

Dear Marit-Solveig Seidenkrantz and reviewers,

We thank you for giving us the opportunity to revise our manuscript. We also appreciate the reviewer's constructive comments and suggestions that helped to improve the manuscript. In the revised version we marked changes in red. In the reply letter below we explain how we addressed every point raised by you and the reviewers.

Looking forward to hearing from you.

Thank you and best regards.

Mingming Ma on behalf of all co-authors

### **Editor**

Before potential publication, the authors should add a discussion on the mechanisms causing the described climate change. However, at present the review process can start and an expansion of the discussion can wait till after the first round of reviews, if these are sufficiently favourable.

**Response:** We added a short discussion on the potential mechanisms that probably related to the paleomonsoon in Lines 513-530 as you suggested.

### **Referee 1**

Detailed comparison of paleoclimatic records between land and ocean is essential to evaluate the global paleoclimate pattern. This study constructed new data across the Cretaceous-Palaeogene boundary boundary in the Nanxiong Basin (SE China). On the basis of previous paleomagnetic studies, authors provided a new interpretation of magnetostratigraphy, and found that patterns of paleoclimatic proxies (magnetic susceptibility and Neel temperature) from the studied profile are similar to the global  $\delta^{18}O$  curves. Then they divided the results into three stages with distinct patterns. Overall, this study is interesting because it provides new results from the terrestrial media and thus has global paleoclimatic significances. However, the following two issues need further clarifications:

1) The fidelity of the magnetostratigraphy Authors provided an new interpretation in section 4.1. This new interpretation is the foundation of the whole story. From lines 302-309, there are still presence of ambiguities even for the new interpretation. Therefore, more subtle discussions on the magnetostratigraphy are still needed.

Response: We added more subtle discussions on the magnetostratigraphy, please see lines 336-347.

2) Magnetic susceptibility is a complicated proxy. Authors need more discussions on the exact variation mechanism for susceptibility. It seems that hematite is the dominant magnetic minerals, it will be more direct to measure hematite-related proxies, e.g., HIRM, DRS results, etc.

Response: 1) We added more discussions on the variation mechanism for susceptibility that probably related to the paleomonsoon, please see lines 513-530.

2) HIRM has been shown in section 3.3 and Fig. 4 already.

3) We added DRS results in the revised manuscript, please see lines 175-180, 184-196 and Fig. 2.

## **Referee 2**

In this paper, Ma et al. proposed a new age model for this section and reviewed the paleoenvironment and paleoclimate changes during the K-Pg boundary interval. Overall, I commend the authors for applying new method on this topic and propose new ideas. However, the interpretations and conclusions need to be major modified before publication.

1. The authors claimed that the C30R and C31N was missing due to the covered strata. However, this is just the authors' speculation, and there is no further evidences. The authors also concluded that the age between the Zhenshui and Zhutian formations is ~71.5 Ma according to their new age model. However, this age is inconsistent with the biostratigraphic data they cited, which suggests the Zhutian Formation is lower

Santonian-Campanian in age.

Response: We added more subtle discussions on the magnetostratigraphy, please see lines 336-347.

2. The authors suggested that "the haematite was the dominant magnetic mineral in the red strata, and the variation trend of magnetic susceptibility was consistent with the oxygen isotope records from deep-sea sediments, which indicates that the pedogenic intensity was controlled by global climate". I can not understand the logic relationship in this sentence. Are their samples for magnetic susceptibility all collect from the palaeosols? Please clarify. In addition, if the age model is not valid, the consistency between the magnetic susceptibility and  $\delta^{18}\text{O}$  would not exist.

Response: 1) Yes, we suggested that all the samples were collected from palaeosols, the difference is that moderately to fully mature soils with diagnostic characters such as Bk horizons, wormholes and root traces formed in sandy mudstone and muddy sandstone layers. No typical palaeosols were found in the coarse sandstone or conglomerate layers because of the lack of essential conditions for soil formation, but many root traces were preserved which can be called "weakly developed soils". Please see more details in section 4.2. Haematite was generated during pedogenic processes, the relationship between  $\chi$  and haematite content can be explained by the "pedogenic-plus hypothesis": more haematite formed during warmer and wetter periods with stronger pedogenesis, and caused a higher  $\chi$ , and opposite conditions yielded lower  $\chi$  values. So we concluded that the pedogenic intensity indicated by the content of haematite (i.e.  $\chi$ ) was controlled by global climate. However, we would like to change this sentence to "the haematite was the dominant magnetic mineral in the red strata, and the variation trend of magnetic susceptibility was consistent with the oxygen isotope records from deep-sea sediments, which indicates that the content of haematite was controlled by global climate" (lines 33-36), so as not to confuse the readers.

2) As age model, please see last response.

3. The authors classified the climate evolution into three stages. But the proposed trend is similar to that established by other proxies and no substantial promotion, still qualitative.

Response: We agree with your comments that the constructed climate evolution revealed by magnetic parameters is still qualitative, however, it shows more details than other proxies or the marine record, such as the several sub-fluctuations during each stage, which probably indicates that the climate changes from 72 to 62.8 Ma were extremely instable with more fluctuations, and this needs our further work to provide quantitative and higher resolution results in the future. See lines 596-601.

However, we add more discussions on the potential mechanisms causing the described climate change that is not mentioned in previous studies, please see lines 513-530.

13 **Abstract:** The climate during the Cretaceous Period represented one of the  
14 “greenhouse states” of Earth’s history. Significant transformation of climate patterns  
15 and a mass extinction event characterised by the disappearance of dinosaurs occurred  
16 across Cretaceous–Palaeogene boundary. However, most records of this interval are  
17 derived from marine sediments. The continuous and well-exposed red strata of the  
18 Nanxiong Basin (SE China) provide ideal material to develop continental records.  
19 Considerable research into stratigraphic, palaeontological, chronologic,  
20 palaeoclimatic, and tectonic aspects has been carried out for the Datang Profile, which  
21 is a type section of a non-marine Cretaceous–Palaeogene stratigraphic division in  
22 China. For this study, we reviewed previous work and found that: 1) the existing  
23 chronological framework of the Datang Profile is flawed; 2) precise palaeoclimatic  
24 reconstruction is lacking because of the limitations of sampling resolution (e.g.  
25 carbonate samples) and/or the lack of efficient proxies; and 3) comparisons of climate

26 changes between marine and continental records are lacking. To resolve these  
27 problems, detailed field observations and sampling, as well as environmental  
28 magnetic and rare earth element (REE) measurements, were carried out. The results  
29 show that: 1) more accurate ages of the Datang Profile range from 72 Ma to 62.8 Ma,  
30 based on a combination of the most recently published radiometric, palaeontological  
31 and palaeomagnetic ages; 2) there is considerable evidence of palaeosol generation,  
32 which indicates that the red strata formed in a long-term hot, oxidizing environment  
33 that lacked of underwater condition; 3) haematite was the dominant magnetic mineral  
34 in the red strata, and the variation trend of magnetic susceptibility was consistent with  
35 the oxygen isotope records from deep-sea sediments, which indicates that the content  
36 of hematite was controlled by global climate; and 4) the palaeoclimate changes from  
37 72 Ma to 62.8 Ma in the Nanxiong Basin were consistent with global patterns, and  
38 can be divided into three stages: a relatively hot and wet stage during 72–71.5 Ma, a  
39 cool and arid stage during 71.5–66 Ma, and a relatively hot and wet stage again  
40 during 66–62.8 Ma with a notable drying and cooling event at 64.7–63.4 Ma.  
41 Moreover, there are several sub-fluctuations during each stage. This work provides  
42 basic information for further palaeoclimate reconstruction with higher resolution and  
43 longer time scales for the Cretaceous to Palaeocene in the Nanxiong Basin, and may  
44 even help to test ocean–land climate interactions in the future.

## 47 **1 Introduction**

48 The Earth existed in a greenhouse state during the Late Cretaceous (Hay, 2011;  
49 Friedrich et al., 2012; Wang et al., 2014); palaeoclimate studies show that based on

50 marine records, the seawater surface temperature near the equator reached up to 36°C  
51 during the Late Cretaceous (Linnert et al., 2014), and reconstructed CO<sub>2</sub>  
52 concentrations reach up to 837 ppm across the Cretaceous–Tertiary boundary, as  
53 recorded in palaeosol carbonates in NE China (Huang et al., 2013). The correlation  
54 between extreme greenhouse climate and high CO<sub>2</sub> concentration across this  
55 boundary may provide insights for global warming in the present (Wang et al., 2013b).  
56 The palaeotemperature decreased significantly from the Mesozoic Era to the Cenozoic  
57 (Zachos et al., 2001; Hay, 2011), and a mass extinction event occurred across the  
58 Cretaceous–Palaeogene boundary (Schulte et al., 2010; Renne et al., 2013); climate  
59 changes and biological evolution during this interval have therefore become a  
60 research hotspot. However, most studies of climate change across the Cretaceous–  
61 Palaeogene boundary have been derived from marine records (Huber et al., 1995;  
62 Barrera and Savin, 1999; Cramer et al., 2009; Friedrich et al., 2012; Bodin et al.,  
63 2015). Terrestrial palaeoclimate records are few, and published comparisons and  
64 correlations between marine and terrestrial palaeoclimate records are even fewer  
65 (Wang et al., 2013b).

66 There are many basins with Cretaceous continental sediments distributed across  
67 China (Li et al., 2013), such as the Songliao Basin (NE China, Wu et al., 2009;  
68 Bechtel et al., 2012; Chamberlain et al., 2013; Wang et al., 2013a, b; Wan et al.,  
69 2013), the Sichuan Basin (SW China; Li, 1988; Huang et al., 2012; Li et al., 2015),  
70 and the Nanxiong Basin (SE China; Zhao et al., 1991, 2002, 2009; Buck et al., 2004;  
71 Clyde et al., 2010; Li et al., 2010; Wang et al., 2015), which provide ideal records for  
72 investigation of Cretaceous climate change. Among these basins, continuous and  
73 well-exposed red strata consisting of mudstone and sandstone are preserved in the  
74 Nanxiong Basin, and many fossils have been found in these red strata, such as

75 charophytes, palynomorphs, ostracods, dinosaurs, dinosaur eggs, and mammals  
76 (Zhang, 1992; Zhang et al., 2006, 2013; Clyde et al., 2010; Li et al., 2010). Many  
77 studies have focused on the Datang Profile, which is also called the CGY–CGD  
78 profile by Chinese and Germany scientists (Zhao et al., 1991; Yang et al., 1993; Zhao  
79 & Yan, 2000). Studies of this profile have investigated its stratigraphy, palaeontology,  
80 geochronology, and palaeoclimatology (Zhao et al., 1991; Zhang, 1992; Zhang et al.,  
81 2006, 2013; Clyde et al., 2010; Tong et al., 2013; Wang et al., 2015), because it spans  
82 from the Upper Cretaceous to the Lower Palaeocene and is a type section for non-  
83 marine Cretaceous–Palaeogene stratigraphic division in China. However, precise  
84 reconstruction of the palaeoclimatic evolution of this section and comparison with  
85 marine records are still lacking because of the lack of efficient proxies. Moreover,  
86 many Cretaceous–Palaeogene records are also lacking from low-latitudes in this part  
87 of the world, therefore, it is of great significance to carry out paleoclimate change  
88 studies here.

89 Environmental magnetism as a proxy has been widely used in the studies of  
90 palaeoclimatic changes in Quaternary loess–palaeosol successions (Evans & Heller,  
91 2001; Hao & Guo, 2005; Maher & Possolo, 2013; Maher, 2016), Tertiary red clay  
92 successions (Liu et al., 2003; Nie et al., 2008; Zhao et al., 2016), and other older  
93 aeolian deposits (Hao et al., 2008; Tao et al., 2011), as well as in studies of lake  
94 sediments (Snowball et al., 1999; Fu et al., 2015; Hu et al., 2015), and marine  
95 sediments (Larrasoña et al., 2008; Peters et al., 2010). In this paper, we review  
96 previous work (mainly in terms of geochronology and palaeoclimatology) and report  
97 some defects in the established chronological framework and palaeoclimatic record.  
98 Therefore, the aims of this work are to: 1) establish a new chronological framework  
99 for the Datang Profile, 2) reinterpret the environment in which the red strata formed, 3)

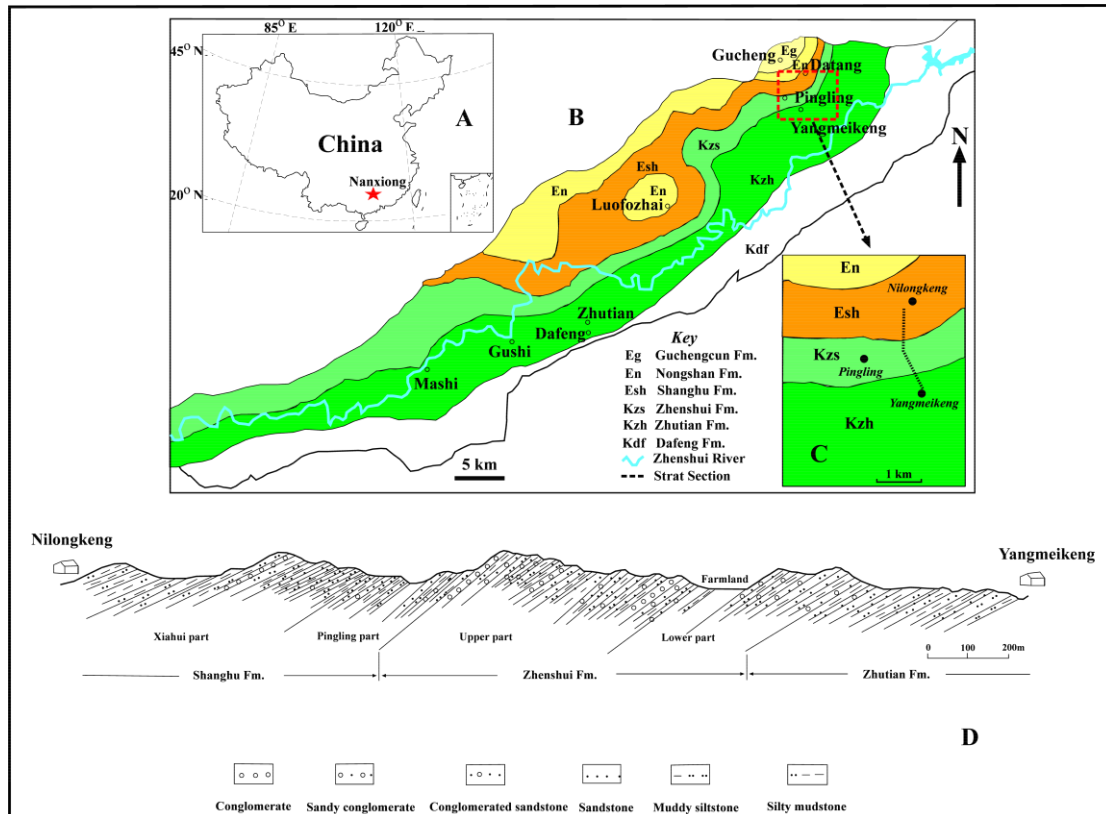

100 try to reconstruct the palaeoclimatic changes using magnetic parameters, and 4)  
101 compare the terrestrial records with marine records to provide reliable terrestrial  
102 records for future investigation of ocean–land climate interactions.

## 103 **2 Geological background, materials, and methods**

### 104 **2.1 Geological background**

105 The Nanxiong Basin (25°03′–25°16′N, 114°08′–114°40′E) is a rift basin that  
106 developed on pre-Jurassic basement, and is controlled by the Nanxiong Fault (Shu et  
107 al., 2004). Most of this basin is located in northern Guangdong Province, SE China  
108 (Fig. 1A). The basin is elongated with its axis oriented northeast–southwest (Fig. 1B),  
109 and is distributed in an area between the Zhuguang and Qingzhang granites (Shu et al.,  
110 2004). The modern mean annual rainfall and temperature are ~1,555 mm and ~19.9°C,  
111 respectively (data from China Meteorological Data Service Center). Continuous  
112 successions of red fluvial–lacustrine clastics, with a maximum thickness of more than  
113 7 km, are preserved in the basin. These successions span the Upper Cretaceous,  
114 represented by the dinosaur-bearing Nanxiong Group (Changba, Jiangtou, Yuanpu,  
115 Dafeng, Zhutian, and Zhenshui Formations), and the Lower Palaeocene, represented  
116 by the mammal-bearing Luofuzhai Group (Shanghu, Nongshan, and Guchengcun  
117 Formations) (Zhang et al., 2013). Components of conglomerate and coarse-grained  
118 sandstone in the basin are similar to those of adjacent strata; moreover, pebbles found  
119 in the basin are relatively coarse, poorly sorted, and sharp-edged, which implies that  
120 the sediment source was not far from the basin (Shu et al., 2004), and that erosion was  
121 stable though the Late Cretaceous to Early Palaeocene (Yan et al., 2007).

122

123 **Fig. 1** Sketch map of the Nanxiong Basin: A) location of Nanxiong Basin, B)  
 124 stratigraphy of the Nanxiong Basin (from the Dafeng Formation to the Guchengcun  
 125 Formation, modified from Li et al., 2010), C) sampling route of the Datang Profile, D)  
 126 stratigraphy of the Datang Profile (modified from Zhang et al., 2006). **Note that the**  
 127 **Zhutian Formation in Datang Profile is just the top part of the whole Zhutian**  
 128 **Formation.**

129 Several profiles in the basin have been investigated since the 20th century (Zhao  
 130 et al., 1991, 2002; Zhang & Li, 2000; Zhang et al., 2006, 2013; Zhang & Li, 2015). Of  
 131 these profiles, the Datang Profile (Fig. 1C), with a vertical thickness of ~700 m, was  
 132 the most thoroughly investigated because of clear stratigraphic succession and  
 133 abundant fossils. The Datang Profile consists of three formations (Fig. 1D, Zhang et  
 134 al., 2006); from bottom to top these are the Zhutian Formation (105 m), the Zhenshui

135 Formation (295.5 m), and the Shanghu Formation (288.3 m), which are described in  
136 detail below (Zhang et al., 2006; Wang, 2012; Zhang, 2016).

137 The Zhutian Formation consists mainly of brown-red, dark purple muddy  
138 siltstone, and silty mudstone with fine sandstone interbeds. Large quantities of  
139 ostracods and charophytes, and minor amounts of gastropods, conchostracans, and  
140 dinosaur footprints have been discovered. Several moderately to fully mature  
141 palaeosol layers with calcareous nodules generated in this formation.

142 The Zhenshui Formation is predominantly composed of coarse clastic deposits,  
143 represented by grey-purple sandstone and conglomerate with red silty mudstone  
144 interbeds. This formation is rich in vertebrate and dinosaur eggs, with minor amounts  
145 of ostracods, charophytes, bivalves, and gastropods. A few moderately to fully mature  
146 palaeosol layers generated in this formation.

147 The Shanghu Formation is predominantly composed of purple and dark brown  
148 muddy siltstone and silty mudstone with numerous calcareous nodules and thin  
149 interbeds of sandstone and conglomerate. This formation is rich in microfossils such  
150 as ostracods and charophytes, and also contains fossils of mammals, turtles,  
151 gastropods, and pollen. A great deal of moderately to fully mature palaeosol layers  
152 generated in this formation.

## 153 **2.2 Materials and methods**

154 Powder samples were collected from the Datang Profile; because of strong  
155 weathering of the Zhenshui Formation, the sampling intervals for this formation were  
156 larger than those for the other formations. To eliminate the effects of particle size on  
157 magnetic parameters, the selected samples were mainly muddy siltstone or silty

158 mudstone. All samples were dried naturally in a laboratory, gently ground to  
159 disaggregate the grains, and then packed into small non-magnetic plastic boxes (8 cm<sup>3</sup>)  
160 before measurement. Magnetic susceptibility ( $\chi$ ) was measured using a Bartington  
161 MS2-B meter at 470 Hz and then normalised by mass. Anhysteretic remanent  
162 magnetisation (ARM) was imparted with a peak AF field of 100 mT and a DC bias  
163 field of 0.05 mT using a Molspin alternating field demagnetiser, and then measured  
164 with a Molspin Minispin magnetometer. Isothermal remanent magnetisation (IRM)  
165 was conducted using a Molspin 1 T pulse magnetiser and measured by employing the  
166 Minispin magnetometer. The IRM at 1 T was regarded as saturation IRM (SIRM).  
167 Backfield remagnetisation of SIRM was carried out using reverse fields at 10 mT  
168 steps, and remanence coercivity (B<sub>cr</sub>) was calculated using linear interpolation. High-  
169 temperature magnetic susceptibility curves ( $\kappa$ -T curves) were obtained using an Agico  
170 KLY-3 Kappabridge with a CS-3 high-temperature furnace.

171 Rare earth element (REE) measurements were completed using an X-SERIES  
172 inductively coupled plasma-mass spectrometer (ICP-MS). Before measurement, bulk  
173 samples were successively treated with HF and HNO<sub>3</sub> (3:1), HClO<sub>4</sub>, HNO<sub>3</sub>  
174 (HNO<sub>3</sub>:H<sub>2</sub>O = 1:2), and ultrapure water.

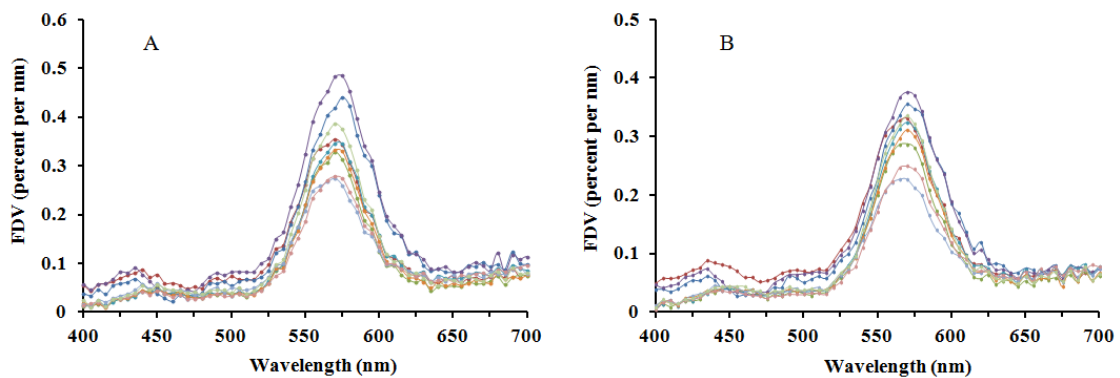

175 The diffuse reflectance spectroscopy (DRS) of fine powdered samples (<38  $\mu$ m,  
176 both before and after heated by 200°C for 2 hours) was recorded from 190 to 1100 nm  
177 in 5 nm steps, using a UV-2600 spectrophotometer (Shimadzu Instruments  
178 Manufacturing Co., Ltd.). In this study, only the records from 400 to 700nm ( visible  
179 spectrum) were shown and the first derivative spectral patterns were calculated to  
180 determine the presence of hematite/goethite.

181 All measurements were conducted at the Key Laboratory for Subtropical  
182 Mountain Ecology, Fujian Normal University.

183 **3 Results**

184 **3.1 DRS**

185 The DRS technique provides a quantitative method to determine the haematite  
186 and goethite, which has been successfully used in marine deposits (Balsamand Deaton,  
187 1991) and loess sections from the Chinese Loess Plateau (Ji et al., 2001; Balsam et al.,  
188 2004; Torrent et al., 2007). The peaks of the bands at 575 nm and 435/535 nm in the  
189 first derivative spectral (FDV) patterns are interpreted as haematite and goethite,  
190 respectively. However, the clay minerals (such as Chlorite and Illite) also show peaks  
191 at 435nm (Ji et al., 2006). In Fig.2, all curves show significant peak at ~575 nm,  
192 indicating the existence of haematite. Besides, there are small peaks at ~440nm which  
193 maybe related to goethite or clay minerals. However, the ~440nm peaks are still exist  
194 even after 200°C heated for 2 hours (Fig. 2B). Goethite will be transformed to  
195 haematite under 200°C (Ma et al., 2013), so the ~440nm peaks probably related to the  
196 clay minerals but not goethite.

197

198 Fig.2 First-derivative curves of pilot samples before (A) and after 200°C heated (B).

199 After 200°C heated, the presence of first-derivative peaks are similar with before  
200 heated. All curves show significant peak at ~575 nm, indicating the existence of  
201 haematite.

## 202 3.2 $\kappa$ -T curves

203 High-temperature  $\kappa$ -T curves can be used to identify magnetic phases according  
204 to their Curie/Neel temperatures ( $T_c/T_N$ ) or specific decomposition temperatures  
205 during the heating process; for example, the  $T_c/T_N$  of magnetite and haematite are  
206  $\sim 580^\circ\text{C}$  (Smith, 1956; Levy et al., 2012) and  $\sim 670^\circ\text{C}$  (Lu & Meng, 2010), respectively.  
207 Partial substitution of Fe in magnetite or haematite with Ti or Al will decrease their  
208  $T_c$  temperatures (Jiang et al., 2012, 2015). Maghemite generated during pedogenic  
209 processes is generally unstable during heating, as represented by its transformation to  
210 haematite at  $300\text{--}400^\circ\text{C}$  (Liu et al., 1999). In addition to being affected by the  
211 magnetic mineral type,  $\kappa$ -T curves are also affected by magnetic particle size due to  
212 that some fine particles could change their domain state during the heating/colling  
213 process (Liu et al., 2005).

214 The  $\kappa$ -T curves of pilot samples from the Datang Profile are similar (Fig. 3);  
215 heating curves decrease with increasing temperature from room temperature to  
216  $\sim 200^\circ\text{C}$ , which suggests the presence of paramagnetic minerals (Evans & Heller,  
217 2003). And then gradually increases from  $200^\circ\text{C}$  to  $\sim 500\text{--}600^\circ\text{C}$ , which may be  
218 related to the unblocking effects of fine magnetic particles (Liu et al., 2005). After  
219 this step, a  $T_N$  of about  $640\text{--}660^\circ\text{C}$  is shown, which indicates the presence of  
220 haematite, and the decreased  $T_N$  temperatures may be related to partial substitution of  
221 Fe elements with Al (Jiang et al., 2013, 2014). Most heating and cooling curves are  
222 nearly reversible, which indicates that no new magnetic minerals are generated during  
223 the heating process; therefore, the haematite is original in the samples.

224

225 **Fig. 3** The  $\kappa$ -T curves of pilot samples from the Datang Profile (red lines represent  
 226 heating curves, whereas blue lines indicate cooling curves)

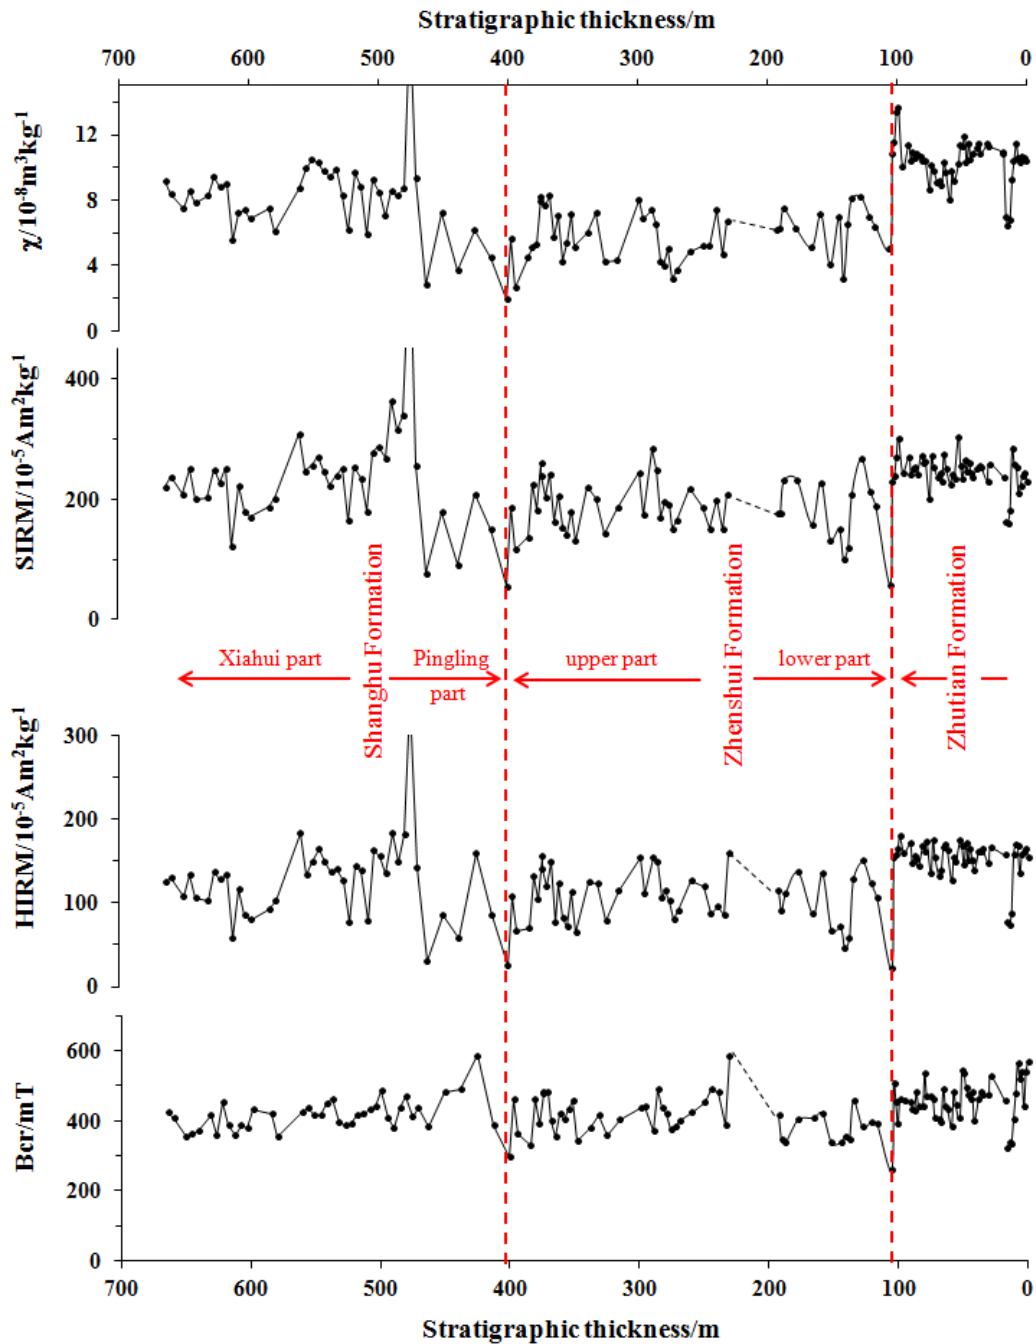

227 **3.3  $\chi$ , SIRM, HIRM, and  $B_{cr}$**

228 The  $\chi$  values are controlled by the types, concentrations, and particle sizes of  
 229 magnetic minerals in the samples; all ferromagnetic, ferrimagnetic, antiferromagnetic,  
 230 and paramagnetic minerals have effects on  $\chi$ . In contrast, SIRM, HIRM, and  $B_{cr}$  are  
 231 not affected by paramagnetic minerals or superparamagnetic particles. Therefore,  
 232  $\chi$  and SIRM can be used to indicate the concentration of magnetic minerals in cases  
 233 where one magnetic mineral is dominant. **HIRM can be used to indicate the**  
 234 **concentration of hard magnetic minerals such as haematite.** The value of  $B_{cr}$  can be  
 235 used to indicate the ratio of hard to soft magnetic minerals (Thompson & Oldfield,  
 236 1986; Evans & Heller, 2003). As shown in Fig. 4, the values of  $\chi$ , SIRM, and HIRM  
 237 are low:  $\chi$  varies from 1.67 to  $19.14 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$  with an average value of  $7.25 \times$   
 238  $10^{-8} \text{ m}^3 \text{ kg}^{-1}$ ; SIRM varies from 55.27 to  $626.26 \times 10^{-5} \text{ Am}^2 \text{ kg}^{-1}$  with an average  
 239 value of  $212.36 \times 10^{-5} \text{ Am}^2 \text{ kg}^{-1}$ ; **HIRM varies from 24.42 to  $341.87 \times 10^{-5} \text{ Am}^2 \text{ kg}^{-1}$**

240 with an average value of  $124.11 \times 10^{-5} \text{ Am}^2 \text{ kg}^{-1}$ . In addition, the variation trends of  
241 these three parameters are similar: high with clear fluctuations in the Zhutian  
242 Formation, a sharply decrease from the Zhutian Formation to the Zhenshui Formation,  
243 low values with numerous fluctuations in the Zhenshui Formation, an increase in the  
244 Pingling Part of the Shanghu Formation, and an overall decrease again with significant  
245 variations in the Xiahui Part of the Shanghu Formation. The  $B_{cr}$  values vary from 300  
246 to 600 mT with an average value of 430 mT, which indicate the dominant role of hard  
247 magnetic minerals.

248 In addition to haematite, there were significant amounts of paramagnetic  
249 minerals in the samples, as shown in  $\kappa$ -T curves (Fig. 3); the presence of  
250 paramagnetic minerals may affect  $\chi$  when the overall value of  $\chi$  is low. However,  
251 SIRM and HIRM are not affected by paramagnetic minerals, and their variation trends  
252 are similar to those of  $\chi$ , which suggests that the variations of  $\chi$ , SIRM, and HIRM  
253 are mainly controlled by the concentration of haematite (Thompson & Oldfield, 1986).

254

255 **Fig. 4** Magnetic parameter variations of the Datang Profile; X axis indicates the  
 256 stratigraphic thickness from the Zhutian Formation to the Shanghu Formation.

257 **3.4 REEs**

258 There are a variety of distribution patterns of REEs in different types of  
 259 sediments because of their diverse origins and sources, and the evolution of the

260 palaeoenvironment. Therefore, REEs can be used as efficient tracer elements (Shunso  
 261 et al., 2010; Fagel et al., 2014). The  $\Sigma$ REE values of the Datang Profile samples vary  
 262 from 153.71 to 210.18  $\mu\text{g/g}$ , with an average value of 183.28  $\mu\text{g/g}$ . The REE  
 263 distribution patterns of the pilot samples nearly overlap (Fig. 5); these patterns are  
 264 characterised by a negative slope, moderate enrichment of LREEs, and a relatively  
 265 flat HREE pattern, as well as by a prominent negative Eu anomaly, which suggests  
 266 that the provenance of the red strata remained stable (Yan et al. 2007). These patterns  
 267 are consistent with those of eight samples from the Zhuguang and Qingzhang granites  
 268 (Shu et al., 2004), which indicates that they are closely related. However, the Eu  
 269 anomaly of the granites is more significant than those of the red strata, which is likely  
 270 related to post-depositional chemical weathering or mixing with other Cambrian–  
 271 Jurassic sediments (Shu et al., 2004).

272  
 273  
 274 **Fig. 5** REE distribution patterns (normalised by chondrite) of pilot samples from the  
 275 Datang Profile and samples of the surrounding granite (average values of eight  
 276 samples, Shu et al., 2004)

277

## 278 **4 Discussion**

### 279 **4.1 Chronological framework of the Datang Profile**

280 A great deal of geochronology research, including palaeomagnetic, isotopic, and  
281 palaeontological studies, has been carried out on the Datang Profile (Zhao et al., 1991;  
282 Zhang et al., 2006; Clyde et al., 2010; Li et al., 2010; Tong et al., 2013). The most  
283 significant event recorded in this profile is the extinction of the non-avian dinosaurs  
284 and the subsequent evolutionary radiation of mammals, which indicate the end of the  
285 Cretaceous and the beginning of the Palaeogene (Zhao et al., 1991; Zhang et al., 2006;  
286 Clyde et al., 2010). Based on the palaeontological data and two basalt K–Ar ages  
287 ( $67.04 \pm 2.34$ ,  $67.37 \pm 1.49$  Ma) from the top of the Yuanpu Formation (which  
288 corresponds to the Zhutian Formation in this paper), Zhao et al. (1991) suggested that  
289 the palaeomagnetic age of the Datang Profile is between 27R and 31R (Fig. 6A).  
290 However, Russell et al. (1993) challenged this chronology because of the wide  
291 variation of sedimentation rate, which varied by more than an order of magnitude  
292 during each chron, proposed an alternative (Fig. 6B), and suggested that several  
293 millions of years of deposition was absent from the lowermost part of Palaeocene  
294 record. However, there are some fundamental flaws in Russell et al.'s age model. First,  
295 a lack of exact ages for palaeomagnetic chron identification made the age model  
296 inconclusive. Secondly, based on field observations, no hiatus occurred between the  
297 Shanghu Formation and the Zhenshui Formation (Ye et al., 2000; Zhang et al., 2006).  
298 Thirdly, it is reasonable to assume that the sedimentary rate differed during different  
299 chrons in the Nanxiong Basin, as a continental basin (Ye et al., 2000). Moreover, two  
300 U–Pb ages ( $59.76 \pm 0.78$ ,  $60.76 \pm 0.90$  Ma) of a tephra layer from the middle part of

301 the Nongshan Formation, above the Shanghu Formation, were recently obtained  
 302 (Tong et al., 2013), and confirm that the age model of Russell et al. was incorrect. To  
 303 further clarify the palaeomagnetism framework of the Datang Profile, Clyde et al.  
 304 (2010) collected samples from the uppermost 465 m of the Datang Profile (i.e. the  
 305 lower part of Zhenshui Formation and Shanghu Formation) and the DT05 profile  
 306 (Nongshan Formation and the lower part of Guchengcun Formation), and combined  
 307 the results with palaeontological data and  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  isotopic composition data  
 308 from palaeosol carbonates. The results show that the upper 465 m of the Datang  
 309 Profile has five well-defined polarity zones (30N, 29R, 29N, 28R, and 28N), whereas  
 310 the DT05 section is characterised by a single long, reversed-polarity zone (26R),  
 311 which has been confirmed by the U–Pb ages of the tephra layer from the Nongshan  
 312 Formation (Tong et al., 2013), and suggests that this chronological work is reasonable.  
 313 However, the ages of the Zhutian Formation to the upper part of Zhenshui Formation  
 314 remain unclear.

316 **Fig. 6** Palaeomagnetic chronology framework of Datang Profile, A) Zhao et al., 1991;  
317 B) Russell et al., 1993; C) Clyde et al., 2010; D) this paper; E) Magnetic polarity time  
318 scale (Gradstein et al., 2012)

319 The age of the Zhutian Formation to the upper part of the Zhenshui Formation in  
320 Zhao's model is controversial; the basalts whose age was used for palaeomagnetic  
321 chron identification were actually intrusive rocks that formed after the Zhutian  
322 Formation was deposited, and therefore cannot be regarded as the top age of the  
323 Zhutian Formation. Thus, the top age of the Zhutian Formation should be older than  
324 67.4 Ma (Zhang & Li, 2000), and it was confirmed with biostratigraphic data  
325 (*Tenuestheria*) that the Zhenshui Formation correlates with Maastrichtian formations,  
326 whereas the Zhutian Formation correlates with lower Santonian–Campanian  
327 formations (Li et al., 2010). Therefore, it was incorrect to use 67.4 Ma as the top age  
328 of the Zhutian Formation in Zhao's model. The Zhenshui Formation is predominantly  
329 composed of coarse clastic deposits, and the top 45.2 m of the lower part is covered in  
330 farmland (Fig. 1D and Fig. 6); therefore, it is not possible to obtain samples for  
331 palaeomagnetic analysis, which likely led to the absence of two short time chrons—  
332 30R (0.173 Ma, Gradstein et al., 2012) and 31N (0.9 Ma, Gradstein et al., 2012)—  
333 from the palaeomagnetic results. Therefore, a new alternative can be proposed, as  
334 shown in Fig. 6D: 30R, 31N, and 31R in Zhao's model are modified to 31R, 32N.1n,  
335 and 32N.1r. The calculated boundary age of the Zhenshui and Zhutian Formations is  
336 ~71.5 Ma according to the new age model. **This is slightly differ from the**  
337 **biostratigraphic age (~72.1Ma, i.e. the boundary age between Maastrichtian and**  
338 **Campanian), the reasons probably are 1) the samples for biostratigraphic age were**  
339 **collected from the whole Zhutian Formation that is more than 1000m in depth, while**  
340 **the Zhutian Formation in Datang Profile is just the top part of the whole Zhutian**

341 Formation (Fig.1), and 2) the dereferences in sampling or time resolution between  
342 these two dating methods; therefore, it is reasonable to cause a little error between  
343 palaeomagnetic and biostratigraphic ages. If 72.1Ma (within C32N.2n) was regarded  
344 as the boundary age of the Zhenshui and Zhutian Formations, then 30R (0.173 Ma),  
345 31N (0.9 Ma), 31R (2.18Ma) and 32N.1n (0.24Ma) were missing due to the covered  
346 farmland, and thus only 45.2m sediments deposited during more than 3.4Ma, which  
347 seems unreasonable to have such a low sedimentary rate in this period. According to  
348 the chronological framework obtained above, the bottom and top ages of the Datang  
349 Profile can be calculated using linear extrapolation as 72 Ma and 62.8 Ma,  
350 respectively.

#### 351 **4.2 Sedimentary environment analysis**

352 Many aquatic fossils, such as ostracods and charophytes, were found in the red  
353 strata, and there are many coarse sandstone and conglomerate layers; therefore, the  
354 sediments were interpreted as fluvial or lacustrine facies in previous studies (Zhang et  
355 al., 2006; Clyde et al., 2010; Wang et al., 2015). In greater detail, the Zhutian  
356 Formation was regarded as floodplain and shallow lake deposits, the Zhenshui  
357 Formation was interpreted as fluvial deltaic deposits, and the Shanghu Formation was  
358 regarded as shallow lake deposits (Wang, 2012). However, there are dozens of  
359 calcareous nodule layers (Fig. 7A and 7B), generated by pedogenic processes,  
360 distributed in muddy sandstone and sandy mudstone layers (Clyde et al., 2010; Wang,  
361 2012), especially in the Shanghu and Zhutian Formations. In addition to calcareous  
362 nodules, other evidence for palaeosol formation was found, such as wormhole  
363 remains (Fig. 7C and 7D), root traces (Fig. 7E) and obvious rhizoliths (Fig. 7F).  
364 Moreover, many mud-cracks are observed in the Datang Profile (Figs. 7G and 7H).

365 Mud-cracks mainly form under alternating dry–wet environments, which have  
366 traditionally been regarded as an indicator of arid or seasonally arid environments.  
367 Environmental magnetic results (Figs. 3 and 4) show that haematite is the dominant  
368 magnetic minerals in the red strata. Haematite is an iron oxide that mainly forms and  
369 is preserved in oxidising environments, and will be dissolved or transformed under  
370 excessively wet and reducing conditions. The widely distributed haematite and  
371 palaeosols in the Datang Profile suggest that the sediments were exposed in a  
372 relatively arid and oxidising environment.

373

374 **Fig. 7** Evidence of palaeosols in the Datang Profile: calcareous nodule layers  
375 generated during pedogenic processes (A and B), wormhole remains filled with  
376 calcite (C) and grey mudstone (D), root traces (E) and obvious rhizolith (F), as well as  
377 mud-cracks (G and F).

378 The climate during the Cretaceous represented one of the “greenhouse states” of  
379 Earth history; the maximum CO<sub>2</sub> concentration was nearly 10 times higher and the  
380 temperature 3–10°C higher than those prior to the Industrial Revolution (Huber et al.,  
381 2002; Wilson et al., 2002; Retallack, 2009). Although the CO<sub>2</sub> concentration  
382 decreased in the Late Cretaceous, it was still higher than today (Wang et al., 2014,  
383 and the references therein). The Nanxiong Basin was belonged to a hot and arid belt  
384 according to the palaeoclimate classification of Chumakov et al. (2004). Clumped  
385 isotope analysis of pedogenic carbonates has shown that the palaeotemperature could  
386 reach up to 27.3–38.2°C, with an average value of 34°C (Zhang, 2016), which  
387 suggests that the temperature during the Late Cretaceous to Early Palaeocene was  
388 much higher than that of the present in this area. In addition, the CaCO<sub>3</sub> contents are  
389 10–20% (wt, Yang et al., 2007) in the red strata, and there are many pedogenic  
390 carbonate layers in the sandy mudstone and muddy sandstone, which suggest that the  
391 leaching process was weak and that rainfall was moderate (Retallack, 1999, 2005;  
392 Yan et al., 2007). TOC concentration is very low (0.027–0.258 wt%, Yan et al., 2007),  
393 which is likely related to the sparse vegetation coverage or oxidising conditions  
394 unfavourable for TOC preservation. Therefore, all geochemical parameters indicate  
395 that the overall climate during the Late Cretaceous to Early Palaeocene in the  
396 Nanxiong Basin was tropical (semi-) arid.

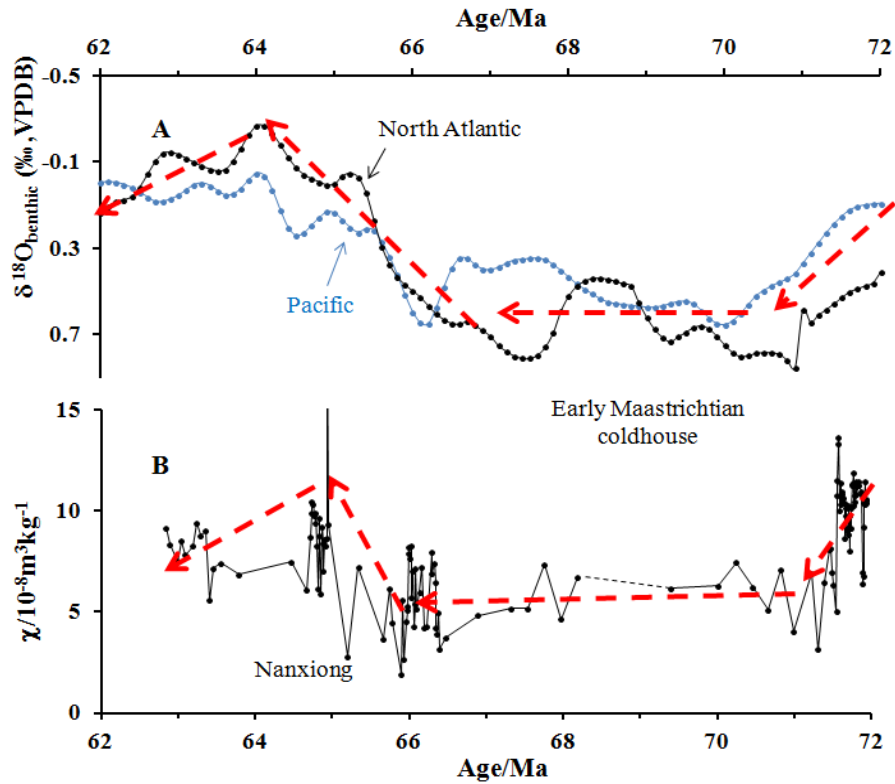

397 Therefore, the depositional processes of red strata in the Nanxiong Basin under  
398 (semi-) arid climate conditions can be inferred as follows. Weathered materials were  
399 transported from the surrounding area by runoff caused by rainfall and were then  
400 deposited in the basin. During the interval with greater rainfall, temporary rivers or  
401 lakes appeared in the basin and provided a habitat for the low-level aquatic organisms  
402 such as ostracods and charophytes, and left abundant fossils of these organisms in the

403 strata. However, the rivers or lakes could not persist for long in a hot, (semi-) arid  
404 climate; after the weathered materials were deposited in the basin, these temporary  
405 rivers and lakes disappeared because of strong evaporation, and the sediments were  
406 then exposed to an oxidising environment. Haematite was thus generated, and the  
407 organic matter rapidly decomposed, which led to very low TOC values (Yan et al.,  
408 2007). Pedogenic processes then developed, and moderately to fully mature soils with  
409 diagnostic characters such as Bk horizons, wormholes and root traces formed in sandy  
410 mudstone and muddy sandstone layers. No typical palaeosols were found in the  
411 coarse sandstone or conglomerate layers in the Zhenshui Formation because of the  
412 lack of essential conditions for soil formation, but many root traces were preserved  
413 (Figs. 7E and 7F), which can be called “weakly developed soils”.

#### 414 **4.3 Comparison between $\chi$ and $\delta^{18}\text{O}$ , and the corresponding mechanism**

415 At present, most high-resolution records of palaeoclimate changes during the  
416 Late Cretaceous to Early Palaeogene were derived from marine sediments, with few  
417 from continental sediments, which has limited comparison between marine records  
418 and continental records and even the study of the dynamic mechanism of  
419 palaeoclimate evolution (Wang et al., 2013b). The  $\delta^{18}\text{O}$  values of benthic foraminifera  
420 in marine sediments faithfully recorded global palaeotemperature changes over the  
421 past 200 Ma (Zachos et al., 2001; Friedrich et al., 2012; Bodin et al., 2015), which has  
422 provided a high-resolution reference for the study of continental records (Fig. 8A). As  
423 shown in Fig. 8, there is a significant negative correlation between  $\chi$  and  $\delta^{18}\text{O}$  for the  
424 Pacific and South Atlantic (Friedrich et al., 2012) from 72 Ma to 62.8 Ma: high (low)  
425  $\chi$  values correlate with low (high)  $\delta^{18}\text{O}$  values, which suggest that  $\chi$  values likely  
426 recorded the global palaeoclimate evolution.

427

428 **Fig. 8** Correlations between  $\delta^{18}\text{O}$  from Pacific and North Atlantic records (A) and  
 429  $\chi$  from the Datang Profile (B) from 72 Ma to 62.8 Ma; higher  $\delta^{18}\text{O}$  values correlate  
 430 with lower  $\chi$  values

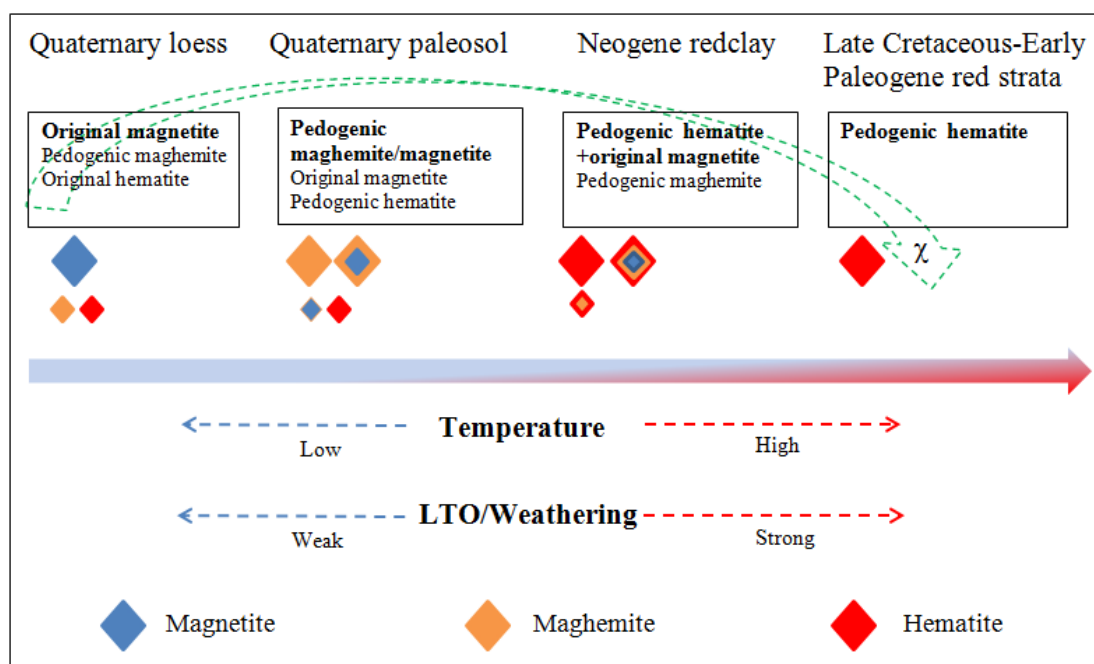

431 The parameter  $\chi$  has been widely applied in Chinese Quaternary loess–palaeosol  
 432 and Tertiary red clay sequences as an efficient palaeoclimatic indicator, and correlates  
 433 well with the  $\delta^{18}\text{O}$  values of marine records (Liu, 1985; Nie et al., 2008). Multiple  
 434 glacial–interglacial cycles occurred during the Quaternary, and the climate during  
 435 interglacial periods was warmer and more humid than that of glacial periods, which  
 436 led to the formation of palaeosols. Palaeosols are magnetically enhanced because of  
 437 in-situ pedogenic formation of magnetite and maghemite under elevated temperature  
 438 and rainfall conditions, which lead to higher  $\chi$  values in palaeosol layers than in loess  
 439 layers in the Chinese Loess Plateau (CLP, Zhou et al., 1990; Liu et al., 1992; Maher et  
 440 al., 1994; Chen et al., 2005; Hao & Guo, 2005). The climate was warmer and more

441 humid during the Tertiary than in Quaternary interglacial periods, according to red  
442 clay records (Ding et al., 1999, 2001), but most  $\chi$  values of red clays were lower than  
443 those of Quaternary palaeosols and even lower than those of loess layers (Nie et al.,  
444 2008), which indicates that the pedogenic hypothesis cannot be simply applied in red  
445 clay layers. The dominant magnetic minerals in loess are original magnetite and  
446 haematite, with minor amounts of pedogenic maghemite. In contrast, in palaeosol  
447 layers, the dominant magnetic minerals are pedogenic maghemite and magnetite, with  
448 minor amounts of magnetite, and in red clay layers, the dominant magnetic minerals  
449 are pedogenic haematite with minor pedogenic maghemite (Xie, 2008). As mentioned  
450 above, the climate when the red clay layers formed was warmer and more humid, and  
451 pedogenesis was stronger; consequently, a large amount of ultrafine strongly  
452 magnetic minerals such as maghemite and magnetite formed (Nie et al., 2007, 2014,  
453 2016). Previous studies have shown that low-temperature oxidation (LTO) of  
454 magnetite is a common process during weathering (VanVelzen & Dekkers, 1999) that  
455 gradually alters magnetite into maghemite (magnetitisation). Moreover, chemical  
456 weathering can transform maghemite into haematite (Sidhu, 1988; Torrent et al., 2006;  
457 Zhang et al., 2012; Fang et al., 2015; Hu et al., 2015). The magnetic minerals in red  
458 clays underwent stronger oxidation than Quaternary loess–palaeosol sequences (Nie  
459 et al., 2016), which likely caused most soft magnetic minerals (magnetite and  
460 maghemite) to transform into hard magnetic mineral-haematite under LTO and  
461 chemical weathering processes, and led to a significant decrease of  $\chi$  values in red  
462 clay. Nonetheless,  $\chi$  values of red clay can still be used as an efficient palaeoclimatic  
463 indicator (Nie et al., 2008; Zhao et al., 2016).

464 Generally, palaeosols, even without burial or original gleisation in deep time,  
465 have systematically lower  $\chi$ , such as observed for Precambrian and Palaeozoic

466 palaeosols (Retallack et al., 2003). Two possible explanations for this finding have  
467 been proposed: 1) recrystallisation and metamorphism of magnetite and maghemite  
468 (Retallack, 1991), and 2) lower biological productivity of such deeply buried and  
469 ancient soils (Schwartzmann and Volk, 1991). However, these two possibilities  
470 require further testing of palaeosols with a wider range of geological ages and degrees  
471 of burial alteration (Retallack et al., 2003). Despite the low values of  $\chi$  in many of  
472 these deep time palaeosols, many studies have concluded that the magnetic minerals  
473 preserved in these soils are pedogenic (Rankey and Farr, 1997; Cogoini et al., 2001;  
474 Tramp et al., 2004). Therefore, we propose another possibility to explain the low  $\chi$  in  
475 the Nanxiong red strata. The global climate during the Late Cretaceous to Early  
476 Palaeocene was much warmer than that of the Neogene and Quaternary (Friedrich et  
477 al., 2012; Bodin et al., 2015). The Chemical Index of Alteration (CIA) values of red  
478 strata in the Nanxiong Basin (70–80, Yan et al., 2007) are higher than those of  
479 Quaternary loess–palaeosol and Tertiary red clay (61–71, Chen et al., 2001; Xiong et  
480 al., 2010), which suggests that the red strata underwent stronger chemical weathering.  
481 The climate during the Late Cretaceous to Early Palaeocene in the Nanxiong Basin  
482 was hot and (semi-) arid, with a certain amount of rainfall, as represented by the  
483 presence of temporary rivers and shallow lakes (or low-lying land) and palaeosols  
484 with calcareous nodules (Retallack, 1999, 2005), which favoured the LTO of  
485 magnetite and the transformation of maghemite to haematite through chemical  
486 weathering, caused haematite to be the main magnetic mineral in the red strata (Figs.  
487 2 and 3) and significantly decreased  $\chi$ . This process is summarised in Fig. 9. The  
488 global climate was unstable from 72 Ma to 62.8 Ma, as represented by multiple cycles  
489 of cold/warm changes (Fig. 8A). Higher  $\chi$  values occurred in warmer periods (lower  
490  $\delta^{18}\text{O}$  values), which is similar to the correlation between the  $\chi$  values of Chinese

491 loess–palaeosol/red clay successions and  $\delta^{18}\text{O}$  (Liu, 1985; Nie et al., 2008). There  
 492 may be two reasons for the changes in  $\chi$  : 1) changes of sediment provenance, and 2)  
 493 palaeoclimatic evolution. REE distribution patterns show that the sediment  
 494 provenance remained similar in the Datang Profile (Fig. 4), and even across the whole  
 495 basin (Yan et al., 2007), which indicates that palaeoclimatic evolution was the main  
 496 reason for changes in  $\chi$ . There are significantly positive correlations between  $\chi$ , SIRM,  
 497 and HIRM (Fig. 4), which suggest that  $\chi$  was controlled by the concentration of  
 498 haematite (Figs. 3 and 4), whereas haematite was generated through LTO and  
 499 chemical weathering during pedogenesis. Thus, the relationship between  $\chi$  and  
 500 haematite content can be explained by the “pedogenic-plus hypothesis”: more  
 501 haematite formed during warmer and wetter periods with stronger pedogenesis, and  
 502 caused a higher  $\chi$ , and opposite conditions yielded lower  $\chi$  values. The similarity of  
 503 the  $\chi$  and  $\delta^{18}\text{O}$  curves suggests that the climate changes in the Nanxiong Basin during  
 504 72–62.8 Ma were similar to global trends; therefore,  $\chi$  can still be used as an efficient  
 505 indicator for palaeoclimate changes in this basin.

506

507

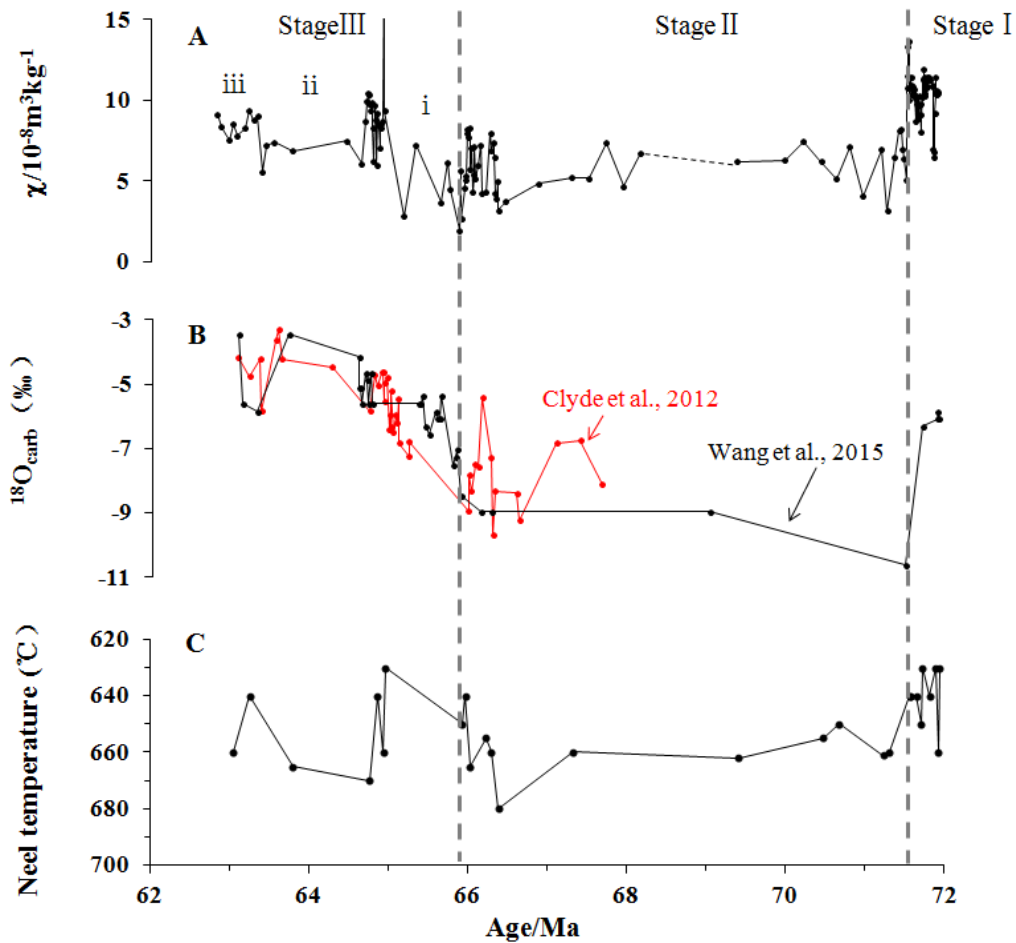

508 **Fig. 9** Cartoon illustrating the dominant magnetic minerals and  $\chi$  changes from  
509 Quaternary loess–palaeosol (CLP)→Neogene red clay (CLP)→Upper Cretaceous–  
510 Lower Palaeogene red strata in Nanxiong Basin along with the increased temperature  
511 and LTO/chemical weathering (the size of the symbols means the contribution to  
512  $\chi$  but not the real size of magnetic particles).

513 Hasegawa et al., (2012) found that the subtropical high-pressure belt was located  
514 between ca. 31 °N and 37 °N during the Late Cretaceous based on spatio-temporal  
515 changes in the latitudinal distribution of deserts in the Asian interior, thus the  
516 Nanxiong Basin (~20 °N, Scotese, 2014 ) was out of the area covered by subtropical  
517 high-pressure belt. Besides, computer simulation results revealed that the prevailing  
518 wind directions showed a remarkable seasonal variation over East Asia at 66Ma,  
519 which indicates a monsoon feature over East Asia at that time (Chen et al., 2013), and  
520 even more remarkable compared to the present day, this was supported by the  
521 geological evidences (Jiang et al., 2008), rainfall also showed a seasonal variation  
522 between dry and wet seasons corresponding to the monsoon (Chen et al., 2013). In  
523 addition, the root traces in Zhenshui Formation consisting of elongate gray mottles  
524 with red or purple hypocoatings (Fig. 7E) indicate a relatively well-drained soil  
525 condition (Krous et al., 2006), which is favourite for the formation and preservation of  
526 haematite. Therefore, the monsoon system already existed and the rainfall also  
527 showed seasonal variation across the Cretaceous–Palaeogene boundary, but the  
528 climate was more hotter and drier than present, so a great deal of haematite generated  
529 during pedogenic processes under well-drained condition, and thus recorded the  
530 global climate evolutions.

#### 531 **4.4 Palaeoclimatic evolution of the Nanxiong Basin during 72–62.8 Ma**

532           Based on changes of the relative content of clay, the ratio of feldspar to quartz  
533 (F/Q) and the  $\delta^{18}\text{O}$  of pedogenic carbonates, Wang et al. (2012, 2015) divided the  
534 palaeoclimatic changes recorded in the Datang Profile into three stages: an arid to  
535 semi-arid climate from the Zhutian Formation to the bottom of the Pingling part of the  
536 Shanghu Formation, a semi-arid to hot and humid climate from the bottom of the  
537 Pingling part to the bottom of the Xiahui part of the Shanghu Formation, and the  
538 semi-arid climate of the Xiahui part. Their age model follows the palaeomagnetic  
539 framework of Zhao et al. (1991, Fig. 6A). In contrast, Yan et al. (2007) suggested that  
540 a long period of extremely dry climate occurred in the Late Cretaceous, and that the  
541 climate then became relatively wet in the Early Palaeocene, based on  $\text{CaCO}_3$  and  
542 TOC contents as well as the ratios of Rb/Ti and Cs/Ti. Furthermore, quantitative  
543 palaeotemperature data have been successfully determined; for example, clumped  
544 isotope analysis of pedogenic carbonates revealed that the palaeotemperature reached  
545 up to 27.3–38.2°C with an average value of 34°C (Zhang, 2016). Although a  
546 considerable amount of work has been conducted on these palaeoclimatic changes, the  
547 reconstructed results cannot be compared efficiently with global records. One reason  
548 may be the low resolution of quantitative palaeotemperature data due to the  
549 limitations of sampling (e.g. pedogenic carbonates), and another may be that the  
550 geochronological framework is incorrect (section 4.1). As shown in previous studies,  
551 the  $\delta^{18}\text{O}$  of pedogenic carbonates was found to be an efficient palaeotemperature  
552 indicator in terrestrial sediments; greater  $\delta^{18}\text{O}$  values indicate higher  
553 palaeotemperatures (Han et al., 1997; Chamberlain et al., 2012; Gao et al., 2015). In  
554 addition, the haematite in the Nanxiong Basin is partially Al-substituted (Fig. 3);  
555 indoor examination revealed that there was a negative correlation between  $T_N$  and the

556 Al content of Al-substituted haematite (Jiang et al., 2012), and greater Al content in  
 557 haematite likely indicates stronger pedogenesis. Therefore, we combined these results  
 558 with the  $\chi$  curve,  $\delta^{18}\text{O}$  of pedogenic carbonates (Fig. 10B, Clyde et al., 2010; Wang,  
 559 2012), and  $T_N$  of the pilot samples (Fig. 10C) to reconstruct the climatic evolution of  
 560 the Nanxiong Basin during 72 to 62.8 Ma.

561

562 **Fig. 10** Combined proxies for palaeoclimatic changes in the Nanxiong Basin from 72  
 563 to 62.8 Ma, A)  $\chi$  curve, B)  $\delta^{18}\text{O}$  of pedogenic carbonates (Clyde et al., 2010; Wang,  
 564 2012), and C)  $T_N$  of Al-substituted haematite of pilot samples

565 Although the palaeoclimate from 72 to 62.8 Ma in the Nanxiong Basin was  
 566 overall hot and (semi-) arid, it can be divided into three stages, as shown in Fig. 10.

567 For stage I (from 72 to 71.5 Ma, Zhutian Formation),  $\chi$  and  $\delta^{18}\text{O}$  values of pedogenic  
568 carbonates are relatively high, and  $T_N$  is relatively low and varies from 630 to 660°C  
569 with a mean value of 640°C, whereas the  $\delta^{18}\text{O}$  values of marine sediments are  
570 relatively low (Fig. 8); the sediments are mainly composed of muddy siltstone and  
571 silty mudstone (shallow lake facies), which indicate a relatively hot and wet climate  
572 with stronger pedogenic processes and clear fluctuations, such as the rapid drying and  
573 cooling event at ~71.7 Ma, represented by low  $\chi$  values. In stage II (from 71.5 to 66  
574 Ma, Zhenshui Formation),  $\chi$  decreases sharply at 71.5 Ma and then fluctuates steadily,  
575  $\delta^{18}\text{O}$  values of pedogenic carbonates show a similar trend to  $\chi$ ,  $T_N$  is relatively high  
576 and varies from 640 to 680°C with a mean value of 660°C,  $\delta^{18}\text{O}$  of marine sediments  
577 first increases and then fluctuates at a high level, and the sediments are mainly  
578 composed of coarse sandstone and conglomerate (fluvial delta facies), which indicate  
579 a relatively cool and arid climate with weak pedogenesis; these findings are supported  
580 by sparse pollen data that show the appearance of the Pinaceae and disappearances of  
581 tropical plants in the upper Zhenshui Formation, which indicate a cold climate (Erben  
582 et al., 1995). In Stage III (from 66 to 62.8 Ma, Shanghu Formation):  $\chi$  increases  
583 sharply from 66 to ~64.7 Ma, then decreases sharply at 64.7 Ma, and maintains  
584 relative low values from 64.7 to ~63.4 Ma, and then returns high values from 63.4 to  
585 62.8 Ma;  $\delta^{18}\text{O}$  values of pedogenic carbonates increase rapidly from 66 to ~64.7 Ma  
586 and then maintain high values from 64.7 to ~62.8 Ma;  $T_N$  of pilot samples and  $\delta^{18}\text{O}$  of  
587 marine sediments show opposite trends from  $\chi$ ; the sediments from 66–62.8 Ma are  
588 mainly composed of muddy siltstone and silty mudstone (shallow lake facies). In  
589 addition, sparse pollen analyses have shown that the climate was temperate–  
590 subtropical at the bottom of the Pingling part (~66 to ~65 Ma) (Li, 1989), whereas it

591 was cool and arid in the Xiahui part (Zhang et al., 1981); therefore, the climate  
592 changes in this stage can be divided into three sub-stages: in sub-stage i (66–64.7 Ma),  
593 the climate quickly became relatively hot and wet from relatively cool and arid  
594 conditions; in sub-stage ii (64.7–63.4 Ma), the climate was relatively drying and  
595 cooling event represented by low  $\chi$  values; in sub-stage iii (63.4–62.8 Ma), the  
596 climate became relatively hot and wet again. **Although the constructed climate**  
597 **evolution revealed by magnetic parameters is still qualitative, it shows more details**  
598 **than other proxies or the marine record, such as the several sub-fluctuations during**  
599 **each stage, which probably indicates that the climate changes from 72 to 62.8 Ma**  
600 **were probablyly instable with more fluctuations, and this needs our further work to**  
601 **provide quantitative and higher resolution results in the future.**

## 602 **5 Conclusions**

603 1. Some defects have been identified in the previous palaeomagnetic  
604 chronological frameworks because of the lack of reliable control ages for  
605 identification of palaeomagnetic chrons. Combined with the most recently published  
606 isotopic ages of volcanic ash and biostratigraphic dating, a new chronological  
607 framework has been proposed; the results show that the age of the Datang Profile is  
608 between 72 to 62.8 Ma.

609 2. Many aquatic fossils, such as ostracods and charophytes, were found in the red  
610 strata, and the sediments were interpreted as fluvial or lacustrine facies; however,  
611 haematite is the dominant magnetic mineral throughout the profile, and furthermore,  
612 palaeosol layers, pedogenic carbonates, wormhole remains, root traces, clear  
613 rhizoliths and mud-cracks were found, which indicate that those rivers or lakes, if  
614 present, appeared only temporarily in these hot and (semi-) arid environments, such

615 that the sediments were exposed to (semi-) arid and oxidising condition for long  
616 periods of time and experienced different degrees of pedogenesis.

617 3. The variations of  $\chi$  were controlled by the concentration of haematite, which  
618 was generated through LTO and chemical weathering during pedogenesis in hot and  
619 (semi-) arid environment. Moreover, the stronger the pedogenic processes, the more  
620 haematite was generated, and the higher the  $\chi$  values.

621 4. The  $\chi$  curve of the Datang Profile is similar to the  $\delta^{18}\text{O}$  curves of  
622 corresponding marine sediments, which suggests that climate changes in the  
623 Nanxiong Basin during 72–62.8 Ma were similar to global trends, and can be divided  
624 into three stages: 1) a relatively hot and wet climate from 72 to 71.5 Ma with a rapid  
625 drying and cooling event at ~71.7 Ma; 2) a relatively cool and arid climate with  
626 secondary fluctuations from 71.5 to 66 Ma; and 3) a relatively hot and wet climate  
627 again from 66 to 62.8 Ma, which can be divided into 3 sub-stages: i) the climate  
628 quickly became hot and wet from 66 to 64.7 Ma, ii) a notable drying and cooling  
629 event at 64.7–63.4 Ma, and iii) a relatively hot and wet climate from 63.4 to 62.8 Ma.

630 **Author contribution:** Mingming Ma and Xiuming Liu designed the experiments and  
631 Wenyan Wang carried them out. Mingming Ma prepared the manuscript with  
632 contributions from all co-authors.

633 **Competing interests:** The authors declare that they have no conflict of interest.

634 **Acknowledgement:** The authors thank Xianqiu Zhang (China New Star (Guangzhou)  
635 Petroleum Corporation) for his generous help in field work. This research was  
636 supported by National Science Foundation of China (Grant Nos. 41210002, 41602185  
637 and U1405231), Natural Science Foundation of Fujian Province (Grant No.  
638 2016J05095), and Non-Profit Research Funds of Fujian Province (Grant No.  
639 2016R10323).
