the difference between the coupled LGM and PI experiments (Cpl-LGM - Cpl-PI). Solid contour lines denotes positive changes in SST by 4 and 8 °C, while negative changes in SST are denoted by dashed lines at 4 and 8 °C.

**Figure 2.** Annual average sea-ice cover for (a) the Cpl-PI Northern Hemisphere, (b) the Cpl-LGM Northern Hemisphere, (c) the Cpl-PI Southern Hemisphere, (d) the Cpl-LGM Southern Hemisphere. The red and blue contour lines in each projection represent the maximum and minimum seasonal sea ice extents (where sea ice concentration equals 15 % as per Gersonde et al. (2005)). In panel (b), the dashed orange contour line represents the maximum seasonal sea ice extent produced by the IPSL climate system model, which took part in the PMIP3 LGM experiment, and is broadly consistent with the results of other PMIP3 models. In panel (d), the coloured markers represent locations where winter sea ice was deemed to have been present (blue) and absent (red) at the LGM according to Gersonde et al. (2005).

**Table 2.** Changes in sea surface temperature (SST), sea ice extent and large scale circulation between the LGM and PI simulations. SST changes are compared with proxy reconstructions of SST generated by Waelbroeck et al. (2009) and Ho and Laepple (2015) whom use different proxies for their reconstructions to produce the differences depicted here and discussed in the text. The values of AABW and NADW formation provided by the models from the Palaeoclimate Modelling Intercomparison Project Phase II (PMIP2) are presented by Otto-Bliiesner et al. (2007). The transport rate of the Antarctic Circumpolar Current (ACC) for the PMIP2 models is presented by Lynch-Stieglitz et al. (2016). The estimates of NADW production provided by the PMIP3 models were taken from Muglia and Schmittner (2015).

		$\Delta$ SST ( $^{\circ}$ C)			
		15 $^{\circ}$ S–15 $^{\circ}$ N	30 $^{\circ}$ S–30 $^{\circ}$ N	60 $^{\circ}$ S–60 $^{\circ}$ N	90 $^{\circ}$ S–90 $^{\circ}$ N
Simulated	Global	-3.3	-3.2	-3.9	-3.2
	Atlantic	-3.6	-3.4	-3.9	-3.3
Waelbroeck et al. (2009)	Global	-1.7 $\pm$ 1.0	-1.5 $\pm$ 1.2	-1.9 $\pm$ 1.7	-1.9 $\pm$ 1.8
	Atlantic	-2.9 $\pm$ 1.3	-2.3 $\pm$ 1.5	-2.6 $\pm$ 2.0	-2.4 $\pm$ 2.2
Ho and Laepple (2015)	Global		-5.1 to -2.17 $\pm$ 1.43		-12.52 to -2.17 $\pm$ 1.43

	Sea ice extent (10 $^6$ km $^2$ )				
	SH maximum	SH minimum	NH maximum	NH minimum

	LGM	46.3	13.3	36.6	19.9
(Gloersen et al., 1993)	PI	19	3.5	16	9
(Gersonde et al., 2005)	LGM	39			

	Overturning metrics			
	AABW $^a$ (Sv)	AMOC $^b$ (Sv)	ACC transport $^c$ (Sv)	
Simulated	PI	10.3	15.6	140
	LGM	20.2	11.4	309
PMIP2 models	PI	10.4–16.2	18.6–19.4	50–300
	LGM	19.6–40.0	13.9–30.7	80–350
PMIP3 models	PI		12.6–23.0	
	LGM		21.4–31.6	

$^a$  The rate of Antarctic Bottom Water (AABW) formation is calculated as the annual average of the most negative rate of overturning (Sv) in the Southern Ocean south of 60 $^{\circ}$  S and deeper than 500 m.

$^b$  The rate of overturning in the Atlantic Meridional Overturning Circulation (AMOC) is calculated as the annual average of the most positive rate of overturning (Sv) in the North Atlantic Ocean north of 0 $^{\circ}$  and deeper than 500 m.

$^c$  The transport of water by the Antarctic Circumpolar Current (ACC) is calculated as the annual and zonal average of the barotropic streamfunction at 60 $^{\circ}$  S.

**Table 3.** Global ocean averaged diagnostics from the model simulations described in Table 1. The subscript organic refers to the remineralisation computed from the apparent oxygen utilization. POC and PIC refer to the annual export of particulate organic and inorganic carbon from the upper 50 m, respectively. The tracer columns refer to global ocean inventory or global ocean mean values. Global inventory of phosphate was 2.68 Pmol in all simulations. White space for experiments O-PI<sup>LGM</sup><sub>CO<sub>2</sub></sub>, O-PI<sup>LGM</sup><sub>sol</sub>, and O-PI<sup>LGM</sup><sub>ice</sub> indicate no difference with experiment O-PI.

Model	Atmospheric <sup>a</sup> CO <sub>2</sub> (ppm)		POC (Pg Cy <sup>-1</sup> )		PIC (Pg Cy <sup>-1</sup> )		Δ Carbon <sup>b</sup> (Pg C)		C <sub>org</sub> (Pg C)		Oxygen (mean) (mmol m <sup>-3</sup> )		Depth <sup>c</sup> (m) where Ω <sub>cc</sub> = 1

O-LGM <sup>BGGC</sup> <sub>PIC</sub>	185	4.48	0.76	0.76	0.00	-293	-451	+158	665	280	262	300	3196
O-LGM <sup>BGGC</sup> <sub>sol</sub>	185	4.86	3.43	3.43	0.00	+317	-419	+737	1004	251	264	237	2839

<sup>a</sup> Atmospheric CO<sub>2</sub> is prescribed in each experiment.

<sup>b</sup> Change in the ocean inventory of carbon relative to experiment O-PI with atmospheric pCO<sub>2</sub> at 280 ppm.

<sup>c</sup> Where the calcite saturation horizon (Ω<sub>cc</sub> = 1) exceeds the depth of the ocean, the lower depth bound of the deepest grid box was included in the averaging process.

<sup>d</sup> All grid boxes south of 45° S.

<sup>e</sup> All grid boxes above 2,000 m depth.

<sup>f</sup> All grid boxes below 2,000 m depth.

<sup>g</sup> Steady state carbon content of the global, upper and deep ocean under Pre-Industrial conditions is 34,114, 17,458 and 16,656 PgC, respectively.

**Table 4.** A summary of the total changes in ocean carbon storage and their drivers between our simulated Pre-Industrial (PI) and Last Glacial Maximum (LGM) climates. We use the increase in carbon of our O-LGM<sup>BGC</sup><sub>all</sub> experiment of 317 Pg C, which falls within the estimate range of ocean carbon storage at the LGM (Ciais et al., 2011), and our simulated loss of 1,290 Pg C from the PI ocean with an atmospheric  $p\text{CO}_2$  of 185 ppm to determine the contribution of physical and biogeochemical drivers in ppm of  $\text{CO}_2$ . For example, an addition of 1,607 Pg C in excess of experiment O-PI<sup>LGM</sup> <sub>$\text{CO}_2$</sub>  (+317 Pg C in column 2) would constitute a contribution of 95 ppm. BGC refers to biogeochemistry.

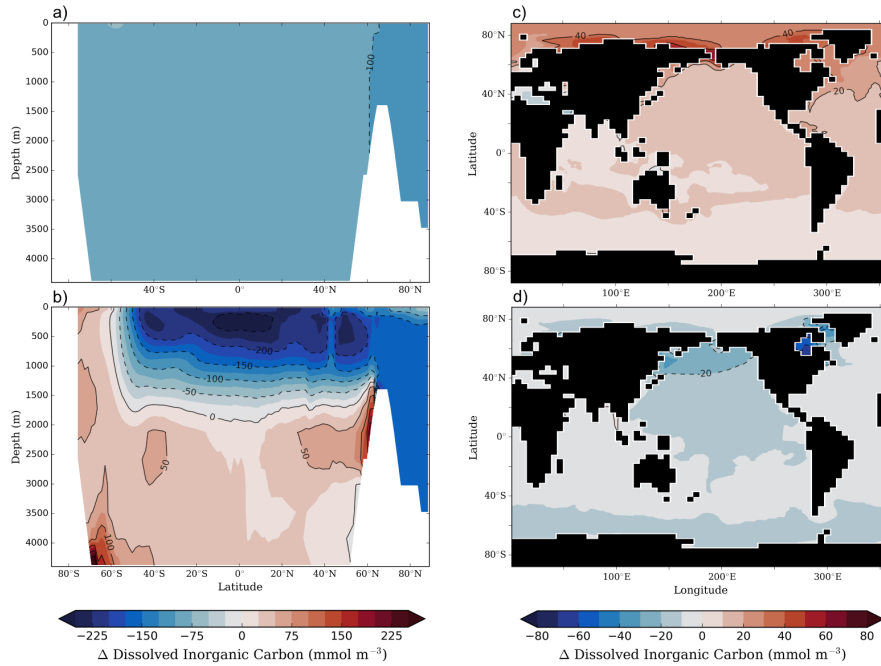

Estimate	$\Delta\text{Carbon}$ (Pg C)	Contribution (ppm $\text{CO}_2$ )
Ciais et al. (2011)	$520 \pm 400^a$	+80-100
LGM (all physical changes) - modified BGC <sup>b</sup> (O-LGM <sup>BGC</sup> <sub>all</sub> )	+317	+95
PI - unmodified BGC ( $p\text{CO}_2 = 280$ ppm)	0	
PI - unmodified BGC ( $p\text{CO}_2 = 185$ ppm)	-1290	0
LGM (solubility) - unmodified BGC	-941	+21
LGM (sea ice) - unmodified BGC	-1450	-9
LGM (circulation) - unmodified BGC	-857	+28
LGM (all physical changes) - unmodified BGC	-622	+40
LGM (biological pump) - modified BGC	-351	+55

<sup>a</sup> Estimate of increase in ocean carbon content during the LGM made by Ciais et al. (2011), whereby atmospheric carbon was reduced by  $194 \pm 2$  Pg C and terrestrial carbon was reduced by  $330 \pm 400$  Pg C.

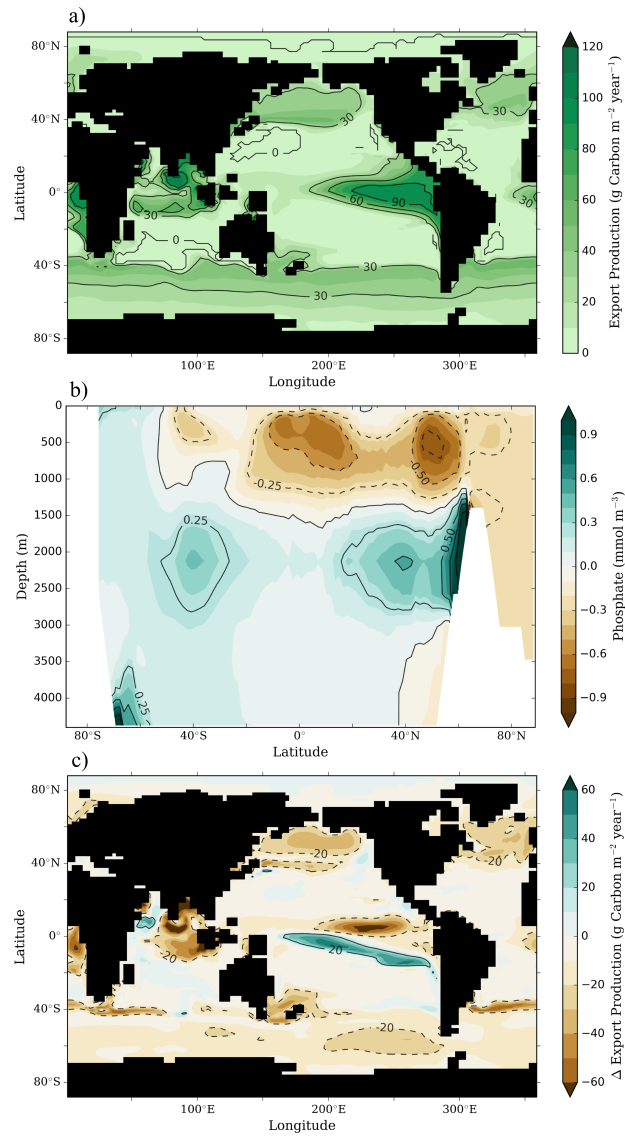

<sup>b</sup> Assumes all three biological modifications that were postulated (see Table 1, experiments O-LGM<sup>BGC</sup><sub>poc</sub>, O-LGM<sup>BGC</sup><sub>rem</sub> and O-LGM<sup>BGC</sup><sub>pic</sub>) occurred to provide an upper bound estimate of ocean carbon storage.

**Figure 3.** The upper panels depict the total meridional overturning streamfunction (Sv) for the global ocean in the (a) Cpl-PI and (b) Cpl-LGM simulations. The bottom panels depict the total meridional overturning streamfunction (sv) for the Atlantic ocean in the (c) Cpl-PI and (d) Cpl-LGM simulations. Note that those latitudes corresponding to the Southern Ocean are obscured for panels (c) and (d) in the Atlantic Ocean, as these overturning velocities are invalid considering that waters can exit to the east and west and that the streamfunction does not account for these losses.

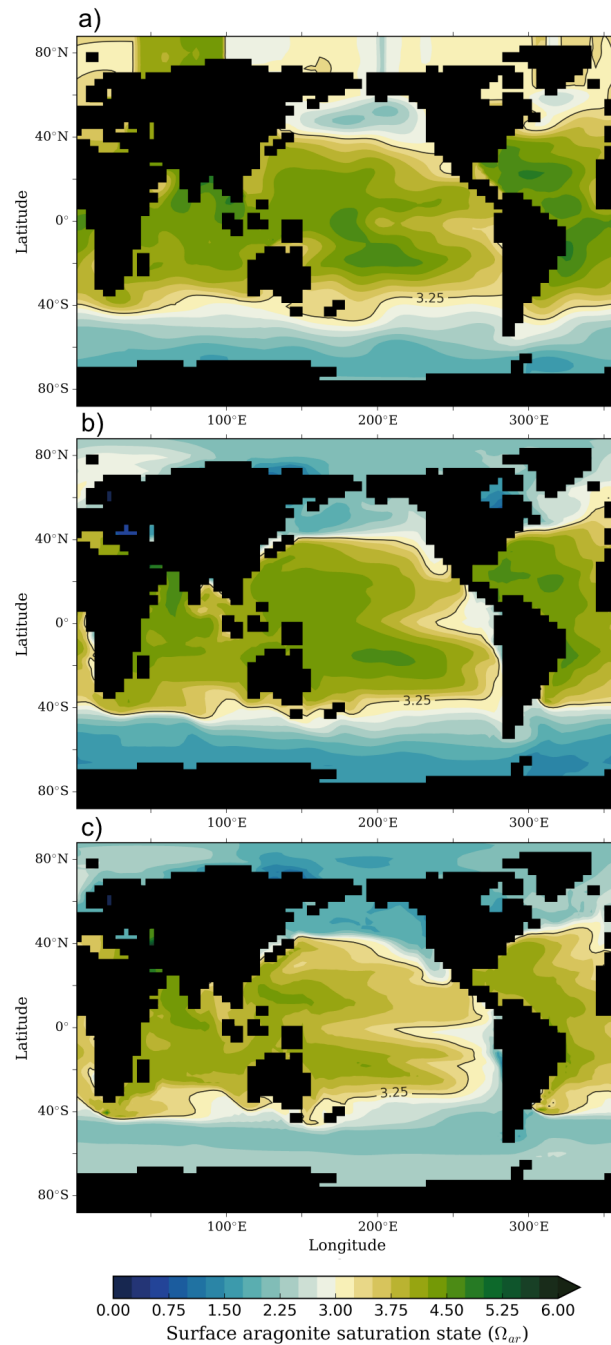

**Figure 4.** Changes in the concentration of dissolved inorganic carbon ( $\text{mmol m}^{-3}$ ) of the ocean due to physical differences between the Pre-Industrial (PI) and Last Glacial Maximum (LGM). Panels on the left represent the zonally-averaged differences between experiments (a) O-PI<sup>LGM</sup><sub>CO<sub>2</sub></sub> and (b) O-LGM with the O-PI experiment, and therefore show total changes in carbon content due to all physical changes associated with the LGM climate. Panels on the right represent the depth-averaged differences between experiments (c) O-PI<sup>LGM</sup><sub>sol</sub> and (d) O-PI<sup>LGM</sup><sub>ice</sub> with the O-PI<sup>LGM</sup><sub>CO<sub>2</sub></sub> experiment, and therefore represent the contribution of solubility and sea ice changes at the LGM to carbon storage in the ocean.

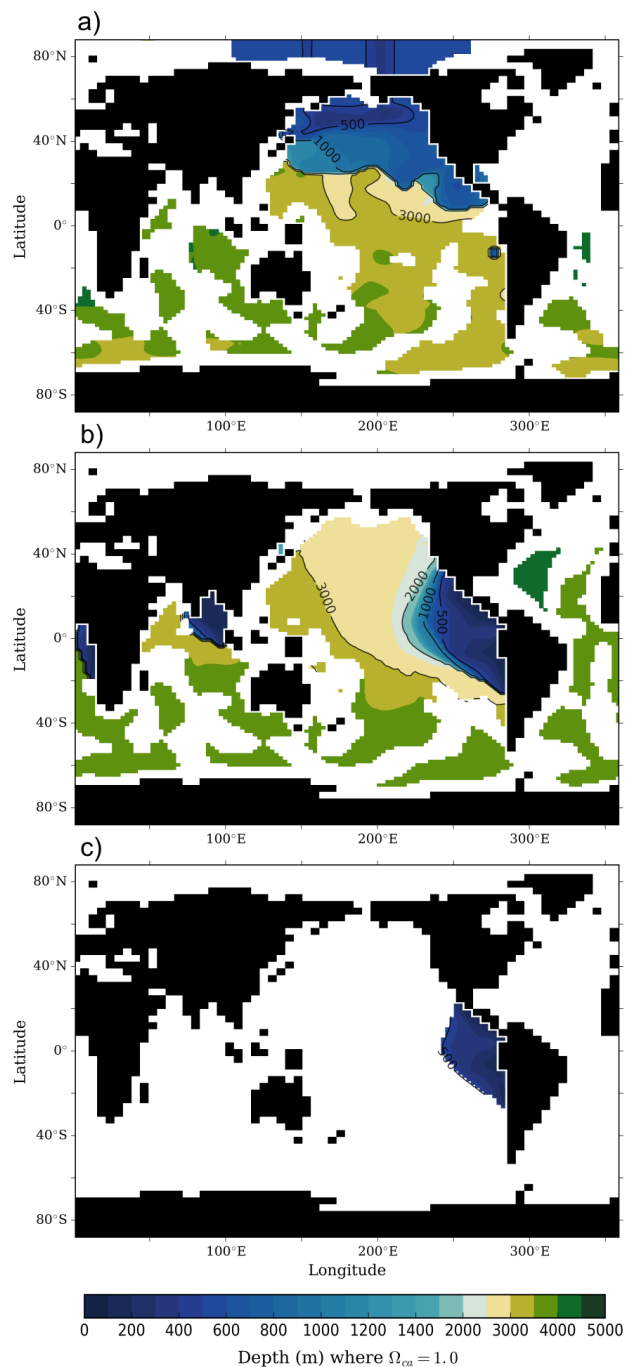

**Figure 5.** Changes in the export production of Particulate Organic Matter (POC) and Phosphate concentrations between the O-LGM and O-PI experiments. (a) Annually averaged export of POC from the upper 50 m ( $\text{g Carbon m}^{-2} \text{ year}^{-1}$ ) for O-PI, (b) the O-LGM – O-PI difference in Phosphate concentrations ( $\text{mmol m}^{-3}$ ), and (c) the O-LGM – O-PI difference in export production of POC from the upper 50 m ( $\text{g Carbon m}^{-2} \text{ year}^{-1}$ ).

**Figure 6.** Change in the zonally-averaged global distribution of (a) alkalinity ( $\text{mmol Eq m}^{-3}$ ), and (b) salinity (psu) between the O-LGM and O-PI experiments (O-LGM – O-PI). Despite the strong reduction in salinity in upper ocean of the O-LGM experiment relative to O-PI, the whole-ocean salt content was greater by 1.0 psu.

**Figure 7.** The annual average surface aragonite saturation state ( $\Omega_{ar}$ ) calculated from (a) the observations of Key et al. (2004), (b) the O-PI experiment, and (c) the O-LGM experiment.

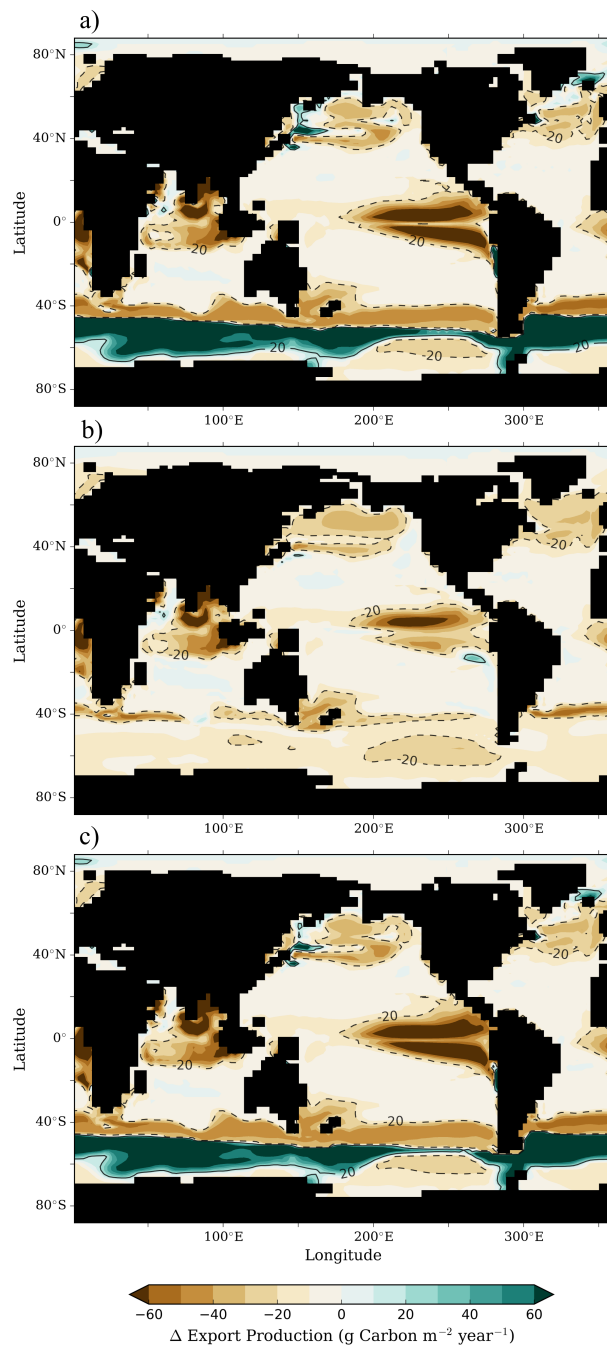

**Figure 8.** The depth at which calcite becomes undersaturated in the water column (where  $\Omega_{ca} = 1$ ) calculated from (a) the observations of Key et al. (2004) (global mean calcite saturation horizon = 2610 m), (b) the O-PI experiment (global mean calcite saturation horizon = 2666 m), and (c) the O-LGM experiment (global mean calcite saturation horizon = 3208 m). The contour lines represent 500, 1000, 2000 and 3000 metres depth. Note that the O-LGM experiment, which is unmodified in its biogeochemistry relative to the O-PI experiment, is completely saturated for calcite across the majority of the ocean (white space).

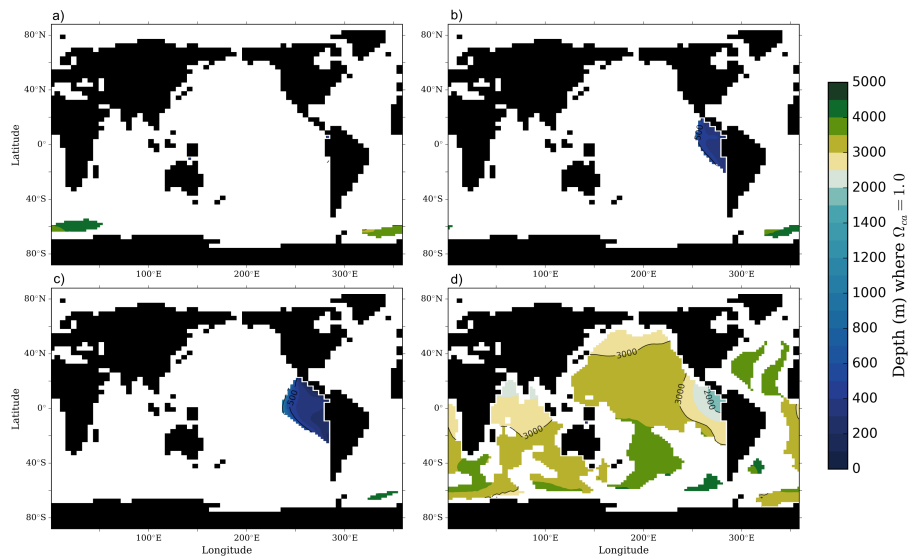

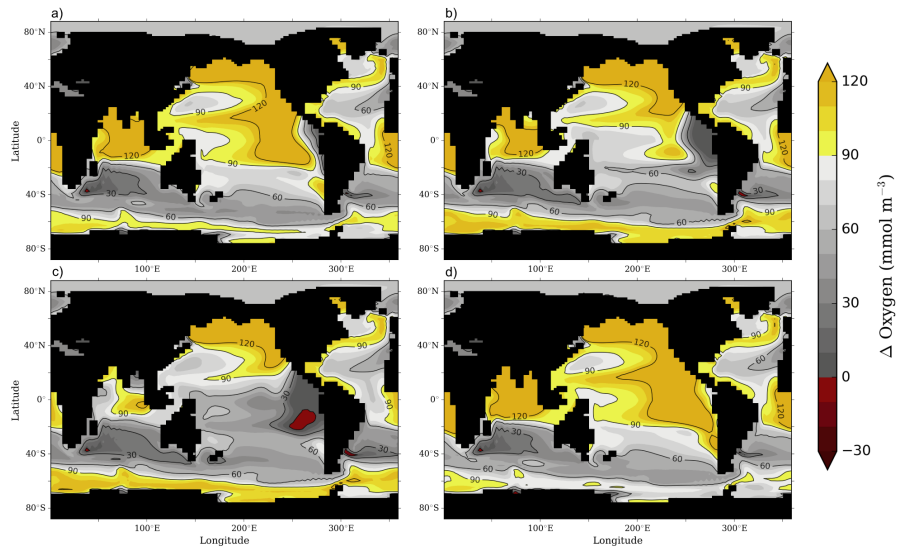

**Figure 9.** Zonally-averaged dissolved oxygen concentrations (mmol m<sup>-3</sup>) in (a) the modern ocean according to the World Ocean Atlas (Garcia et al., 2013), (b) the O-PI experiment, and (c) the O-LGM experiment.

**Figure 10.** Change in annually averaged export of particulate organic carbon from the upper 50 m ( $\text{g Carbon m}^{-2} \text{ year}^{-1}$ ) between the LGM and PI from the experiments with modified biogeochemical formulations for (a)  $\text{O-LGM}_{poc}^{BGC} - \text{O-PI}$ , (b)  $\text{O-LGM}_{rem}^{BGC} - \text{O-PI}$ , and (c)  $\text{O-LGM}_{all}^{BGC} - \text{O-PI}$ . It should be noted that the export production field of particulate organic carbon for experiment  $\text{O-LGM}_{pic}^{BGC}$ , whereby particulate inorganic carbon was set to zero, did not differ from unmodified experiment O-LGM and is therefore not shown. For this comparison, the reader is directed to Figure 5.

**Figure 11.** The depth at which calcite becomes undersaturated in the water column (where  $\Omega_{ca} = 1$ ) for the experiments with modified biogeochemical formulations. (a) O-LGM $_{poc}^{BGC}$ , (b) O-LGM $_{rem}^{BGC}$ , (c) O-LGM $_{pic}^{BGC}$ , and (d) O-LGM $_{all}^{BGC}$ . The white areas in the ocean are regions where calcite is completely saturated throughout the water column.

**Figure 12.** Change in oxygen concentration ( $\text{mmol m}^{-3}$ ) at 500 m between the LGM and PI for the experiments with modified biogeochemical formulations. (a)  $\text{O-LGM}^{BGC} - \text{O-PI}$ , (b)  $\text{O-LGM}^{BGC}_{rem} - \text{O-PI}$ , (c)  $\text{O-LGM}^{BGC}_{pic} - \text{O-PI}$ , and (d)  $\text{O-LGM}^{BGC}_{all} - \text{O-PI}$ . A depth of 500 m is representative of the depth at which the greatest extent of low oxygen water exists in the simulated PI climate. It should be noted that the oxygen field for experiment  $\text{O-LGM}^{BGC}_{pic}$ , whereby particulate inorganic carbon was set to zero, did not differ from the unmodified glacial experiment O-LGM and can therefore be used here as a reference to that simulation.

**Figure 13.** Change in oxygen concentration ( $\text{mmol m}^{-3}$ ) at 3,500 m between the LGM and PI for the experiments with modified biogeochemical formulations. (a)  $\text{O-LGM}_{poc}^{BGC} - \text{O-PI}$ , (b)  $\text{O-LGM}_{rem}^{BGC} - \text{O-PI}$ , (c)  $\text{O-LGM}_{pic}^{BGC} - \text{O-PI}$ , and (d)  $\text{O-LGM}_{all}^{BGC} - \text{O-PI}$ . A depth of 3,500 m is representative of the deep ocean. It should be noted that the oxygen field for experiment  $\text{O-LGM}_{pic}^{BGC}$ , whereby particulate inorganic carbon was set to zero, did not differ from the unmodified glacial experiment O-LGM and can therefore be used here as a reference to that simulation.
