24 **Abstract**

25 We present a 2700-year annually-resolved chronology and snow accumulation history for the
26 Roosevelt Island Climate Evolution (RICE) ice core, Ross Ice Shelf, West Antarctica.

27 The timescale was constructed by identifying annual cycles in high-resolution impurity records,
28 and it constitutes the top part of the Roosevelt Island Ice Core Chronology 2017 (RICE17). The
29 timescale was validated by volcanic and methane matching to the WD2014 chronology from
30 the WAIS Divide ice core, and the two timescales are in excellent agreement.

31 The RICE snow accumulation history shows that Roosevelt Island experienced slightly
32 increasing accumulation rates between 700 BCE and 1300 CE, with an average accumulation
33 of 0.25 ± 0.02 m water equivalent (w.e.) per year. Since 1300 CE, trends in the accumulation
34 rate have been consistently negative, with an acceleration in the rate of decline after the mid-
35 17th century. The current accumulation rate at Roosevelt Island is 0.211 ± 0.002 m w.e. y^{-1}
36 (average since 1965 CE, $\pm 2\sigma$), and rapidly declining with a trend corresponding to 0.8 mm y^{-2} .
37 The decline observed since the mid-1960s is 8 times faster than the long-term decreasing
38 trend taking place over the previous centuries, with decadal mean accumulation rates
39 consistently being below average.

40 Previous research has shown a strong link between Roosevelt Island accumulation rates and the
41 location and intensity of the Amundsen Sea Low (ASL), with significant impact on regional

1 sea ice extent. The decrease in accumulation rates at Roosevelt Island may therefore be
2 explained in terms of a recent strengthening of the ASL and expansion of sea ice in the Eastern
3 Ross Sea. The start of the rapid decrease in RICE accumulation rates observed in 1965 CE may
4 thus mark the onset of significant increases in regional sea ice extent.

5 **1. Introduction**

6 Accurate timescales are fundamental for reliable interpretation of paleoclimate archives,
7 including ice cores. Ice-core chronologies can be produced in a variety of ways. Where annual
8 snow deposition is sufficiently high and reasonably regular throughout the year, seasonal
9 variations in site temperature and atmospheric impurity deposition lead to annual cycles in the
10 ice-core water isotope and impurity records (Dansgaard, 1964; Hammer et al., 1978). By
11 identifying and counting the annual cycles, an annual-layer-counted ice-core timescale can be
12 produced (Sigl et al., 2016; Steig et al., 2005; Svensson et al., 2008). This technique is
13 commonly employed for producing ice-core timescales at sites with moderate to high snow
14 accumulation, including coastal Antarctica. Annual-layer-counted ice-core timescales have
15 traditionally been obtained by manual counting, but this task can now be performed using
16 machine-learning algorithms for pattern recognition (Winstrup et al., 2012).

17 Where possible, identification of annual layers allows the development of a high-resolution ice-
18 core chronology, but unless constrained by other data, the uncertainty of such a timescale will
19 increase with depth, as the number of uncertain layers accumulate to produce some age
20 uncertainty (Andersen et al., 2006; Rasmussen et al., 2006). Marker horizons found in the ice-
21 core records can be used to evaluate the accuracy of a layer-counted timescale, or, alternatively,
22 to constrain the timescale. Such marker horizons carry evidence of events of global or regional
23 nature, and may be; (a) layers of enhanced radioactivity resulting from nuclear bomb tests
24 (Arienzo et al., 2016); (b) sulfuric acids (Hammer, 1980) and/or tephra (Abbott et al., 2012)
25 from volcanic eruptions; or (c) enhanced flux of cosmogenic radionuclides caused by changes
26 in solar activity, reduction of the Earth's magnetic field, or cosmic events (Muscheler et al.,
27 2014; Raisbeck et al., 2017; Sigl et al., 2015).

28 Ice cores can also be stratigraphically matched using records of past atmospheric composition
29 from trapped air in the ice (Blunier, 2001; Blunier et al., 1998; EPICA Community Members,
30 2006). Variations in atmospheric composition are globally synchronous. Accounting for the
31 time required to sequester the air into the ice, the ice-core gas records can be used also for
32 stratigraphic matching of records measured on the ice matrix. Even during periods of stable
33 climate, the atmospheric composition displays multi-decadal fluctuations (Bender et al., 1994;
34 Mitchell et al., 2011, 2013) allowing synchronization on sub-centennial timescales.

35 Annually-resolved ice-core chronologies provide long-term reconstructions of annual snow
36 accumulation (Alley et al., 1993; Dahl-Jensen et al., 1993): Annual layer thicknesses can be
37 converted to past accumulation rates by applying corrections due to density changes during the
38 transformation from snow to ice (Herron and Langway, 1980), and thinning of annual layers
39 caused by ice flow (Nye, 1963). Reconstructions of past accumulation rates are important for
40 improving our understanding of the natural fluctuations in snow accumulation and their climate
41 drivers. Such knowledge is essential to accurately evaluate the current and future surface mass
42 balance of glaciers and ice sheets, a critical and currently under-constrained factor in sea level
43 assessments (Shepherd et al., 2012).

44 Here we present an ice-core chronology and accumulation history for the last 2,700 years from
45 Roosevelt Island, an ice rise located in the Eastern Ross Embayment, Antarctica (Fig. 1). The
46 ice core was extracted as part of the Roosevelt Island Climate Evolution (RICE) project (2010-

1 2014) (Bertler et al., 2018). RICE forms a contribution to the Antarctica2k network (Stenni et
2 al., 2017; Thomas et al., 2017), which seeks to produce Antarctica-wide ice-core
3 reconstructions of temperature and snow accumulation for the past 2000 years.

4 ECMWF ERA-Interim (ERAi) reanalysis fields (Dee et al., 2011) indicate that precipitation at
5 Roosevelt Island is strongly influenced by the Amundsen Sea Low (ASL) and associated
6 ridging (Raphael et al., 2016), and anti-correlated with precipitation in Ellsworth Land and the
7 Antarctic Peninsula (Bertler et al., 2018; Emanuelsson et al., 2018; Hosking et al., 2013). These
8 differences emphasize the need for high spatial and temporal coverage when reconstructing
9 regional mass balance patterns. With few other ice cores from the Ross Sea region, the RICE
10 accumulation history adds information on past changes in mass balance from an otherwise
11 poorly-constrained sector of the Antarctic continent.

12 **2. Site characteristics**

13 Roosevelt Island is located within the eastern part of the Ross Ice Shelf (Fig. 1), from which it
14 protrudes as an independent ice dome that is grounded 214 meters below sea level. Snow
15 accumulates locally on the ice dome, with ice originating from the Siple Coast ice streams
16 flowing around the island in the Ross Ice Shelf. Geophysical and glaciological surveys across
17 Roosevelt Island in the 1960s established ice thickness, surface topography, surface velocity
18 and accumulation rate (Bentley and Giovinetto, 1962; Clapp, 1965; Jiracek, 1967). The island
19 was revisited during 1974-75 as part of the Ross Ice Shelf Project. During this project, shallow
20 cores (up to 70m) were collected across the ice shelf, including two firn cores from Roosevelt
21 Island summit (Clausen et al., 1979). The shortest (11 m) firn core from near the summit was
22 measured for water isotopes and total β -activity in high resolution; we here refer to it as RID-
23 75 (Table 1). Results from the shallow cores show that seasonal signals of stable isotopes and
24 ionic chemistry are well preserved in the ice (Clausen et al., 1979; Herron and Langway, 1979;
25 Langway et al., 1974).

26 Ice-penetrating radar surveys of Roosevelt Island that took place in 1997 revealed a smoothly
27 varying internal stratigraphy of isochronal reflectors (Conway et al., 1999). There was no
28 evidence of disturbed internal layering that would indicate high strain rates or buried crevasses,
29 suggesting the summit of the island to be a good place for an ice core. Of special interest was a
30 distinctive arching pattern of the internal layers beneath the divide. This pattern has
31 implications for the ice history, since isochronal layers arch upward beneath divides that are
32 stable and frozen at the bed (Raymond, 1983). Analyses of the geometry of this so-called
33 Raymond stack indicate that the current divide-type ice-flow regime started about 3000 years
34 ago (Conway et al., 1999; Martín et al., 2006), and thus has been in existence throughout the
35 time period investigated in this paper. At mid-depths, the Raymond arches are offset from the
36 current topographic summit by ~500m towards north east, indicating a slight migration of the
37 ice divide in past centuries. Combined with a recently-measured vertical ice velocity profile at
38 the ice divide (Kingslake et al., 2014), the stability of the ice flow regime at Roosevelt Island
39 facilitates interpretation of past accumulation rates from annual layers in the RICE ice core.

40 The RICE deep ice core was drilled at the summit of Roosevelt Island (79.364S, 161.706W,
41 550 m above sea level (Bertler et al., 2018)), and less than 1 km from the old RID-75 shallow
42 core. It was drilled in austral summers of 2011/12 and 2012/13. During the first season, the core
43 was dry-drilled down to 130 m, and then the borehole was cased. An Estisol-240/Coasol drilling
44 fluid mixture was used to maintain core quality during the second drilling season. The ice
45 thickness is 764.6 m. The upper 344 m of the core spans the past 2700 years; the period for
46 which an annual-layer-counted timescale can be constructed. In addition to the deep core,
47 several shallow cores were drilled in the vicinity. During the 2012/13 field season, a 20 m firn

1 core (RICE-12/13-B) was drilled near the main core, and it was used to extend the records up
2 to the 2012/13 snow surface. Table 1 provides an overview of the relevant firn and ice cores
3 collected at Roosevelt Island. An automated weather station near the RICE drill site recorded
4 mean annual temperatures of -23.5°C over the duration of the RICE project (2010-2014), and
5 an average snow accumulation of approximately $0.20\text{ m w.e. yr}^{-1}$ (Bertler et al., 2018).

6 **Methods**

7 **3. Ice core processing and impurity analysis**

8 The RICE ice cores were processed and analyzed at the GNS Science National Ice Core Facility
9 in Lower Hutt, New Zealand. The cores were cut longitudinally to produce a $15\times 35\text{ mm}$
10 triangular piece for water isotope analysis and two $35\times 35\text{ mm}$ square sticks for continuous flow
11 analysis (CFA) (Fig. 2). The second CFA piece was for use in case the core quality of the
12 primary piece was compromised, or for repeat measurements to test measurement accuracy and
13 system stability.

14 In parallel with ice core cutting and processing, CFA and electrical conductivity measurements
15 (ECM) were carried out. ECM (Hammer, 1980) was measured using a low-power hand-held
16 instrument from Icefield Instruments Inc. directly on the ice-core surfaces after the initial
17 cutting of the core. In 2012, the uppermost section ($8.57\text{-}40\text{ m}$) of the RICE main core was
18 processed and analyzed using the GNS Science melter system, with continuous measurements
19 of stable water isotopes (δD , $\delta^{18}\text{O}$) and black carbon, and discrete sampling of major ion and
20 trace element concentrations. The following year, this set-up was replaced by an expanded
21 version of the Copenhagen CFA system (Bigler et al., 2011), providing high-resolution
22 continuous measurements of liquid conductivity, calcium (Ca^{2+}), insoluble dust particles,
23 acidity (H^+), and black carbon (BC), as well as stable water isotopes (δD , $\delta^{18}\text{O}$) and methane
24 gas concentrations (Table 1). The RICE-12/13-B firn core was analyzed using this system.
25 Next, the RICE main core was melted and analyzed from 40 m to 475 m , at which depth the ice
26 brittle zone was reached. Subsequent repeat measurements of the top section ($8.57\text{-}40\text{ m}$) of the
27 main core were made using the second, parallel CFA stick.

28 Primary adaptations to the Copenhagen CFA system involved: 1) Depth assignment via a digital
29 encoder using a 1-second sampling rate (Keller et al., 2018); 2) Continuous analysis of stable
30 water isotopes ($\delta^{18}\text{O}$, δD) using a Los Gatos Research (LGR) analyzer (Emanuelsson et al.,
31 2015); 3) Black carbon analysis by a Single Particle Soot Photometer (Droplet Measurement
32 Technologies, Boulder, CO; DMT SP2) following the method reported by McConnell et al.
33 (2007); 4) Acidity measurements based on direct registration of H^+ concentrations using an
34 optical dye method (Kjær et al., 2016); 5) Continuous methane concentration analysis using a
35 Picarro Cavity Ring-Down Spectroscopy (CRDS) instrument (Stowasser et al., 2012); and 6)
36 Inclusion of three fraction collectors for discrete sample analyses by, respectively, ion
37 chromatography (IC), Inductively-Coupled Plasma Mass Spectrometry (ICP-MS), including
38 measurements of ^{239}Pu using an ICP-SFMS technique (Gabrieli et al., 2011), and measurements
39 of stable water isotopes on the LGR. Figure 3 shows a diagram of the CFA system set-up.

40 The ice was melted at a rate of 3 cm min^{-1} , producing approximately 16.8 mL contamination-
41 free water and gas mixture per minute of melting. Air bubbles were separated in a debubbler,
42 dried, and sent to the Picarro CRDS instrument for methane analysis. Each minute, 5 mL
43 meltwater was directed to each of two fraction collectors (IC and ICP-MS aliquots) and 1.1 mL
44 was used for continuous measurements of water isotopes (0.05 mL) and black carbon (1.05 mL)
45 by the LGR and DMT SP2 instruments. The remaining 1.8 mL was sent to flow-through liquid

1 conductivity and insoluble particle analyzers (Bigler et al., 2011), and then split for continuous
2 analysis of soluble calcium (Traversi et al., 2007) and acidity (Kjær et al., 2016). A third
3 fraction collector was used to collect discrete samples for water isotopes from the melt-head
4 overflow lines originating from the outer core section, these being used for quality assurance
5 of the continuous measurements.

6 On average, 20 metres of ice were melted during a 24-hour period, including measurements,
7 calibrations and routine maintenance. Calibrations for water isotopes, calcium, acidity and
8 black carbon were carried out before and after each melting run, which comprised the
9 continuous analysis of 3x1 m long ice rods. Calibrations for methane, based on standard gases
10 with methane concentrations corresponding to glacial and preindustrial Holocene levels, were
11 carried out twice daily. Core breaks and/or contamination in the system caused some sections
12 of missing data. The percentage of affected core varied between chemistry species, ranging
13 from <1% (BC) to 17% (H⁺) (see supplementary Table S1), the majority being small sections
14 of missing data that did not severely impact annual layer interpretation.

15 The CFA chemistry records were very densely sampled (1 data point per mm). Mixing in the
16 tubing as the meltwater sample travelled from melt head to the analytical systems caused
17 individual measurements to be correlated, and hence the effective depth resolution of the system
18 was significantly less than the sampling resolution. This was especially the case for the RICE
19 CFA set-up owing to the relatively small fraction of total meltwater directed to the continuous
20 measurement systems. Following the technique used in Bigler et al. (2011), the effective depth
21 resolution for the CFA measurements was estimated to range from 0.8 cm (conductivity) to 2.5
22 cm (Ca²⁺) (Table S1).

23 **4. Constructing the Roosevelt Island Ice Core Chronology,** 24 **RICE17, for the last 2700 years**

25 The Roosevelt Island Ice Core Chronology 2017, RICE17, was constructed using multiple
26 approaches, as necessitated by changing properties and availability of data with depth. This
27 section describes the methodology used to construct the most recent 2700 years of RICE17, the
28 period for which annual layer identification was feasible. For the deeper part of the core,
29 RICE17 was constructed by gas matching to the WAIS Divide ice core on the WD2014
30 chronology, as reported in Lee et al. (2018).

31 **4.1. Overview of the annual-layer counting strategy**

32 The uppermost section (0-42.34 m) of the core was dated by manual identification of annual
33 cycles in records of water isotopes and ice impurities from the RICE main core as well as the
34 RICE-12/13-B shallow core. For this most recent period, several distinct marker horizons from
35 well-known historical events were used to constrain the chronology (section 4.2).

36 Below 42.34m (1885 CE), the timescale was augmented using the *StratiCounter* layer-counting
37 algorithm (Winstrup et al., 2012) applied to multiple CFA impurity records from the RICE main
38 core (section 4.3). A previously-dated tephra layer at 165 m (Pleiades; 1251.6±2 CE according
39 to WD2014) was used to optimize the algorithm settings, but other than that, RICE17 is a fully
40 independent layer-counted ice-core chronology.

41 The layer-counted part of RICE17 stops at 343.72 m (700 BCE). At this depth, the annual layers
42 are too thin (<6 cm, i.e. less than 8 independent data points/year in the best resolved records)
43 for reliable layer identification in data produced by the RICE CFA set-up. To extend the
44 RICE17 timescale further back, the layer-counted timescale was combined with the gas-derived

1 timescale, which covers the entire core with lower resolution (Lee et al., 2018). Excellent
2 agreement (± 3 years) between the layer-counted timescale and the independent gas-derived age
3 at 343.7m allows us to produce the combined Roosevelt Island Ice Core Chronology 2017,
4 RICE17, by joining the two without any further adjustments.

5 **4.2. Manual layer interpretation with historical constraints (0 - 42.34 m;** 6 **2012 - 1885 CE)**

7 The top 42.34 m of the RICE17 chronology was obtained by manually counting annual layers
8 in the combined set of discretely-measured IC and ICP-MS data, where available, as well as
9 the continuous water isotope and chemistry records produced by the RICE CFA system. The
10 RICE main core starts at 8.65 m depth, so the top part of the timescale is based exclusively on
11 the RICE-12/13-B shallow core. At 12.5 m, both cores display a distinct peak in their isotope
12 profiles, showing that they can be spliced directly without need for any depth adjustments.
13 Layer marks for the top 12.5 m were placed according to the RICE-12/13-B shallow core; lower
14 layer marks refer to the main core. In the overlap section (8.65-19.55m), we used the combined
15 data set from both cores to reduce the risk of timescale errors caused by core breaks or bad data
16 sections.

17 Layer identification in this section of the core relied predominantly on annual signals in non-
18 sea-salt sulfate (nss-SO_4^{2-}), acidity (H^+) and iodine (I), as these records displayed the most
19 consistent annual signals (Fig. 4). Extreme sea-salt influx events occasionally caused large
20 sulfate peaks, necessitating the removal of the sea-salt sulfate fraction before layer
21 identification. For the top 20 m, the water isotope records also significantly strengthened the
22 annual layer interpretations. Smoothing through diffusion of water molecules in the firn,
23 however, causes the annual signal in the water isotope records to diminish with depth, resulting
24 in a loss of annual signals below 20 m.

25 Summers could be identified as periods with high stable water isotope ratios, high
26 concentrations of nss-SO_4^{2-} and associated acidity [originating from phytoplankton activity in
27 the surrounding ocean during summer (Legrand et al., 1991; Udisti et al., 1998)], and low iodine
28 concentrations [due to summertime photolysis of iodine in the snowpack (Frieß et al., 2010;
29 Spolaor et al., 2014)]. Layer marks were placed according to the depths of concurrent summer
30 peaks in water isotope ratios, nss-SO_4^{2-} concentrations, and acidity levels, and assigned a
31 nominal date of January 1st.

32 The uppermost 42.34 m of the RICE17 chronology was tied to several distinctly identifiable
33 marker horizons found in the ice-core records relating to well-known historical events (sections
34 4.2.1-4.2.3; Table 2). A confidence interval was assigned to the timescale by classifying layers
35 as certain or uncertain (Fig. 4), while accounting for age constraints from marker horizons. We
36 conservatively estimated the age uncertainty of the marker horizons to be ± 1 year, thereby
37 allowing for some uncertainty in timing of deposition of e.g. volcanic material. Some uncertain
38 layers were counted as a year in the timescale, while others were not. In this way, a most likely
39 timescale was constructed along with an uncertainty estimate, which we interpret as the 95%
40 confidence interval of the age at a given depth, similar to that obtained from automated layer
41 identification deeper in the core (section 4.3).

42 **4.2.1. The 1974/75 snow surface**

43 The uppermost age constraint was established by successfully matching the RICE water isotope
44 profile to that from the RID-75 firn core (Fig. 5). Drilled in austral summer 1974/75, the snow
45 surface in RID-75 provided the first tie-point for the RICE17 chronology at a depth of 14.62m
46 (Table 2).

4.2.2. Nuclear bomb peaks

High-resolution ^{239}Pu measurements on the upper part of the RICE core show a significant rise in plutonium levels, starting from very low background levels at 22m and reaching peak values at 21.6m. This increase can be attributed to atmospheric nuclear bomb testing during the Castle Bravo Operation, Marshall Islands, in March 1954, which globally caused large amounts of nuclear fallout over the following year (see e.g. Arienzo et al. (2016)).

Total specific β -activity levels in the RID-75 core show the same evolution (Clausen et al., 1979), confirming both the isotopic matching between the two cores, and the age attribution of this event (Fig. 5). The abrupt increase in ^{239}Pu -fallout at 22m was used as age constraint for the RICE17 chronology. Subsequent peaks in the ^{239}Pu and β -activity records can be attributed to successive nuclear tests and subsequent test ban treaties (Table 2). These changes were much less distinct, and were therefore not used during development of the timescale.

4.2.3. Recent volcanic eruptions

A couple of volcanic horizons in RICE during this most recent part could be related to well-known volcanic eruptions. Rhyolitic tephra located between 18.1-18.2m was found to have a similar geochemical composition as a tephra layer found in the WAIS Divide core deposited late 1964 CE (Wheatley and Kurbatov, 2017). The tephra likely originates from Raoul Island, New Zealand, which erupted from November 1964 to April 1965. This is consistent with the RICE17 chronology, according to which the tephra is located in early 1965 CE (Table 2).

Only two volcanic eruptions could be unambiguously identified in the acidity records over this period; the historical eruptions of Santa Maria (1902 CE; 37.45m) and Krakatau (1883 CE; 42.34m) (Table 2). These two horizons were used to constrain the deeper part of the manually-counted interval of RICE17, which terminates at the Krakatau acidity peak. Deposition age of volcanic material for these events was assumed identical to those observed in the WAIS Divide ice core (Sigl et al., 2013). Imprints from other large volcanic eruptions taking place during recent historical time, such as Agung and Pinatubo, did not manifest themselves sufficiently in the RICE records to be confidently identified.

4.3. Automated annual layer identification (42.34 - 343.7 m; 1885 CE - 700 BCE)

For the section 42.34-343.7 m (1885 CE - 700 BCE), the RICE17 annual layer-counted timescale was produced using the StratiCounter algorithm (Winstrup et al., 2012), extended to interpret the annual signal based on multiple chemistry series in parallel (Winstrup, 2016).

StratiCounter is a Bayesian algorithm built on machine-learning methods for pattern recognition, using a Hidden Markov Model (HMM) framework (Rabiner, 1989; Yu, 2010). StratiCounter computes the most likely timescale and the associated uncertainty by identifying annual layers in overlapping data batches stepwise down the ice core. For each batch, the layering is inferred by combining prior information on layer appearance with the observed data, thereby obtaining a posteriori probability distributions for the age at a given depth. The output of StratiCounter is the most likely annual timescale, along with a 95% confidence interval for the age as function of depth. The confidence interval assumes the timescale errors to be unbiased, implying that uncertainties in layer identification partly cancel out over longer distances.

StratiCounter was applied to the full suite of CFA records: black carbon, acidity, insoluble dust particles (42.3-129m), calcium, and conductivity. See supplementary S2 for the specifics of the algorithm set-up. Annual cycles in the high-resolution black carbon (BC) record became more distinct prior to 1900 CE, and it was one of the most reliable annual proxies in the core (section

6). As observed in the topmost part of the core, acidity also displayed a distinct annual signal, although the relatively low effective depth resolution of the acidity record (Table S1) made it much less useful with depth. From 0 to 129 m, an irregular annual signal was also observed in the insoluble particle record, but data below 129 m was corrupted by the presence of drill fluid in the CFA system, which forced us to exclude the deeper part of this record. The calcium and conductivity records frequently displayed multiple peaks per year, limiting their contribution to the annual layer interpretations. The discretely-sampled ICP-MS data records did not have sufficient resolution to resolve annual layers.

Decreasing layer thicknesses caused the annual signal in the impurity records to become increasingly difficult to identify with depth, and the layer-counted timescale stops at 343m (700 BCE).

5. Reconstructing past accumulation rates

The accumulation rate history at Roosevelt Island can be inferred from depth profiles of annual-layer thicknesses in the RICE core, when corrected for firn densification and thinning of layers due to ice flow.

5.1. Changes in density with depth

Bag-mean densities were measured on the main RICE core for the interval 8-130 m, at which depth ice densities were reached (see supplementary S3). A steady-state Herron-Langway density model (Herron and Langway, 1980) fitted to the measurements was used to extend the density profile to the surface. Using an initial snow density of 410 kg m^{-3} , a surface temperature of -23.5°C , and an accumulation rate of $0.22 \text{ m w.e yr}^{-1}$, the modelled density profile fits well the observed values (Fig. S2). At 8 m depth, the model agrees with the measured values, providing a smooth transition between observed and modelled densities.

5.2. Thinning of annual layers due to ice flow

The annual layer thickness profile must be corrected for the amount of vertical strain experienced by the ice. This correction factor can be represented by a thinning function, which informs on the cumulative effects of ice flow on the thickness of an ice layer after it was deposited at the surface (this being the ice equivalent accumulation rate at that time). A thinning function appropriate for RICE was produced using vertical velocity profiles obtained by fitting a simple ice-flow model (Lliboutry, 1979) to englacial velocities deduced from repeat radar measurements (Kingslake et al., 2014), while (a) constraining the model parameters to match the present-day accumulation rate and ice-sheet thinning, and (b) accounting for velocity changes caused by the shift in position of the ice divide at Roosevelt Island within the past centuries.

Near-surface vertical strain rates are more compressive near ice divides than on the flanks. Hence, due to migration of the ice divide at Roosevelt Island, ice recovered from different depths in the RICE core has experienced different regimes of vertical strain. Informed by the architecture of the Raymond stack (Fig. 6c), we assumed the following divide-migration history: Until 500 years before ice core drilling (1512 CE), the divide was located 500 m east of the present position, as indicated by the position of the deeper Raymond arches. Since 500 years ago, the divide migrated westward, arriving at its present position by 1762 CE (250 years ago).

Radar measurements of near-surface vertical strain rates (Fig. 6b in Kingslake et al. 2014) show that the transition from divide- to flank-type flow at Roosevelt Island occurs over a distance of

1 ~900 m. For the older part of the ice core (prior to 1512 CE; ice originating 500 m east of the
2 current divide) we used a vertical velocity profile appropriate for divide/flank transitional-type
3 ice flow. While the ice divide migrated to its present position over the following 250 years
4 (1512-1762 CE), the vertical velocity profile transitioned to the present divide-type flow (Fig.
5 6a).

6 Following Kingslake et al. (2014), the vertical velocity profiles (w) at normalized depth (ζ) was
7 parameterized using a shape factor (p) and the vertical velocity at the surface (w_s) (Lliboutry,
8 1979):

$$9 \quad w(\zeta) = w_s \left(1 - \frac{p+2}{p+1} \zeta + \frac{1}{p+1} \zeta^{p+2} \right)$$

10 The long repeat interval (3 years) for the radar measurements meant that no vertical velocity
11 measurements were obtained in the firn layer (Fig 6a). The velocity profile was therefore
12 linearly extended to the surface, starting at 155m ice equivalent depth. The vertical surface
13 velocity was taken to be 0.26 m ice eq. yr⁻¹, obtained as the sum of the modern accumulation
14 rate (0.24 m ice eq. yr⁻¹, i.e. 0.22 m w.e yr⁻¹) and recent ice-sheet thinning (0.02m ice eq. yr⁻¹;
15 estimated using an ice-flow model to match the dated architecture of the Raymond stack). For
16 divide-type flow with $w_s = 0.26$, the overall misfit to the measured vertical velocity
17 measurements was minimized using $p = -1.22$. For flank-type flow, we used $p = 4.16$
18 (Kingslake et al., 2014). For the divide/flank transitional-type flow prior to 1512 CE was used
19 a linear combination with divide-type velocities weighted by 0.7 and flank-type velocities
20 weighted by 0.3. As the divide migrated, the weighting was changed linearly to obtain full
21 divide-type ice flow velocities by 250 years ago.

22 Figure 6b shows the resulting thinning function derived for the RICE core site. It decreases
23 from 1.0 at the surface (no strain thinning) to 0.24 at 344 m depth. Past annual accumulation
24 rates in water equivalents can be calculated as the annual layer thicknesses divided by the
25 thinning function and multiplied with the firn/ice density.

26 **5.3. Uncertainties in the accumulation history**

27 Uncertainties in the inferred accumulation history originate from three sources: (i)
28 identification of the annual layers; (ii) the density profile; (iii) the derived thinning function.
29 Except for the uppermost part of the record, uncertainty in the thinning function dominates the
30 total uncertainty, and only this factor will be considered here.

31 At the surface, uncertainty in the thinning function is zero (no strain thinning). Increasing
32 uncertainty with depth (Fig. 6b; grey area) arises from: (a) the lack of measurements in the
33 upper 90 m of the ice sheet to constrain the near-surface vertical velocity; (b) variation of the
34 vertical velocity profile over time in ways not accounted for. The second source of uncertainty
35 is partly mitigated because the amplitudes of the Raymond stack constrain the onset of divide
36 flow to about 3000 years ago (Conway et al., 1999; Martin et al., 2006), i.e. prior to the period
37 considered here, and the existence of the Raymond stack reveals that flow conditions have been
38 stable since. Hence, we believe that most uncertainty arises from the lack of vertical velocity
39 measurements in the upper part of the ice sheet.

40 To assess the magnitude of this uncertainty, we compared results using two alternate thinning
41 functions. First, the same method as described above (section 5.2) was used to find the best fit
42 to measured vertical velocities, but using a vertical surface velocity of 0.24 m ice eq. yr⁻¹,
43 thereby neglecting the contribution from surface lowering. Second, we used the best fit derived
44 by Kingslake et al. (2014). The mean difference between the three thinning functions is ~5%,
45 with the largest difference (9%) at 78.5 m depth. Accounting also for unknown factors, the

1 uncertainty of the thinning function was set to increase from 0% at the surface to 10% at 78.5
2 m (1730 CE), and to remain constant at 10% deeper in the core. This translates to approximately
3 the same percentage-wise uncertainty in derived accumulation rates. We suggest to interpret
4 this uncertainty as a 95% (2σ) confidence interval. As the strain increases continuously with
5 depth, the relative uncertainty on the accumulation rates is much smaller than the absolute
6 values.

7 **Results**

8 **6. Seasonality of impurity influx to Roosevelt Island**

9 Using the RICE17 timescale, we can quantify the seasonality of impurity influx to Roosevelt
10 Island visible in the five RICE CFA records: acidity, calcium, conductivity, black carbon and
11 insoluble dust particles. Figure 7 shows the average seasonal pattern of the impurities at
12 different depths, assuming constant snowfall through the year.

13 **6.1. Acidity**

14 The CFA acidity record is driven primarily by the influx of non-sea-salt sulfur-containing
15 compounds, as evident by its high resemblance to the IC non-sea-salt sulfate and ICP-MS non-
16 sea-salt sulfur records in the top part of the core (Fig. 4). Sulfur-containing compounds have a
17 variety of sources, one of which is dimethylsulfide (DMS) emissions by phytoplankton activity
18 during summer (Legrand et al., 1991; Udisti et al., 1998). Correspondingly, acidity displays a
19 regular summer signal, with maximum values in late austral summer (January/February), and
20 minimum values from June through October. This is similar in timing to the seasonal pattern
21 of non-sea-salt sulfate at Law Dome (Curran et al., 1998) and WAIS Divide (Sigl et al., 2016).
22 The acidity contains a faint annual signal even in the deepest part of the layer-counted timescale
23 (Fig. 7a-c).

24 Episodic influxes of sulfuric acids from explosive volcanic eruptions are overprinted on the
25 annual acidity signal. Biogenic peak values of up to 200ppb non-sea-salt sulfate are of the same
26 order as the expected sulfate deposition from large volcanic eruptions, causing the seasonal
27 signal to effectively obscure the volcanic contributions to the non-sea-salt sulfate
28 concentrations. Volcanic signals are slightly more prominent in the acidity record (Fig. 8a).
29 This may be explained by only a fraction of the biogenic sulfur emissions being oxidized to
30 acids, whereas volcanic SO_2 emissions are almost completely oxidized to H_2SO_4 (a strong acid).

31 **6.2. Sea-salt derived species: Calcium and conductivity**

32 As previously noted by Kjær et al. (2016), the RICE conductivity record is almost identical to
33 the mostly sea-salt-derived calcium record (Figs. 4, 8), suggesting sea spray to be responsible
34 also for peaks in liquid conductivity. We hence consider these two records to be representative
35 of sea salt deposition at Roosevelt Island.

36 Both records typically peak during early-to-mid-winter (June/July), but with large spread in
37 magnitude and timing from year to year (Fig. 7d-i), and oftentimes there are multiple peaks per
38 year. The timing of peak values is approximately similar to sea-salt tracers in WAIS Divide
39 (Sigl et al., 2016), and a few months earlier than peak values in Law Dome (Curran et al., 1998).
40 During the most recent period (1900-1990 CE), we observe a summer peak in the average
41 seasonal conductivity signal, which is not present in the calcium record. This is likely the steady
42 summer contribution to conductivity from biogenic acidity, the seasonality of which being
43 sufficiently prominent to show up in seasonal averages of conductivity in the top part of the
44 core.

1 **6.3. Black carbon**

2 Seasonal deposition of black carbon (BC) in Antarctic snow is primarily driven by biomass
3 burning and fossil fuel combustion in the Southern Hemisphere, modulated by changes in
4 efficiency of the long-range atmospheric transport (Bisiaux et al., 2012). Southern Hemispheric
5 fossil fuel emissions have increased since the 1950s (Lamarque et al., 2010), but are still
6 believed to be a minor contributor to total black carbon deposition in Antarctica (Bauer et al.,
7 2013).

8 Biomass burning in the Southern Hemisphere peaks towards the end of the dry season, e.g. late
9 summer (Schultz et al., 2008). Given the distinct annual signal in the black carbon record (Fig.
10 7j-l), StratiCounter was set up to assign peaks in BC a nominal date of January 1st (mid-
11 summer). We note that peaks in BC approximately coincide with peaks in acidity (similar to
12 observed in WAIS Divide), thus ensuring consistency of nominal dates throughout the core.
13 Minimum concentration values are reached in Austral winter (June/July).

14 The annual signal in black carbon changes with depth in the RICE core. During the 20th century,
15 annual cycles exist, but are not very prominent (Fig. 7j). Prior to 1900 CE, the signal is much
16 more distinct, with larger seasonal amplitude as well as higher annual mean concentrations (Fig.
17 7k-l). A recent decrease in BC concentrations has been observed also in the WAIS Divide and
18 Law Dome ice cores, and attributed to a reduction in biofuel emissions from grass fires (Bisiaux
19 et al., 2012). At WAIS Divide and Law Dome, however, the shift takes place several decades
20 later than observed in RICE.

21 With increasing depth in the ice core, thinner annual layers cause the amplitude of the seasonal
22 signal to slowly be reduced. Yet, aided by the high effective depth resolution of the black carbon
23 record, the seasonal cycle persists to great depths in the RICE core, with the deepest part of the
24 layer-counted RICE17 timescale primarily relying on the annual signal in this parameter.

25 **6.4. Dust**

26 The seasonal pattern in insoluble dust particle concentrations showed a weak annual signal,
27 with a tendency to peak in summer. The simultaneous deposition of black carbon and dust is
28 consistent with both tracers arriving via long-range transport from southern hemispheric
29 continental sources. The dust record showed large non-annual variability, and had limited
30 contribution to the annual layer identification in RICE17.

31 **7. The layer-counted RICE17 chronology**

32 The layer-counted timescale was constructed back to 700 BCE (0-343.72 m), and it forms the
33 most recent part of the Roosevelt Island Ice Core Chronology 2017 (RICE17). It is an
34 independent timescale, constrained only by a few well-known historical events over the last
35 hundred years. Its independence is reflected in the timescale uncertainty: Age confidence
36 intervals show an approximately linear increase with depth (Fig. 8b), reaching a maximum age
37 uncertainty of ± 45 years (95% confidence) at 700 BCE, the end of the layer-counted timescale.

38 RICE17 was evaluated by comparing to the highly accurate annual-layer-counted WD2014
39 chronology from WAIS Divide (Sigl et al., 2015, 2016). Timescale comparison was aided by
40 the relative proximity of the two ice cores, and accomplished using two complementary
41 approaches: 1) matching multi-decadal variations in the RICE methane record to a similar
42 record from WAIS Divide; and 2) by matching volcanic marker horizons in the two cores. The
43 two matching procedures were performed independently, and are described in the following
44 sections.

1 Volcanic matching allows very precise age comparisons, but suffers from the risk of incorrect
2 event attribution. Erroneous alignment is less likely to occur when matching records of methane
3 concentration variability. This approach does not allow as high precision, however, due to the
4 multi-decadal nature of the methane variations, as well as the need to account for the gas-age-
5 ice-age difference. Combining the two lines of evidence, the methane match points were used
6 to validate the absolute ages of the timescale (relative to WD2014), and to confirm the
7 independently-obtained volcanic match points. Based on the volcanic matches, a high-precision
8 comparison to WD2014 was achieved, allowing an in-depth quality assessment of the RICE17
9 chronology.

10 **7.1. Timescale validation using multi-decadal variability in methane** 11 **concentrations**

12 Centennial-scale variations in methane concentrations observed in the RICE gas records can
13 also be found in similar records from WAIS Divide (Mitchell et al., 2011; WAIS Divide Project
14 Members, 2015). Stratigraphic matching of these records allowed a comparison of the
15 respective ice-core timescales.

16 The gas records from RICE and WAIS Divide were matched using a Monte Carlo technique
17 reported in Lee et al. (2018). The feature matching routine employed discretely-measured
18 records of methane as well as isotopic composition of molecular oxygen ($\delta^{18}\text{O}_{\text{atm}}$). Over recent
19 millennia, however, the $\delta^{18}\text{O}_{\text{atm}}$ concentrations have been stable, and hence provided minimal
20 matching constraints. An average spacing of 26 years between successive RICE methane
21 samples contributed to the matching uncertainty. The matching routine identified 18 match-
22 points over the past 2700 years, i.e. an average spacing of 150 years. Subsequent visual
23 comparison of the methane profiles suggested minor manual refinements of the match-points
24 (8 years on average, maximum 23 years; all within the uncertainty of the automated matching).
25 These adjustments resulted in a slightly improved fit.

26 Through methane feature matching, WAIS Divide ages could be transferred to the RICE gas
27 records, i.e. provide an estimate for the RICE gas ages. During the snow densification process,
28 there is a continuous transfer of contemporary air down to the gas lock-in depth, resulting in an
29 offset (Δage) between the ages of ice and gas at a given depth (Schwander and Stauffer, 1984).
30 To obtain the corresponding ice-core ice ages relevant for this study, Δage was calculated using
31 a dynamic Herron-Langway firn densification model (Herron and Langway, 1980) following
32 Buizert et al. (2015). The approach is described in detail in Lee et al. (2018). The model is
33 forced using a site temperature history derived from the RICE stable water isotopes, and the
34 firn column thickness is constrained by the isotopic composition of molecular nitrogen ($\delta^{15}\text{N}$
35 of N_2). In addition to Δage , this formulation of the Herron-Langway densification model
36 produces as output a low-resolution accumulation rate history (section 8.3).

37 Compared to most other Antarctic sites, the relatively high surface temperature and
38 accumulation rate at Roosevelt Island give rise to low Δage values (averaging 160 years over
39 recent millennia) associated with small uncertainties (~ 36 years; 1σ). Combined with the
40 feature matching uncertainty (average: 48 years), total age uncertainty (1σ) in the transfer of
41 WD2014 to the RICE core is on average 64 years (maximum: 101 years) over the last 2700
42 years.

43 The RICE17 timescale is consistent with the WD2014 age of the methane match points (Fig.
44 8b). Based on the automatic matching routine, agreement of RICE17 to the gas-matched
45 WD2014 ages is better than 33 years for all age markers, with a root-mean-square (RMS)
46 difference of 17 years. Agreement between the two timescales is even better when using the

1 manually-adjusted match-points, for which the RMS difference is reduced to 13 years. We
2 observe, however, that all methane match points below 275 m are associated with older ages in
3 WD2014 than in RICE, suggesting a small bias in the deeper part of RICE17.

4 **7.2. Timescale evaluation from volcanic matching**

5 Using the layer counts in RICE17 as guide, volcanic horizons identified in RICE could be
6 linked to the WAIS Divide volcanic record (Sigl et al., 2013, 2015), allowing a detailed
7 comparison of their respective timescales. Identification of volcanic eruptions in the RICE
8 records was non-trivial, but feasible after the introduction of two new volcanic tracers,
9 described below.

10 **7.2.1. New and conventional ice-core tracers for volcanic activity**

11 With its coastal location and low altitude, the RICE drilling site receives significant seasonal
12 influx of sulfuric acids from biological oceanic sources, which tends to obscure sulfur
13 deposition from volcanic eruptions (section 6.1). Traditional volcanic ice-core tracers, ECM
14 and sulfur, were generally of limited value for identifying volcanic horizons. The ECM record
15 was very noisy, with few peaks extending above the noise level. Resolution of the discretely-
16 sampled sulfur record was too low (below 67m: 5 cm, i.e. less than 4 samples/year), and even
17 large volcanoes only left a vague imprint in form of slightly increased sulfur levels over a multi-
18 year period (Fig. 9a). Detection of volcanic horizons in the RICE core therefore primarily relied
19 on two new high-resolution tracers for volcanic activity: direct measurements of total acidity
20 and estimated non-sea-salt liquid conductivity.

21 Peaks in the RICE liquid conductivity record were caused primarily by sea salts, and thus this
22 record could not on its own be used as volcanic tracer. However, from the close similarity of
23 the conductivity and the mostly sea-salt-derived calcium record (Figs. 4, 9), we could extract a
24 signal of non-sea-salt conductivity, obtained as the conductivity-to-calcium excess. Being a
25 secondary product, this tracer is prone to measurement errors, calibration and co-registration
26 uncertainties, and further complicated by differences in measurement resolution. Nevertheless,
27 peaks in the conductivity-to-calcium excess showed high consistency with peaks in total
28 acidity, and it proved to be a reliable tracer for volcanic activity.

29 Based on the combined evidence from all proxies, we were able to identify volcanic horizons
30 in RICE. A sequence of volcanic signals is shown in Figure 9a. Compared to acidic peaks
31 resulting from unusually high biogenic summer activity, volcanic imprints could be
32 distinguished as more prominent and/or broader features. Small and short-lived volcanic
33 eruptions, however, were not easily identified.

34 **7.2.2. The Pleiades: A tephra-chronological marker horizon**

35 A visible tephra layer was found in RICE at 165m depth, with a RICE17 age of 1251.5 ± 13 CE.
36 Geochemistry of the tephra particles is consistent with an eruption from the Pleiades (Kalteyer,
37 2015; Kurbatov et al., 2015), a volcanic group located in Northern Victoria Land, Antarctica
38 (Fig. 1). Tephra of similar geochemistry has been found in several other Antarctic cores dated
39 to approximately the same time, including WAIS Divide (1251.6 ± 2 CE; Dunbar et al. 2010)
40 and Talos Dome/TALDICE (1254 ± 2 CE; Narcisi, Proposito, and Frezzotti 2001; Narcisi et al.
41 2012). The Pleiades tephra horizon allowed a firm volcanic matching of the RICE and WAIS
42 Divide ice cores at this depth (Fig. 9).

43 The Pleiades tephra horizon was used to select the optimal settings for the StratiCounter
44 algorithm, seeking to reproduce the WD2014 age of the tephra layer as well as possible. The
45 observed compliance of the two age-scales at this depth is therefore to be expected. However,
46 we note that our use of this layer as chronological marker had little impact on the resulting

1 RICE17 timescale: All StratiCounter solutions produced very similar ages for the tephra
2 horizon, and, within the age-scale uncertainties, all were in agreement with the WD2014 age of
3 the tephra.

4 **7.2.3. Volcanic matching to WAIS Divide**

5 Based on the layer counts in RICE17, we could match up volcanic horizons observed in RICE
6 with the WAIS Divide volcanic record (Sigl et al., 2013, 2015). The matching relied on
7 identifying sequences of volcanic events in the two cores with similar age spacing according to
8 their respective timescales. Taking this approach was especially important due to the few
9 prominent volcanic horizons in the RICE core, and the risk of confounding volcanic and
10 biogenic signals. Reliability increased with density of match points in the volcanic sequence.
11 In some sections such sequences were hard to identify, either due to timescale differences, too
12 many or too few volcanic events. For sections without CFA data, a tentative attribution was
13 made based on the limited evidence from the non-sea-salt sulfur and ECM records, where
14 possible. The volcanic matches are provided in Table 2.

15 The volcanic matching was in excellent agreement with the independently-obtained methane
16 matching, especially when using the manually-adjusted match points (Fig. 8b). A majority of
17 the volcanic links identified between the RICE and WAIS Divide ice cores have previously
18 been classified as bipolar signals, originating from large tropical volcanoes (Sigl et al., 2013,
19 2015). This further strengthens our trust in the volcanic matching, since these large eruptions
20 usually deposit acids over an extended area and period, and therefore are expected to be
21 recognizable from the RICE volcanic records.

22 **7.2.4. Quality assessment of RICE17**

23 The volcanic matching to WAIS Divide allowed a detailed evaluation of RICE17. The WD2014
24 counting uncertainty is merely 7 years over the last 2700 years, much less than the uncertainty
25 associated with RICE17, and we hence consider it to be the more accurate of the two. Within
26 their respective uncertainties, the RICE17 and WD2014 chronologies are in full agreement at
27 all volcanic marker horizons (Table 2; Fig. 8b). Indeed, the age differences are much less than
28 the accumulated RICE17 age uncertainties. We hence conclude that the inferred confidence
29 bounds on the RICE17 chronology are reliable, if somewhat conservative.

30 Agreement between the two ice-core timescales is particularly remarkable down to 285 m (~150
31 CE). For this most recent part of the RICE17 timescale, the age discrepancy is less than 7 years
32 at all marker horizons, with a RMS age difference of 3 years. Below 285 m, the volcanic
33 matches indicate that RICE17 may be slightly biased (~3%) towards younger ages. This is
34 corroborated by the methane match points (section 7.1). At 285 m, the effective depth resolution
35 of the CFA impurity records (1-2 cm) becomes marginal compared to the annual layer
36 thicknesses (7 cm at 285 m), and we suspect that this has caused the thinnest fraction of annual
37 layers to be indiscernible in the ice core records.

38 Consequently, the deepest section of the layer-counted RICE17 chronology slowly diverges
39 from WD2014, reaching a maximum age difference of 30 years at the oldest identified volcanic
40 marker horizon (343.3 m, 691 BCE \pm 45 years; Table 2). This age offset is of similar magnitude
41 to the uncertainty of the methane-derived RICE17 ages at this depth.

42 **8. Roosevelt Island accumulation history**

43 Annual layer thicknesses in the RICE ice core smoothly decrease with depth, starting from more
44 than 40 cm at the surface to ~6 cm at 344 m (Fig. 9a). After corrections for density changes and

1 ice flow thinning of annual layers with depth (section 5), an annual accumulation rate history
2 for Roosevelt Island over the last 2700 years was obtained (Fig. 10f).

3 **8.1. Long-term accumulation trends**

4 Mean accumulation rates at Roosevelt Island over the entire 2700 year period was 0.25 ± 0.02
5 m w.e. yr^{-1} . From 700 BCE to ~ 1300 CE, the accumulation rate at Roosevelt Island shows a
6 slightly increasing trend (Fig. 10f; Table 3), and in 1250 CE, the 20-year running mean
7 accumulation rate reached its maximum over the last 2700 year (0.32 m w.e. yr^{-1}). Since then,
8 accumulation rates have decreased: very slowly until ~ 1650 CE, then more rapidly (0.10
9 mm/yr^2 from 1650-1965 CE; Table 3). A continued acceleration in the decline of accumulation
10 rates is observed towards the present. Change points and trend estimates with their associated
11 uncertainties were identified using a break function regression analysis (Mudelsee, 2009). The
12 analysis revealed that high inter-annual variability in accumulation rates prohibited a very
13 accurate determination of the breakpoints.

14 **8.2. Significant decrease in recent accumulation rates**

15 The Roosevelt Island accumulation history reveals a distinct and rapid accumulation decrease
16 in recent decades (Fig. 11): Since the mid-1960s, the annual accumulation has decreased with
17 a rate corresponding to 0.8 mm/yr^2 , i.e. 8 times faster than the average over previous centuries.
18 We note, however, that the relatively short time period for conducting the trend analysis,
19 combined with the large inter-annual variability in accumulation rates, causes significant
20 uncertainty in the precise timing of the change-point as well as the trend estimate.

21 Considering the period since 1700 CE, the lowest decadal mean value of the accumulation rate
22 is observed in the 1990s (0.194 ± 0.001 m w.e. yr^{-1}). Except for very low accumulation rates
23 during the 1850s and 1800s, the remaining top six decades of lowest mean accumulation take
24 place after 1950 CE (Table 4). Indeed, over the last 50 years, only one decade (1960s) stands
25 out as not having experienced below-average accumulation at Roosevelt Island.

26 The current accumulation rate at Roosevelt Island of 0.211 ± 0.002 m w.e. yr^{-1} (average since
27 1965 CE, $\pm 2\sigma$) is 34% less than the peak accumulation rates around 1250 CE, and 16% below
28 the average of the last 2700 years.

29 **8.3. Comparison to the gas-based accumulation rates**

30 The RICE17 accumulation history is in reasonable agreement with the low-resolution
31 accumulation rate output from the dynamic Herron-Langway firn densification model (section
32 7.1; Fig. 10f, dashed line). The gas-based accumulation rate history does not resolve high-
33 frequency variations, but shows a slow increase in accumulation rates of 0.02 mm/yr^2 , similar
34 to the trend obtained from the annual layer thicknesses prior to 1300 CE. However, in contrast
35 to the accumulation rate history derived here, the firn-based accumulation rates continue to
36 increase until present. Further, the absolute value of the inferred gas-based accumulation rates
37 tend to generally underestimate the accumulation rates by ~ 0.04 m w.e. yr^{-1} (16%).

38 We speculate that the discrepancies may have to do with the shift in RICE water isotope levels
39 occurring around 1500 CE (Fig. 10g), which in the firn model is used to represent temperature
40 change. It has been suggested that this shift is due to other factors than temperature (Bertler et
41 al., 2018), and it coincides with commencement of the divide migration period. By using δD to
42 estimate temperature change, the firn densification model will produce an increase in
43 accumulation rates towards present in order to preserve a constant thickness of the firn column,
44 as indicated by relatively steady values of $\delta^{15}\text{N}-\text{N}_2$ (Fig. 10f, black dots). Further, the model

1 showed a tendency to underestimate the firm column thickness during the earlier part of the
2 period, which may explain the generally lower level of the modelled accumulation rates here.

3 **8.4. Spatial consistency in recent accumulation rates**

4 Spatial representativeness of the RICE accumulation rates was evaluated by comparing year-
5 to-year profiles of layer thicknesses obtained for the overlap sections of the three available
6 cores: RICE main core, RICE-12/13-B, and RID-75 (Fig. 12), with RID-75 located less than 1
7 km away from the two RICE cores. All cores were corrected for density changes and ice flow
8 thinning using the density and thinning profile from the main RICE core.

9 Annual accumulation records from the three cores are very strongly correlated (correlation
10 coefficients ranging between 0.85 and 0.87), indicating the spatial accumulation pattern across
11 Roosevelt Island to be stable through recent time. The spatial consistency of snow deposition
12 at Roosevelt Island is further confirmed by the agreement between their measured water isotope
13 records (Fig. 5a). We may therefore disregard depositional noise, and consider the temporal
14 variability in RICE annual layer thicknesses as representative of local snow accumulation.

15 This consistency in accumulation history is in contrast to a high spatial variability in mean
16 accumulation rates across Roosevelt Island ice divide. Repeat surveys over three years (2010-
17 2013) of 144 survey stakes set across Roosevelt Island showed a strong spatial gradient in snow
18 accumulation across the ice divide: Accumulation rates of up to 0.32 m w.e. yr⁻¹ were measured
19 on the north eastern flank, decreasing to 0.09 m w.e. yr⁻¹ on the south western flank (Bertler et
20 al., 2018). In accordance with these stake measurements, the absolute accumulation rate is
21 found to be significantly less (~7%) for RID-75 than for the two RICE cores. Insignificant
22 differences in accumulation rate were present between the two RICE cores. Spatial variability
23 in mean accumulation rates, combined with different averaging periods, may explain why
24 previous estimates of Roosevelt Island accumulation rates have varied quite significantly
25 (Bertler et al., 2018; Conway et al., 1999; Herron and Langway, 1980; Kingslake et al., 2014).

26 The representativeness of the Roosevelt Island accumulation rates is corroborated by high
27 spatial correlation of the RICE accumulation rates to gridded ERA-interim precipitation data
28 during recent decades (Bertler et al., 2018). These results suggest that precipitation variability
29 at Roosevelt Island is representative for an extended area, which includes the Ross Ice Shelf,
30 the Southern Ross Sea, and the western part of West Antarctica.

31 **8.5. Influence of ice divide migration on the accumulation history**

32 The recent period (~1500-1750 CE) of divide migration at Roosevelt Island may impact
33 interpretation of the climate records from the RICE core. Ice recovered in the deeper part of the
34 RICE core, deposited before divide migration, have originated west of the ice divide. Present
35 accumulation rates show a distinct decrease on the downwind (western) side of the ice divide
36 with a gradient of $\sim 5 \cdot 10^{-3}$ m w.e./km yr⁻¹, although muted around the summit area. Assuming a
37 stable snowfall pattern through time relative to the divide, its migration would have caused
38 reduced accumulation rates to be observed during the early part (until 1500 CE) of the RICE
39 accumulation history. With the ice originating up to 500m west of the divide at time of
40 deposition, our estimates of Roosevelt Island accumulation rates during this early period may
41 therefore have a small negative bias of up to $2.5 \cdot 10^{-3}$ m w.e. yr⁻¹.

42 Correcting for the influence of ice divide migration, the main impact on the Roosevelt Island
43 accumulation history is an earlier onset of the period with more rapid decrease in accumulation
44 rates. The differences are small, however, and the overall pattern of trends in accumulation rate

1 through time remains the same. In particular, ice divide migration has no impact on
2 accumulation rate trends observed before and after the migration period.

3 Discussion

4 9. The RICE accumulation history in a regional perspective

5 9.1. Past accumulation trends across West Antarctica

6 Regional differences in accumulation, from Northern Victoria Land across West Antarctica to
7 Ellsworth Land, may be evaluated by accumulation reconstructions based on ice core records
8 (Fig. 10).

9 The RICE accumulation history (Fig. 10f) is much more variable on inter-annual and decadal
10 scales than the accumulation rate reconstruction from e.g. WAIS Divide (Fig. 10d). Snowfall
11 at Roosevelt Island is dominated by large and episodic precipitation events (Emanuelsson et
12 al., 2018), which likely contributes to the high inter-annual variability in RICE accumulation
13 rates. A highly dynamic synoptic-scale system brings this precipitation to Roosevelt Island:
14 Positive RICE precipitation anomalies have been linked to the increased occurrence of Eastern
15 Ross Sea/Amundsen Sea blocking events associated with a weak state of the quasi-stationary
16 Amundsen Sea Low (ASL) pressure system. These blocking events impede the prevailing
17 westerly winds, and direct on-shore winds towards the Eastern Ross Sea, thereby increasing the
18 precipitation at Roosevelt Island and Western Marie Byrd Land (Emanuelsson et al., 2018).

19 Only the WAIS Divide and RICE ice cores are available for evaluating multi-millennial-scale
20 accumulation trends and corresponding change points in West Antarctica. Over the past 2700
21 years, WAIS Divide accumulation rates (Fudge et al., 2016) have continuously decreased from
22 a level approximately 25% higher than today (Fig. 10d). Accumulation rates declined slowly (-
23 0.01 mm/yr²) until around 900 CE, after which the decline became more rapid (-0.04 mm/yr²).
24 This change took place a few centuries before the trend in RICE accumulation rates turned from
25 positive to negative (1300 CE). Covering the last 800 years, the Talos Dome accumulation
26 record (Fig. 10c) shows a relatively constant level during this early period, albeit with large
27 decadal variability (Stenni et al., 2002).

28 Considering accumulation changes over the last century, more ice-core accumulation records
29 are available from across West Antarctica; from Victoria Land through to Ellsworth Land. Most
30 West Antarctic ice cores display decreasing accumulation rates over recent decades, but timing
31 and strength of the decrease is location-dependent. The strongest and most recent decrease is
32 observed at RICE (rate change at 1965 CE, this work), with Siple Dome accumulation rates
33 starting to decrease slightly later (1970 CE, Fig. 10e; Kaspari et al., 2004). The WAIS Divide
34 site displays the latest and weakest change of rate (ca. 1975 CE; estimated from nearby firn
35 cores; Burgener et al., 2013). An extension of the Talos Dome accumulation record to 2010CE
36 using snow stakes (Fig. 10c), suggests a recent decrease in accumulation rate also at this
37 location (Frezzotti et al., 2007). In contrast, significant increases in accumulation rates are
38 observed in ice cores from Ellsworth Land, where accumulation rates have shown a steady and
39 marked increase during the 20th century (Fig. 10b, Thomas et al. 2015).

40 The difference in accumulation rate trends across West Antarctica may to a large extent be
41 explained by changes in location and intensity of the ASL over time. The ASL influences
42 accumulation rates in a dipole pattern: By reducing the number of blocking events, a strong

1 state of the ASL leads to less accumulation over the Ross Ice Shelf area, and greater
2 accumulation over Ellsworth Land and the Antarctic Peninsula (Emanuelsson et al., 2018;
3 Raphael et al., 2016). Thus, imposed on West Antarctic-wide accumulation trends, the RICE
4 accumulation history likely reflects the state of the ASL back in time. The accumulation dipole
5 is centered at the West Antarctic ice divide. Hence, the WAIS Divide ice core should be
6 minimally influenced by the strength of the ASL, and may therefore be considered
7 representative for West Antarctica as a whole (Fudge et al., 2016). The Northern Victoria Land
8 region, located west of the Ross Ice Shelf, appears to be relatively unaffected by this ASL-
9 induced dipole effect which influences Ellsworth Land and West Antarctica. The recent
10 accumulation decrease observed at Talos Dome has been suggested to be caused partly by
11 increased wind-driven sublimation after deposition, due to an increase in mean wind velocities
12 associated with the deepened ASL (Frezzotti et al., 2007).

13 **9.2. Connection to sea ice variability in the Ross Sea**

14 Throughout the satellite era, RICE accumulation rates are strongly correlated (Bertler et al.,
15 2018) with sea ice extent in the Ross-Amundsen Sea (Jones et al., 2016): Years of reduced sea
16 ice extent are associated with higher accumulation of more isotopically enriched snow and
17 above-normal air temperatures (Bertler et al., 2018).

18 The expansion of sea ice in the Ross Sea during recent decades has taken place concurrently
19 with a marked reduction of sea ice in the Bellingshausen Sea (Comiso and Nishio, 2008), and
20 both trends have been associated with a strengthening of the ASL: The deepened pressure
21 system causes warm poleward-flowing air masses to cross the Bellingshausen Sea, while the
22 returning cold air passes over the Ross Sea, allowing conditions favorable for sea ice expansion
23 (Hosking et al., 2013; Raphael et al., 2016; Turner et al., 2016). The strength of the ASL
24 concurrently affects RICE accumulation rates (section 9.1), with a deep pressure system
25 causing less accumulation at Roosevelt Island. In addition, an extended regional sea ice cover
26 reduce the availability of local moisture sources. With ~40-60% of the precipitation arriving to
27 Roosevelt Island originating from local sources in the Southern Ross Sea (Tuohy et al., 2015),
28 the relationship between sea ice extent and accumulation rate at Roosevelt Island may also be
29 ascribed a longer distillation pathway of moist air masses during periods of extended sea ice
30 (Kuttel et al., 2012; Noone and Simmons, 2004).

31 The rapid recent decline in Roosevelt Island accumulation rates likely reflects the recent
32 increase in regional sea ice extent, and we suggest 1965 CE to mark the modern onset of rapid
33 sea ice expansion in the region. Further investigations are required to determine if the strong
34 relationship between Roosevelt Island accumulation rates and Western Ross Sea sea-ice extent
35 holds over longer timescales. However, the decline in RICE accumulation rates observed since
36 1300 CE is consistent with previous research indicating that the present increase in sea ice
37 extent in the Ross-Amundsen Seas is part of a long-term trend, having lasted at least the past
38 300 years (Thomas and Abram, 2016).

39 **9.3. Large-scale circulation changes and implications for recent and** 40 **future trends in Roosevelt Island accumulation**

41 The ASL is sensitive to large-scale circulation patterns, in particular the Southern Annual Mode
42 (SAM) [positive SAM: stronger ASL (e.g. Hosking et al., 2013)] and via teleconnections to the
43 tropical El Niño-Southern Oscillation (ENSO) [stronger ASL during La Niña phase (e.g. Yuan
44 & Martinson 2000)], and the degree to which the two are acting in phase (Clem and Fogt, 2013).
45 A recent strengthening of SAM has been reported (Marshall 2003), consistent with the recent
46 deepening of the ASL (e.g. Raphael et al. 2016).

1 It is not clear whether the recent trends in ASL and Ross Sea sea-ice extent can be ascribed to
2 natural variability. Some studies have attributed the positive trend of SAM in recent decades to
3 Antarctic stratospheric ozone depletion and/or global warming from greenhouse gas emissions
4 (Kushner et al., 2001; Turner et al., 2009), thus suggesting that anthropogenic forcing may play
5 a role. In the future, the competing effects of the two (Arblaster et al., 2011) may define the
6 future state of the ASL, and thereby the accumulation trends observed at Roosevelt Island and
7 across West Antarctica.

8 Most other coastal Antarctic sites have experienced a significant increase (~10%) in
9 accumulation rates since the 1960s (Frezzotti et al., 2013). The broad similarities and
10 differences noted here raise the question of whether West Antarctic accumulation, as a whole,
11 is decreasing, or whether the observed trends merely represent a redistribution of precipitation.
12 It highlights the issue that the current trend in total Antarctic mass balance can only be fully
13 understood pending large spatial data coverage.

14 **10. The RICE volcanic record**

15 **10.1. A record biased towards regional volcanism**

16 The coastal setting of Roosevelt Island challenged the identification of volcanic eruptions in
17 the RICE records, as high background levels of marine sulfate efficiently masked the presence
18 of sulfate from volcanic eruptions. The RICE volcanic proxy records contained a large number
19 of significant peaks without counterpart in WAIS Divide. While some of these may be
20 explained as extreme events of seasonal biogenic sulfur influx, others may have been produced
21 by regional volcanism.

22 Apart from sulfate, many volcanoes emit acidic compounds based on halogens, e.g. bromine,
23 chlorine and fluoride. The halide acids are highly soluble, and will be removed from the
24 atmosphere relatively quickly during transport. Hence, they will contribute to increased ice
25 acidity in ice cores located close to the eruption site, whereas only sulfate is deposited from
26 distant volcanic eruptions. By focusing on acidity as volcanic tracer instead of sulfur, the RICE
27 volcanic proxies may thus be more sensitive to regional volcanism than to larger far-field
28 eruptions. Such geographical bias may be particularly important for the Roosevelt Island ice
29 core record, since there is a prevalence of quiescent regional volcanism with relatively high
30 halogen content in West Antarctica (Zreda-Gostynska et al., 1997).

31 **10.2. Dipole effect in deposition of volcanic tracers across West** 32 **Antarctica**

33 Differences in snow deposition across West Antarctica, influenced by the ASL, may further
34 complicate volcanic matching between ice cores in this region. The ASL dipole acts to direct
35 storm systems either toward the Antarctic Peninsula/Ellsworth Land region, or toward the
36 western Marie Byrd Land/Ross Ice Shelf region. As these storm tracks are associated with
37 snowfall and wet deposition of ions, this is likely to favor deposition and preservation of
38 volcanic signals in one location (e.g. Antarctic Peninsula) at expense of the other (RICE, Siple
39 Dome).

40 An anti-phase in snow accumulation may be part of the explanation for the difference between
41 the WAIS Divide and RICE volcanic records. While most of the major volcanic signals in
42 WAIS Divide also exist in RICE, they are not necessarily associated with a prominent signal.
43 Absence of volcanic signal in the RICE core from these large far-field volcanic eruptions may
44 be due to a particularly strong ASL state at the time, directing precipitation and sulfate ions
45 away from Roosevelt Island. A detailed comparison of volcanic records from multiple ice cores

1 is required to evaluate the importance of the ASL for deposition of volcanic tracers across West
2 Antarctica.

3 **10.3. Volcanic synchronization of low-elevation coastal ice cores**

4 A range over obstacles were overcome to carry out volcanic identification in the RICE core.
5 Similar difficulties will likely challenge volcanic synchronization for other low-elevation
6 coastal Antarctic ice cores (Philippe et al., 2016), for which many drilling projects are planned
7 within the near future. The methods proposed here may be relevant also for these cores.

8 Robust volcanic matching of RICE and WAIS Divide was possible only by the aid of accurate,
9 high-resolution ice-core timescales for both cores. This demonstrates the importance of
10 building an Antarctic-wide network of accurately-dated volcanic reference horizons, based on
11 tephra, sulfate and acidity. Particular emphasis should be placed on the production of annually-
12 counted timescales for Antarctic ice cores, especially as new and/or improved measurement
13 methods allow the production of high-resolution impurity records for relatively high-
14 accumulation Antarctic sites, such as RICE.

15 **Conclusions**

16 The upper part of the RICE ice core from Roosevelt Island, Ross Ice Shelf, West Antarctica,
17 was dated by annual layer counting back to 700 BCE based on multiple high-resolution
18 impurity records. The timescale covers a period of stable ice flow after establishment of an ice
19 divide at Roosevelt Island. The chronology was validated by comparison to the timescale from
20 the WAIS Divide ice core, West Antarctica, by matching sequences of volcanic events visible
21 primarily in direct measurements of ice-core acidity and non-sea-salt conductivity. The
22 maritime environment at Roosevelt Island gave rise to challenging conditions for identifying
23 volcanic signatures in the ice core, and the volcanic matching was confirmed by matching
24 centennial-scale variability in atmospheric methane concentrations measured in the two ice
25 cores. The RICE17 and WD2014 timescales were found to be in excellent agreement.

26 Based on the layer thickness profile, we produced an annual accumulation record for Roosevelt
27 Island for the past 2700 years. Similar accumulation histories are observed in three Roosevelt
28 Island ice cores covering recent times, giving confidence that RICE is a reliable climate archive
29 suitable for further understanding of climate and geophysical variability across West
30 Antarctica.

31 Roosevelt Island accumulation rates were slightly increasing from 700 BCE until 1300 CE,
32 after which accumulation rates have consistently decreased. Current accumulation trends at
33 Roosevelt Island indicate a rapid decline of 0.8 mm/yr^2 , starting in the mid-1960s. The modern
34 accumulation rate of $0.211 \text{ m w.e yr}^{-1}$ (average since 1965CE) is at the low extreme of observed
35 values during the past several thousands of years. The low present-day accumulation rate has
36 been linked to a strengthening of the Amundsen Sea Low, and expansion of sea ice in the
37 Western Ross Sea. The current increase of sea ice in the Ross Sea is therefore likely part of a
38 long-term increasing trend, although the rapid increase since the mid-1960s may have an
39 anthropogenic origin.

40 **Data availability:**

41 The following data will be made available on the Centre for Ice and Climate website
42 (<http://www.iceandclimate.nbi.ku.dk/data/>) as well as public archives PANGAEA and NOAA
43 paleo-databases: RID-75 isotope and beta-activity records; RICE-12/13-B and RID-75
44 accumulation rates; RICE17 timescale; RICE accumulation rates; and volcanic match points

1 between RICE and WAIS Divide. Roosevelt Island GPS and radar data have been archived at
2 the U.S. Antarctic Program Data Center, available
3 at: <https://gcmd.gsfc.nasa.gov/search/Metadata.do?entry=USAP0944307&subset=GCMD>.

4 Acknowledgements

5 This work is a contribution to the Roosevelt Island Climate Evolution (RICE) Program, funded
6 by national contributions from New Zealand, Australia, Denmark, Germany, Italy, China,
7 Sweden, UK and USA. The main logistic support was provided by Antarctica New Zealand
8 (K049) and the US Antarctic Program. We thank all the people involved in the RICE logistics,
9 fieldwork, sampling and analytical programs. The Danish contribution to RICE was funded by
10 the Carlsberg Foundation's North-South Climate Connections project grant. The research also
11 received funding from the European Research Council under the European Community's
12 Seventh Framework Programme (FP7/2007-2013) ERC grant agreement 610055 as part of the
13 Ice2Ice project. The RICE Program was supported by funding from NSF grants (PLR-1042883,
14 ANT-0837883, ANT-0944021, ANT-0944307 and ANT-1643394) and New Zealand Ministry
15 of Business, Innovation, and Employment grants issued through Victoria University of
16 Wellington (RDF-VUW-1103, 15-VUW-131), GNS Science (540GCT32, 540GCT12) and
17 Antarctica New Zealand (K049). Figure 1 was made using Quantarctica2 (Norwegian Polar
18 Institute) basemaps and QGIS software.

19 We **have presented** here ice core data collected and analyzed by Henrik Clausen, Willi
20 Dansgaard, Steffen Bo Hansen and Jan Nielsen under the Ross Ice Shelf Project (RISP) carried
21 out between 1973 and 1978. We acknowledge the pioneering work conducted by these
22 researchers and the ongoing international collaborations they established.

1 Figures

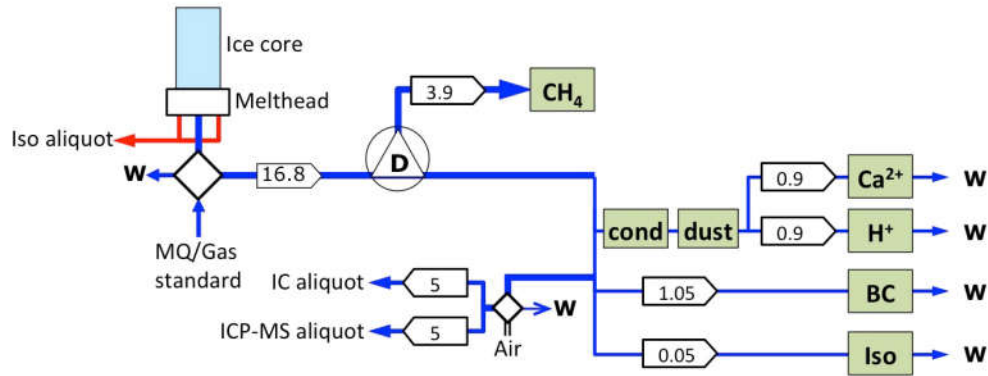

2
3

4 **Figure 1: a, b):** Roosevelt Island is located in the eastern sector of the Ross Ice Shelf
 5 embayment. Locations discussed in the text are represented by triangles (volcanoes) and circles
 6 (ice cores). **RS: Ross Sea; AS: Amundsen Sea; BS: Bellingshausen Sea.** c) MODIS image of
 7 Roosevelt Island (Haran et al. 2013), protruding as an ice dome from the surrounding Ross Ice
 8 Shelf. The RICE ice core is drilled on the ice divide of Roosevelt Island.

9

10 **Figure 2:** The RICE main core cutting plan included 2 CFA sticks of size 35x35mm.

1
 2 **Figure 3:** The RICE CFA set-up. A 1m long ice-core rod (light blue) is placed on a melt head,
 3 which separates melt water from the pristine inner part of the core from that of the more
 4 contaminated outer rim. Meltwater from the outer stream (red) is used for discrete
 5 measurements of water isotopes, while the melt water stream from the inner core section (dark
 6 blue) passes through a debubbler (D), which separates air from the melt water. The air
 7 composition is analyzed for methane concentration, while the meltwater stream is channeled to
 8 various analytical instruments for continuous impurity analysis of dust, conductivity (cond),
 9 calcium (Ca²⁺), acidity (H⁺), black carbon (BC), and water isotopes (Iso), as well as collected
 10 in vials for discrete aliquot sampling by IC and ICP-MS. W denotes waste water. Diamonds
 11 represent injection valves used for introduction of air or water standards when the melter system
 12 is not in use. Arrow boxes indicate liquid flow rates in mL min⁻¹. Green boxes represent
 13 analytical instruments.

14

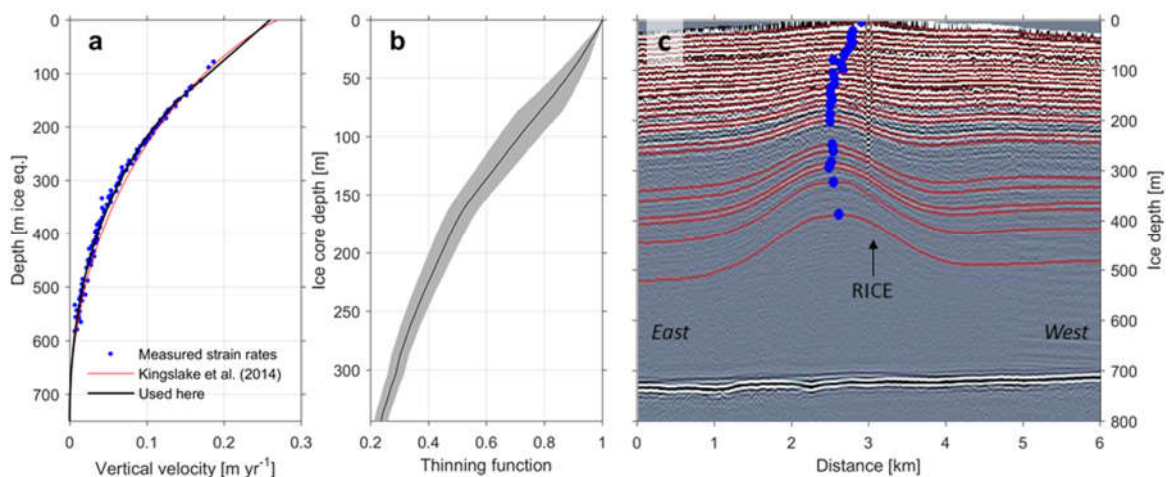

1
 2 **Figure 4:** Assignment of annual layers in an upper section of the RICE core. All units are in
 3 ppb, except for $\delta^{18}\text{O}$ (in ‰), H^+ (in $\mu\text{eq L}^{-1}$), and conductivity (in $\mu\text{S cm}^{-1}$). The CFA chemistry
 4 records are smoothed with a 3-cm moving average filter. Two uncertain layers exist within the
 5 section: At 16.6 m, an uncertain layer is being counted as part of the timescale, in order to match
 6 the tiepoint ages corresponding to the isotope match to RID-75 (cyan bar; 14.6 m) and the Raoul
 7 tephra horizon (red bar; 18.1 m). A second uncertain layer is located at 19.7 m; the sulfate
 8 record suggest that it is an annual layer, but this is not supported by iodine and $\delta^{18}\text{O}$. This layer
 9 is not counted in the RICE17 chronology, in order to match the age of the next tie-point located
 10 at 22 m.
 11

1
 2 **Figure 5:** **a)** RICE water isotope profile (δD) compared to isotope data ($\delta^{18}O$) from the RID-
 3 75 core for the period 1950-1975. Diffusion causes the isotope record to smooth over time, and
 4 a smoothed version of the RID-75 isotope profile (thick blue) highlights its similarities to the
 5 RICE isotope record (black). **b)** Total specific β -activity (in disintegrations per hour, dph) for
 6 the RID-75 core compared to ^{239}Pu measurements (normalized intensities) from the RICE main
 7 core. Both cores show a sharp increase in nuclear waste deposition starting in 1954 CE, and
 8 several broader peaks hereafter.

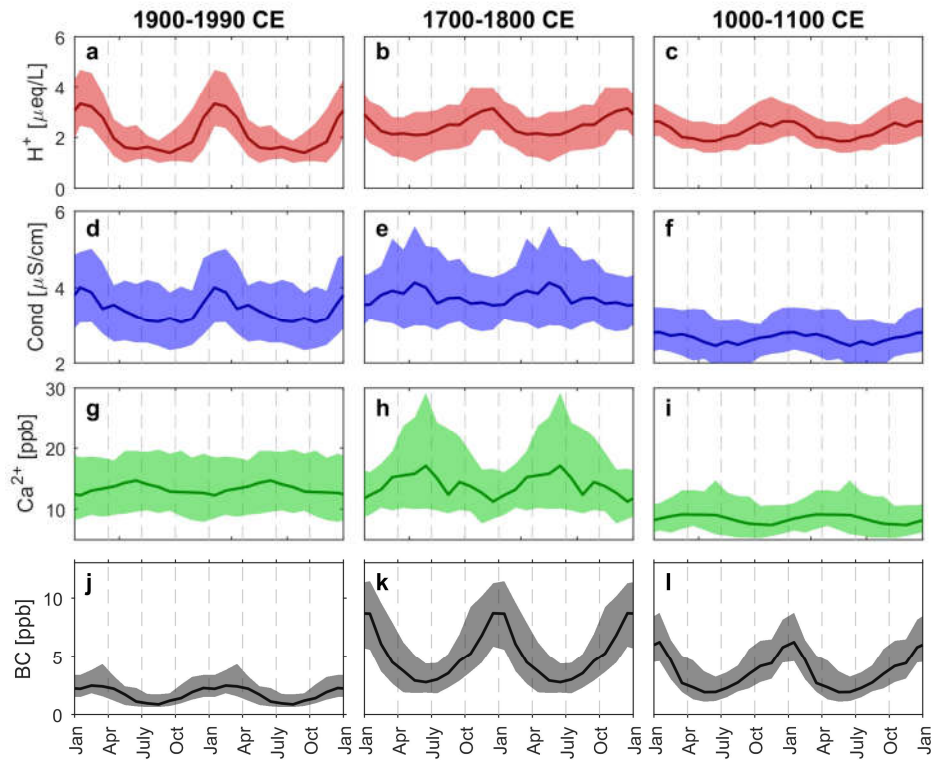

9

10
 11
 12 **Figure 6:** **a)** Vertical velocity measurements (Kingslake et al., 2014) and the associated fitted
 13 functions. Fit used here improves overall misfit and does not have a bias at mid-depth. **b)**
 14 **Thinning function with associated uncertainties (2σ).** **c)** Radar echogram (Kingslake et al.,

1 2014) with traced layers (red) and location of maximum amplitudes of the stack of Raymond
 2 arches (blue circles). The location of the modern topographic ice divide (and the RICE drill
 3 site) is marked by the returns from a pole west of the maximum bump amplitudes at depth, as
 4 indicated with an arrow.

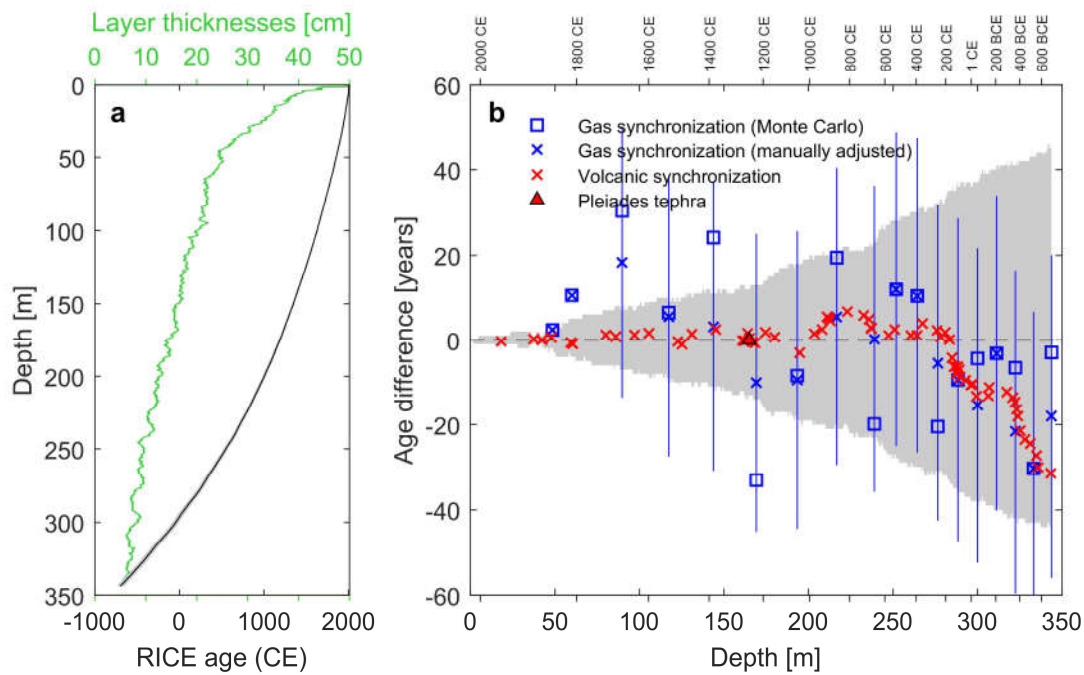

5

6

7 **Figure 7:** Average annual signals of 2 successive years in RICE **a-c)** acidity (H^+), **d-f)**
 8 conductivity (Cond), **g-i)** calcium (Ca^{2+}), and **j-l)** black carbon (BC) during three centuries,
 9 calculated under the assumption of constant snowfall through the year. The main RICE CFA
 10 data only extends to 1990CE. The line shows monthly-averaged median value of measured
 11 concentrations, and colored area signifies the 50% quantile envelope of the value distribution.

12

1
 2 **Figure 8: a)** Depth evolution of RICE17 ages (black), including the associated 95% confidence
 3 interval (grey area, almost invisible due to scale), and corresponding mean layer thicknesses
 4 (50 year running mean; green). **b)** Comparison of RICE17 ages and its confidence interval (grey
 5 area) to WD2014 from volcanic (red) and gas (blue) matching to WAIS Divide. A negative age
 6 difference implies fewer layers in RICE17 than in WD2014. Blue vertical lines indicate 1σ age
 7 uncertainties on Monte Carlo methane matches. A solid red triangle indicates the Pleiades
 8 tephra layer at 165m depth.

1

2 **Figure 9: a)** The RICE volcanic proxy records: non-sea-salt-sulfur (nss-S; orange), ECM
 3 (purple), acidity (H^+ ; red), and non-sea-salt conductivity (nss-cond; blue) based on the
 4 conductivity-to-calcium excess (grey, green). **b)** Matching of the RICE records to the WAIS
 5 Divide non-sea-salt sulfur record (Sigl et al., 2015). Vertical bars indicate volcanic match points
 6 (Table 2), with the red bar representing the Pleiades tephra horizon (1251 CE).

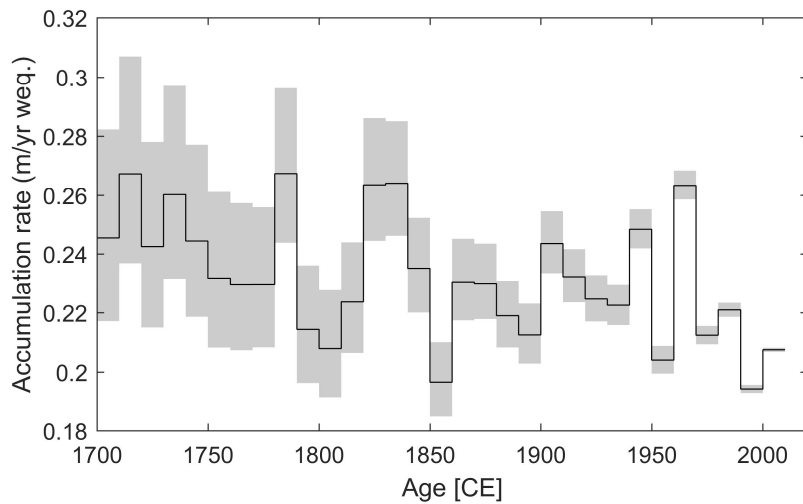

7

1
2 **Figure 10:** **a)** Measured methane concentrations from RICE (blue, on the RICE17 timescale)
3 and from WAIS Divide (red, on the WD2014 timescale). **b)** Bryan Coast (BC11, grey),
4 Ellsworth Land (Thomas et al., 2015), **c)** Talos Dome (TD96, orange), Northern Victoria Land,
5 (Frezzotti et al., 2007; Stenni et al., 2002) (no thinning function applied, extended to 2010 CE
6 using stakes measurements), **d)** WAIS Divide (WDC, red), Central West Antarctica (Fudge et
7 al. 2016) (corrected for ice advection), **e)** Siple Dome (SDM-94, pink), Marie Byrd Land
8 (Kaspari et al. 2004), and **f)** RICE (blue) accumulation histories over the past 2700 years, in
9 annual resolution and 20-year smoothed versions (thick lines). The shaded blue area indicates
10 the 95% confidence interval of the RICE accumulation rates. The short-lived peak in
11 accumulation rates around 320 BCE is likely to be an artefact caused by timescale inaccuracies
12 in this period, during which RICE17 diverges from WD2014 (Fig. 9b). Also shown are the gas-

1 derived accumulation rates for this time interval (f, blue dashed line), and measurements of
 2 $\delta^{15}\text{N}$ of N_2 informing on past firn column thickness (f, black dots; on the RICE gas timescale).
 3 **g**) RICE stable water isotope record (δD). Thick green line is a 20-year smoothed version of
 4 the isotope profile. Grey horizontal lines denote mean values of the respective accumulation
 5 rates and δD over the displayed period. Note that the scale changes at 1900CE (thick vertical
 6 line). The migration period of the Roosevelt Island ice divide is marked with a grey box.

7
 8

9
 10
 11
 12

Figure 11: Decadal accumulation rates at Roosevelt Island since 1700 CE. Grey shadows indicate the 95% uncertainty bounds due to uncertainties in the thinning function.

13
 14 **Figure 12:** Accumulation reconstructions since 1950 CE for the three Roosevelt Island ice
 15 cores described in Table 1.

1 1: Age from Clausen et al. (1979). ★Depths indicate the tephra sampling interval. #: CFA acidity is missing for
2 relevant interval, attribution is based on remaining records. †CFA acidity does not record peak. x: Conductivity
3 and Ca records missing for interval. ‡: CFA and IC data missing, depth annotation based on ECM only. *:
4 Eruption not identified in existing compilation of volcanic eruptions in WAIS Divide (Sigl et al., 2013).

5 **Table 2:** Marker horizons used for development and validation of the RICE17 chronology.
6 Strata in bold were used for constraining the timescale. Volcanic matching to WAIS Divide
7 allows comparison between RICE17 ages (with 95% confidence interval indicated) and the
8 corresponding WD2014 ages with associated uncertainties (Sigl et al., 2015, 2016). Indicated
9 depths and ages correspond to peaks in the volcanic proxies. Below 42.3m, decimal ages have
10 been calculated assuming BC to peak Jan 1st. Historical eruption ages (in column 3) indicate
11 starting date of the eruption. In column 3 is also stated whether the eruption previously has been
12 observed to cause a bipolar signal, based on the compilation in Sigl et al. (2013), here updated
13 to the WD2014 timescale. Since this compilation only identifies bipolar volcanoes back to 80
14 CE, volcanoes prior to this are not classified. Three exceptionally large volcanic signals
15 observed in the RICE core are indicated in italics.

16

Change point	Time period (rounded)	Mean accumulation rate [m. w.e./yr]	Accumulation rate trend [mm w.e. yr ⁻²]
1287 CE (1291 ± 135)*	700 BCE – 1300 CE	0.25 ± 0.02	+0.02 (0.020 ± 0.003)
1661 CE (1675 ± 123)*	1300 CE – 1650 CE	0.26 ± 0.03	-0.04 (-0.03 ± 0.03)
1966 CE (1969 ± 34)	1650 CE – 1965 CE	0.24 ± 0.02	-0.10 (-0.08 ± 0.05)
	1965 CE – 2012 CE	0.211 ± 0.002	-0.80 (-0.84 ± 0.76)

17

*Change point not well-determined from bootstrap analysis.

18 **Table 3:** Mean value and trends in RICE accumulation rates during various time periods.
19 Change points and trends are found using break-fit regression (Mudelsee, 2009). The most
20 likely change-points and trend values are provided, as well as the associated confidence
21 intervals (in parenthesis: median and median absolute deviation; Mudelsee (2000)) determined
22 from block bootstrap analysis. Uncertainties (2σ) on mean accumulation rates are calculated
23 based on the uncertainty in the accumulation reconstruction. Accumulation trends estimates
24 from the bootstrap analysis (in parenthesis) includes uncertainties in determination of the
25 change-point, but not uncertainties associated with the derived accumulation rate history. The
26 analysis does not account for a potential bias due to ice divide migration, which may slightly

1 affect the mean accumulation rate values prior to 1750 CE, and the trend during the period of
2 divide migration (~1500-1750 CE).

3

4

Rank	Decade	Decadal mean accumulation rate [m. w.e./yr]
1	1990-1999	0.194 ± 0.001
2	1850-1859	0.197 ± 0.010
3	1950-1959	0.204 ± 0.006
4	2000-2009	0.207 ± 0.001
5	1800-1809	0.208 ± 0.017
6	1970-1979	0.212 ± 0.004

5

6 **Table 4:** Ranking of decades since 1700 CE according to lowest mean accumulation.
7 Uncertainties (2σ) on the mean values are due to uncertainties in the accumulation
8 reconstruction.
