Abstract

A continuous 305-year (1711-2016) monthly rainfall series is created for the Island of Ireland. Two overlapping data sources are employed: i) a previously unpublished UK Meteorological Office note containing annual rainfall anomalies and corresponding proportional monthly totals based on weather diaries and early observational records for the period 1711-1977
5 and; ii) a long-term, homogenised monthly rainfall series for the island of Ireland for the period 1850-2016. Using estimates of long-term average precipitation from the homogenised series to merge these sources, the new 305-year record is constructed and insights drawn about notable extremes, climate variability and change. The consistency of the resulting series was evaluated by comparison with independent long-term observations and reconstructions of precipitation, temperature and circulation indices from across the British-Irish Isles. Strong decadal consistency is evident throughout the
10 record amongst all series in spring, summer and autumn. The winter series is probably too dry from the 1740s to the 1780s, but strong consistency with other records strengthens confidence from 1790 onwards. The new Island of Ireland series reveals remarkably wet winters during the 1730s, concurrent with a period of strong westerly airflow, glacial advance throughout Scandinavia and near unprecedented warmth in the Central England Temperature record – all consistent with the strong phase of the North Atlantic Oscillation. The driest winter decade in the series coincides with the Laki eruption of
15 1783-1784. Unusually wet summers occurred in the 1750s, consistent with proxy (tree-ring) reconstructions of summer precipitation in the region. In the annual series, the most recent decade (2006-2015) is found to be the wettest in over 300 years. The new series reveals statistically significant (0.05 level) multi-centennial trends in winter (increasing) and summer (decreasing) seasonal precipitation. However, given uncertainties in the early winter record, the former should be treated as tentative. Importantly, we show that the years 1940 to present – the period with the most widely available digitised records –
20 is unrepresentative of long-term changes in all seasons. Although there are recognized uncertainties in the early record, the derived series offers valuable insights for understanding multi-decadal and centennial rainfall variability in Ireland, and provides a firm basis for benchmarking other long-term records and future reconstructions.

25 and Change.*

1 Introduction

Historical weather records are essential for understanding climate variability and change, as well as contextualising extreme events, identifying emerging trends, evaluating climate models, and supporting vulnerability and risk assessment (e.g. Matthews et al., 2016; Wilby and Murphy, 2017). Continuous observations of precipitation in the British-Irish Isles (BI) can be traced back to 1677 – the year the first known rain gauge was developed by Richard Towneley of Burnley, Lancashire, in NW England. Since the early 1700s, at least three precipitation gauges have operated somewhere in the BI every year (Jones and Briffa, 2006). The earliest meteorological observations in Ireland can be traced to the end of the 17th Century (Shields, 1983). However, these early instrumental records, taken in Dublin by William and Samuel Molyneux, have been lost. While discontinuous records exist, systematic weather observing did not begin in Ireland until 1789 when Richard Kirwan set up a series of instruments in Dublin (Shields, 1983). Yet, with the exception of Butler et al. (1998) who analysed the record for Armagh Observatory (commencing in 1838), there has been little work on Irish precipitation measurements prior to 1850, due primarily to the lack of suitable digitised data. There have also been few assessments of qualitative descriptions from weather diaries pre-1850. Exceptions from the 18th Century include analyses of the diary of Thomas Neve from Derry, for the period 1711-1725 (Dixon, 1959), the diary of Isaac Butler from Dublin for the period 1716-1734 (Sanderson, 2017) and Joshua Wight from Cork for the period June 1753 to September 1756 (Tyrell, 1995). Thus, Irish rainfall climatology of the last 300 years remains poorly understood.

The spatially variable nature of precipitation, together with changes in observer practices, gauge location and design, mean that developing reliable, long-term precipitation series can be challenging (Wilby et al., 2017). The development of regional series from individual gauges can be further hampered by changes in the network of gauges through time. Nonetheless, such regional series can provide important insights into precipitation variability and change over the course of centuries. Symons (1866) and later Nicholas and Glasspoole (1931) were among the first to construct a regional average monthly rainfall record for England and Wales extending back to 1727. Despite known homogeneity issues (due to changes in methods of raingauge construction and siting through time), this record led to the development of the England and Wales Precipitation (EWP) series, beginning in 1766 (Wigley et al, 1984; Alexander and Jones, 2001). Similarly, Glasspoole (1924) developed a regional monthly precipitation series representing Ireland for the period 1881-1924. Tabony (1980) and Briffa (1984) developed long-term rainfall series for Irish stations, which have since been updated by others (e.g. Jones, 1983; Gregory et al., 1991; Jones and Conway, 1997). More recently, Noone et al. (2016) constructed a homogenous long-term monthly rainfall network for Ireland (1850-2010), consisting of 25 stations together with an Island of Ireland (IoI) composite series. Subsequent work used the data to evaluate severe Irish droughts from 1850 to present (Wilby et al., 2016; Noone et al., 2017), with protracted droughts being a feature of the 19th Century, but largely missing from recent records – particularly since the mid-1970s (Murphy et al., 2017).

Recently, an unpublished UK Meteorological Office (UKMO) note by Jenkinson et al. (1979) has come to light, located amongst a collection of old files which were found following refurbishment in Met Éireann. Constructed using documentary sources (weather diaries) and early observations, the note provides a continuous monthly rainfall series for IoI covering the period 1711-1977. Given the painstaking work of the original authors in constructing the series, together with the possibility of extending IoI rainfall records to the early 18th Century, revisiting the work of Jenkinson et al. (1979) holds considerable potential for better understanding long-term Irish precipitation climatology. Therefore, this paper (i) presents the previously unpublished Jenkinson et al. (1979) data and its constituent sources; (ii) merges the Jenkinson data with the homogenised Noone et al. (2016) series to produce a continuous monthly rainfall series for Ireland from 1711 to present (henceforth IoI_1711); (iii) assesses confidence in the early record through comparison with other long records of relevant meteorological parameters from the BI region, as well as available proxy and documentary sources; and, (iv) investigates the nature of variability and change in the reconstructed record.

The rest of the paper is organised as follows. Section 2 presents the data used (including the Jenkinson data) in constructing the IoI_1711 series, together with the data used for comparative analysis. Methods employed for exploring variability and change are also presented. Results are presented and described in Section 3. Section 4 provides a discussion of key findings and limitations. Finally, section 5 closes with key conclusions and priorities for future work.

2. Data and Methods

2.1 Deriving the extended Island of Ireland (IoI_1711) series

Two data sources were used to construct the IoI_1711 series. First, is the Noone et al. (2016) IoI composite series (1850-2010) (henceforth IoI_1850 series). This dataset consists of monthly rainfall data for 25 stations across the island, each homogenised using the *HOMogenisation softwarE in R* (HOME, 2013) software package and making recourse to available metadata. These homogenised data were combined via a simple arithmetic mean into a composite monthly precipitation series representing the Island of Ireland (IoI). McCarthy et al. (2016) updated this composite series to February 2016, which are the data used here. The second source is the UKMO note by Jenkinson et al. (1979) (henceforth the Jenkinson series), which contains tables of monthly and annual rainfall representing IoI for the years 1711 to 1977. A copy of the original document is provided in Supplementary Information (SI).

2.1.1 The Jenkinson series

The Jenkinson data are presented as annual totals expressed as a percentage of the mean Annual Average Rainfall (AAR) for the period 1826-1975. Monthly values are provided as a proportion of the rainfall for each year. Annual anomalies and proportionate monthly values, presented in the Appendix of Jenkinson et al. (1979), were transcribed using double keying (by two of the authors) to minimise potential transcription errors. Figure 1 plots the number of constituent sources per year

underpinning the series, along with annual anomalies (relative to 1826-1975) contained in the note for the years 1711-1977. Table 1 provides an overview of the various data sources comprising the Jenkinson series.

The earliest instrumental observations are derived from a rudimentary gauge operated by Thomas Neve in Derry, for the years 1711-1725. Given the scarcity of observations in the early record, at times annual totals were derived from regional series from the UK. For instance, during the period 1757-1839 data from NW England were used as a proxy Irish station. Similarly Scottish data were used for the years 1757-1977. Prior to 1811, the number of sources is typically fewer than four, while for the years 1728-1756 and 1766-1791 the derived series is based on single sources – the weather diary of Dr. John Rutty (1770), who compiled monthly and seasonal weather summaries for Dublin (1716-1765), and a regional series comprising data from NW England and SW Scotland, respectively. The latter were compiled by Jenkinson et al. (1979) using available data from the UKMO. From the 1790s onwards, instrumental observations from across IoI became available, including stations at Dublin, Kilkenny, Derry, Belfast, Armagh, Cork and Sligo.

Methods employed by Jenkinson et al. (1979) to derive annual totals and proportionate monthly values are incompletely documented, but appear similar to those of Glasspoole (1924) and Nicholas and Glasspoole (1931) in deriving regional rainfall series for the UK and Ireland (see Appendix 1 in Wigley et al. 1984 for description). For available stations, monthly values were expressed as a fraction (percentage) of the annual value for each station, and these fractions were then averaged over available stations. Regional estimates of annual totals were constructed by taking an overlapping period of 20-50 years with the Glasspoole series for Ireland (1881-1924) and continuing this overlapping back to the earliest records. According to Jenkinson et al. (1979), overlapping periods were varied according to the rate of change of contributing stations with longer period records taken as optimum. For each overlapping period, estimates of AAR were derived iteratively to provide: i) station AAR; ii) station annual percentages of AAR, and; iii) regional annual percentages of AAR. Only the latter are provided in the Jenkinson note. For any station, estimates of AAR were taken as the arithmetic mean of the available annual totals. Individual years were recorded as percentages of this AAR. The mean of the percentage values for a given year across available stations was then taken as the estimate of the regional percentage of AAR for that year. Finally, Jenkinson et al. (1979) used the mean for all data years to derive the final estimate of the regional AAR (see description of methods in the original document in SI).

The diaries of Thomas Neve (Dixon, 1959), Nicholas Blundell (1968) and Dr John Rutty (1770) are critical sources for the early Jenkinson series. The Neve diary contains estimates of rainfall totals from Derry taken from a rudimentary gauge (described by Dixon (1959)). Nicholas Blundell's diary provides monthly and annual weather summaries for Crosby (Liverpool) in NW England for the years 1711-1715 and 1718-1727. The Rutty diary contains a chronological history of weather in Dublin from 1716-1765, including monthly and seasonal weather summaries. To convert the qualitative descriptions of Blundell and Rutty to a quantitative measure of precipitation, Jenkinson et al. (1979) applied a graded scaling

system, similar to Brázdil et al. (2010), to both diaries. Scores ranging from 1 (exceptionally dry) to 9 (exceptionally wet) were used to rank individual months and aligned with seasonal summaries. Frequencies of rankings for each month over the period 1716-1765 were derived and internal percentages for each month estimated by comparison with frequencies of monthly rankings for the period 1840-1889. These values were used as a percentage of AAR for each month in the period 1716-1765. Monthly and annual percentages were processed to give internal percentages for each year, with the annual percentages of AAR (1825-1977) used to represent a single station (see the original Jenkinson et al. (1979) note in SI). This combination of methods for quantitative and qualitative sources was used by Jenkinson et al. (1979) to produce the final IoI series of annual totals, expressed as a percentage of AAR for the period 1826-1975. The final series was calibrated against Glasspoole's EWR series, however details of the calibration are not provided by Jenkinson et al. (1979). Additionally, although Jenkinson et al. (1979) report annual anomalies relative to 1826-1975, this AAR value does not appear in the publication.

2.1.2 Deriving the IoI_1711 series

The IoI_1850 series is used to estimate this missing AAR and thus to reconstruct the full series. With the exception of the 24 years prior to 1850, there is a large overlap between the normal period applied to the Jenkinson series and the IoI_1850 series. Correlation of annual anomalies derived from the IoI_1850 series using the normal period of 1850-1975 with the anomalies derived from the Jenkinson series for concurrent years, reveals a strong positive correlation (Spearman's $r = 0.95$). The time series of both sets of anomalies is plotted in Figure 1a. Resampling was employed to derive estimates of long-term AAR values from 1000 samples (with replacement) of long-term (100 year) AAR drawn from the IoI_1850 series over the period 1850-2015. Each AAR estimate was used to reconstruct annual totals and subsequently monthly rainfall totals for the years 1711-1849. Post-1850 data remain the homogenised IoI_1850 series of Noone et al. (2016). Resampling the missing AAR from IoI_1850 has two advantages. First, it ensures that the Jenkinson series is mean-adjusted to the homogenised IoI_1850 series. Second, confidence bounds can be generated for the reconstructed series given the uncertainty in the value of AAR. The combined dataset is named the IoI_1711 series and provides a continuous monthly rainfall record from January 1711 to February 2016. Subsequent analysis is performed on the median of the IoI_1711 series.

2.2 Series used for comparison with IoI_1711

Additional long-term observational series of precipitation, temperature, and sea level pressure, proxy reconstructions of precipitation and modes of climate variability and circulation for the region were collated for comparison with the IoI_1711 series. Emphasis is placed on the pre-1850 series as post-1850 has already been interrogated by Noone et al. (2016). Datasets used are listed in Table 2. All reported correlations are derived using Spearman's rank correlation, with significance reported at the 0.05 level. There is a risk of circularity when comparing with precipitation records from the UK since some UK observations and documentary sources are used directly in the Jenkinson et al. (1979) series and the series was calibrated

using EWR. Therefore in presenting the data used, series are grouped into two categories; those where a risk of circularity exists and those that are deemed to be independent, based on examination of data sources.

2.2.1 Comparison series that may not be fully independent

5 *England Wales Rainfall (EWR)*: Nicholas and Glasspoole (1931), building on earlier work by Symons (1866), presented a regional monthly precipitation series for the UK (1727-1931). The annual series was used to calibrate the Jenkinson series for Ireland, so there are obvious circularities. However, we include the years 1727-1765 prior to the modern England and Wales Precipitation (EWP) series that begins in 1766 (see next paragraph). We treat the EWR series by simply appending it to the EWP series (where EWR and EWP are appended in such manner we refer to the resultant series as EWR/EWP).
10 Wigley et al. (1984) note inhomogeneities in the annual totals in the early EWR record, whereby there is a tendency to underestimate precipitation relative to EWP prior to 1870. Moreover, Tabony (1980) suggests that prior to 1820 EWR is unreliable. Knowledge of these discrepancies are useful in themselves for assessing the IoI_1711 series. The stations comprising the early EWR series are unclear and there is a need to reconcile the early EWR series of Glasspoole (1924) with the earlier Symons (1866) work. Glasspoole (1924) mentions that from 1727-1756 at least two stations were available, and
15 from 1757-1774 at least three. Craddock (1976) provides a comprehensive list of stations that would have been available for this period of time – certainly more than used by Glasspoole (1924). Table 3 provides a list of stations that were operational (with at least one year of data) in England (note none listed for Wales) between 1725 and 1766 – i.e. from early in the IoI_1711 series to commencement of the modern EWP series when traceability is clearer. This list of stations is used to identify potential circularity with the IoI_1711 series.

20

England and Wales Precipitation (EWP) Series: The England and Wales Precipitation series from 1766 onwards (Wigley et al., 1984; Alexander and Jones, 2001) and data for key EWP stations that pre-date 1766 are also employed. While EWP runs from January 1766 to present, some of the constituent records extend earlier into the 1700s (e.g. Carlisle, Kew, Spalding (Pode Hole)). The early part of these records often contains data from the stations listed in Table 3. However, many have
25 also undergone additional adjustments to correct uncovered quality issues in the early series. An overview of each series is given in the following paragraphs.

Kew Gardens Precipitation (Kew): Routine rainfall measurements have been taken at Kew since 1871. Prior to this, annual and monthly totals were estimated by Wales-Smith (1971) back to 1697. During the years 1717-1724 and 1725-1744, the
30 Richmond diaries and the diary of George Smith respectively, were used to derive estimates of monthly totals calibrated to observational series at Upminster, Fleet Street and Tonbridge (all in Table 3). For the remainder of the 1700s, data from Tonbridge, Lambeth and Somerset House feature strongly and the former two are noted in the series available to EWR in Table 3. However, monthly and annual totals for 1697-1870 were later revised by Wales-Smith (1980).

Spalding (Pode Hole) precipitation (Spald): The early record for Spalding (1726- present) is a composite of records from the East Midlands developed by Craddock and Wales-Smith (1977) (including Southwick (Oundle) 1726-1736 and Lyndon 1737-1798 from Table 3), while much of the record for the 19th Century derives from South Kyme and Pode Hole thereafter.

5 Tabony (1980) corrected the series for being overly wet during 1770-1870. The quality of the pre-1770 record is largely unknown.

Carlisle Precipitation (Carl): The Carlisle series (1757-present) for NW England was constructed as a composite of stations prior to 1872. An annual series for Carlisle was first developed by Craddock (1976) and a monthly series subsequently

10 developed for the years 1845-1976 by Tabony (1980). The series was further extended to 1757 by Jones (1983). Todd et al. (2015) updated the Carlisle series to present, and assessed the homogeneity of the record. Data for the years 1757-1783 come from observations taken by Dr. J. Carlyle as listed in Table 3. Rainfall totals prior to 1790 were found to be under-representative and were increased by 24 percent, while annual totals during 1827-1850 were also increased by 10 percent (Todd et al., 2015).

15

Oxford Precipitation (Ox): The Radcliffe Observatory, founded in Oxford in 1772, has the longest and best documented continuous series of temperature and rainfall at any single site in the UK. Daily observations are available from April 1814, and continuously since 1827 (Burt and Howden, 2011). A reconstructed monthly precipitation record, first developed by Craddock and Craddock (1977), exists from 1767. Prior to 1815, monthly totals are estimated from the manuscripts of Dr.

20 Thomas Hornsby (often incomplete and fragmentary) and data from Shirburn Castle (12 miles from Oxford), together with estimates from other stations around Oxford (Stroud, Sunbury and Lambeth, the latter is noted in Table 3). The Oxford record is unusual in that a good deal of work has been done to ensure that the entire record is homogenous, including the early measurements from the roof of the Observatory (Burt and Howden, 2011).

25 *North Atlantic Oscillation (NAO) reconstruction (L-NAO)*: Luterbacher et al. (2002) developed a monthly resolution multi-proxy reconstruction of the NAO Index back to 1659 and seasonal reconstructions back to 1500. Full details of the reconstruction methods and constituent data sources are given by Luterbacher et al. (2002). Issues of circularity arise when using Luterbacher et al. (2002) to interrogate the IoI_1711 series because of the inclusion of Kew, Spalding (Pode Hole), EWP and other UK records in the reconstruction. During the 1700s the number of predictors falls rapidly from

30 approximately 40 to less than 20, so these UK precipitation series are likely more heavily weighted in the NAO reconstruction for this period.

Rutty (1770) weather diary (Rutty): The Rutty diary provides qualitative insight to the weather conditions experienced in Ireland during the years 1716-1765. As outlined above, the Rutty diary was used extensively in the Jenkinson series. Nonetheless, drawing on the actual descriptions in the diary is useful to help contextualise conditions in the early record.

2.2.2 Independent comparison series

5 Eight independent datasets consisting of observational and proxy records are also employed:

The Central England Lake District (CELD) precipitation series: Barker et al. (2004) developed a 200-year homogenous monthly composite series for the Central England Lake District (CELD) (1788- 2016). Available stations were bridged to Grasmere High Close using regression to develop seasonal adjustment factors. Much of the pre-1850 record is drawn from
10 sites at Kendall and Keswick. Neither are key stations in the development of EWR/EWP (although Kendall was used as a station for regression development by Wigley et al. (1984)). Wilby and Barker (2016) subsequently updated the CELD series with a further revision of adjustment factors undertaken in 2017.

Hoofddorp (1735-1973) (Hoof): Monthly precipitation data recorded for the Netherlands over the period 1735-1973
15 (Tabony, 1981; Slonosky, 2002), downloaded through the KNMI Climate Explorer website (<http://climexp.knmi.nl/>).

Central England Temperature (CET) record (Manley, G. 1974; Parker et al., 1992): Winter (DJF) temperature data coincident with IoI_1711 is used to assess consistency of rainfall, especially in winter given that warm winters tend to be associated with wet winters.

20

Cork annual rainfall totals (Cork):

In his list of rainfall records operating before 1780, Craddock (1976) cites a number of stations for Ireland including Derry (1711-1724), taken by Thomas Neve; Castle Dobbs, Antrim (1727), taken by A. Dobbs and annual totals for Cork (1738-1748) taken by Dr Timothy Tuckey. While the first two sources are used in the Jenkinson series, the latter for Cork is not.
25 Annual totals for Cork (south Ireland) were published by Wakefield (1812: 207) and transcribed here. Neither the exact gauge location nor the design of Tuckey's gauge is known.

Westerly Index (WI): Barriopedro et al. (2014) developed a monthly index of atmospheric circulation variability over the North Atlantic from 1685-2008. Their index is based on direct observations of wind direction from Royal Navy logbooks
30 from 1685-1850 provided by ship movements in the English Channel. After 1850, the CLIWOC v1.5 (Garcia-Herrera et al., 2005) and the ICOADS v2.1 (Worley et al., 2005) datasets for the same area are used. The so-called Westerly Index (WI) provides a measure of the persistence of westerly winds beneath the exit zone of the North Atlantic extratropical jet-stream (Wheeler et al., 2010). Before 1850, the WI contains only one record of wind direction (measured with a 32-point compass)

per day, with data available for 95 percent of days (Barriopedro et al., 2014). The monthly WI used here is defined as the percentage of days per month with prevailing wind from the west (i.e. blowing from between 225° and 315° from true north).

Paris London (PL) Index: Cornes et al. (2013) developed the Paris London index (1692-2004) as an indicator of the state of the NAO index. This index, developed from recovered and corrected mean sea level pressure (MSLP) data from the respective cities, provides a consistent measure of westerly air flow over northwest Europe. Full details of the construction of the PL index, together with a comparison with available NAO reconstructions, are provided by Cornes et al. (2013). Only seasons with no missing data in any constituent month were employed.

10 *London SLP (L-SLP)*: Cornes et al. (2012) present a 300-year (1692-2007) daily series of MSLP for the city of London. Digitised data were transcribed from multiple sources, quality controlled, corrected and homogenised to represent daily means of MSLP at standard modern-day conditions. Monthly values of MSLP are not reported when missing values exceed 20%. Here seasonal MSLP is only derived when all three months are reported.

15 *Southern England tree ring precipitation reconstruction (TR)*: Rinne et al. (2013) present a 400-year long (1613-2003), annually resolved May – August precipitation reconstruction for southern England developed from oxygen isotope measurements of tree ring cellulose in pedunculate oak (*Quercus robur*). Using these reconstructions (1613-1893) and instrumental data (1894-2003), their derived precipitation series has been shown to be robust back to at least 1697 – the first year of the oldest existing instrumental precipitation series in England (at Kew, see above).

20 **2.3 Quality assurance, variability and change**

The annual and seasonal IoI_1711 series were tested for evidence of step changes in the mean and for change in variance. Application of the Shapiro-Wilks test (Royston, 1982) confirms that the annual and seasonal series conform to a normal distribution. The Pettitt (1979) test and the Standard Normal Homogeneity Test (SNHT) for a single break (Alexandersson, 1986) were used to examine evidence for break points in the mean. Both tests are location specific (i.e. they identify likely year of break). Pettitt is an absolute, non-parametric test and being rank based is less sensitive to outliers. SNHT assumes the data are normally distributed. For all tests the null hypothesis (no change point in time series) against the alternative (an upward or downward change point in a given year) was tested at the 0.05 level.

To test for changes in variance the annual and seasonal series were split into three 100-year sections: 1711-1810, 1811-1910, and 1911-2010. As the winter series commences in 1712 each section was incremented one year (e.g. 1712-1811 and so on). While the F-test is widely used for testing differences in variance, it is extremely sensitive to assumptions of normality (Wang et al., 2008). This is also the case for the Bartlett's test (Bartlett, 1937). Here, application of the Shapiro Wilks test to each annual and seasonal 100-year section reveals a small number of series to be non-normal. Thus, we use Levene's test

which is less sensitive to departures from normality (Conover et al., 1981; Snedecor and Cochran, 1989: 252) to compare variances across each of the three 100-year sections. For all tests the null hypothesis (that each section has identical variance) against the alternative (at least one of the sections has a different variance) was tested at the 0.05 level.

5 All records were standardised (by mean and standard deviation) to the period 1900-1950 for visual comparison. To assess decadal variability and change, annual and seasonal [winter (DJF), spring (MAM), summer (JJA) and autumn (SON)] decadal moving averages were then computed for all long-term datasets. These years are common to all datasets and represent a period of good data coverage and quality. Decades are named according to their start year (i.e. 1950 denotes the ten years 1950-1959). The non-parametric Mann-Kendall (MK) test (Mann, 1945; Kendall, 1975) was used to detect
10 monotonic trends in seasonal and annual totals. The MK test statistic (Z_s) has mean of zero and variance of one. Positive (negative) Z_s indicates a positive (negative) trend in precipitation. The magnitude of Z_s indicates strength of the trend. Trend significance was assessed at the 0.05 level using a two-tailed test. The null hypothesis of no trend was rejected if $|Z_s| > 1.96$. Dependency of trends on the period of record was investigated by deriving MK Z_s for all possible start and end dates with a minimum of 30 years duration (e.g. Murphy et al., 2013; Hall et al., 2014).

15 3. Results

3.1 The IoI_1711 series

To derive the IoI_1711 series 1000 re-samples (with replacement) of long-term (100-year) AAR were drawn from the homogenised IoI_1850 series. These range between 1039 mm to 1120 mm, with a median of 1080 mm. Each re-sample was used to estimate the annual anomalies and subsequently monthly totals from the pre-1850 Jenkinson data. Figure 2 shows the
20 resultant IoI_1711 time-series annual and seasonal totals. The rest of our analysis is based on the IoI_1711 series calculated from the ensemble median.

Application of the Pettit test to the median annual series revealed no statistically significant step change in the mean at the 0.05 level. Evaluation of p-values reveals a significant change at the 0.1 level ($p = 0.053$) in 1922. Noone et al. (2016) found
25 significant breaks ($p < 0.1$) across many of the 25 stations comprising the IoI_1850 series in the early 1920s. Consistency in the timing of these breaks across stations, along with an absence of evidence from metadata describing widespread measurement changes across the island, suggests that this break is due to natural variability. The SNHT test reveals a significant step change in 1976 ($p = 0.027$). The timing of breaks is consistent with an increase in annual totals associated with a shift to a positive phase of the North Atlantic Oscillation around this time (Harrigan et al., 2014). Both tests also
30 reveal a significant upward step change in winter (1864; $p < 0.001$) and downward step change in summer (1855; $p = 0.015$). Neither step change is identified by Noone et al. (2016) for the IoI_1850 series given they occur so close to the start of that record.

Levene's test reveals no significant differences in variance between each of the three 100-year sections analysed for all four seasons. A significant difference ($p = 0.040$) in the variance of the three sections is noted in the annual series. Further investigation reveals that a statistically significant difference ($p = 0.016$) in the variance of annual precipitation totals is evident between the periods 1711-1810 and 1811-1910, with the 1700s (134.3mm) revealing a higher standard deviation than the 1800s (109.5 mm). However, neither section shows significant differences relative to 1911-2010 (standard deviation 114.6 mm).

3.2 Correlation of long records with IoI_1711

Table 4 shows the correlation of individual long-term series with IoI_1711 annual and seasonal totals for the period 1790-2000, the longest overlap between most stations. Note that there are missing data in some series (up to 27 years for Hoofddorp, which ends in 1973). EWP consistently shows the strongest correlation with IoI_1711. Annually, all long-term series show significant correlations with IoI_1711, with EWP ($r = 0.67$), CELD ($r = 0.58$) and Carlisle ($r = 0.52$) revealing strongest correlations ($p = 0.001$). L-SLP shows a modest negative correlation with IoI_1711 annual totals ($r = -0.46$), with weaker positive correlations evident for the PL-index ($r = 0.27$), the WI ($r = 0.41$) and L-NAO ($r = 0.21$). In winter, strongest correlations (all $r > 0.70$) with IoI_1711 are evident for EWP, Oxford and Kew. Indices representing westerly air flow show correlations with winter IoI_1711 ranging from $r = 0.51$ (PL Index) to $r = 0.37$ (L-NAO). In spring, strongest correlations are evident with EWP ($r = 0.73$), CELD ($r = 0.64$) and Carlisle ($r = 0.63$). L-SLP shows significant negative correlation ($r = -0.58$) while the WI shows a significant positive correlation ($r = 0.46$). For summer, strongest correlations are evident with EWP ($r = 0.75$) and L-SLP ($r = -0.71$). The latter indicates the regional influence of blocking on precipitation in summer. Similar, though slightly weaker correlations are evident for autumn.

Associations with selected series are further explored by examining moving 30-year correlations (Figure 3). For comparison, correlations of each variable with EWR/EWP are also included (red line in Figure 3). In winter, the similarity of correlations across both IoI_1711 and EWR/EWP together with the strong multi-decadal variability of correlations is striking. In the pre-1766 winter record, correlations with CET are stronger for IoI_1711 than EWR. Greatest disparity between IoI_1711 and EWR/EWP in winter is shown for correlations with L-SLP, with the latter showing strongest correlations. We also note a decrease in correlation strength of L-SLP with both IoI_1711 and EWR/EWP in the pre-1850 record. In summer, correlations show more variability and are typically weaker (with the exception of L-SLP) than in winter. For IoI_1711 correlations with L-NAO tend to be stronger than for EWR/EWP in the pre-1850 record. Correlations with WI decrease in the early summer record and large disparities between IoI_1711 and EWR are evident in the pre-1750 record. Both EWR/EWP and IoI_1711 show similar correlations with both the PL-index and L-SLP. For the latter, stronger correlations are evident with EWR/EWP throughout the record. Overall, the IoI_1711 series shows expected correlations with different

series and is largely in line with correlations for EWR/EWP. While there is some evidence some correlations weaken in the early series, this is not more so than for EWR/EWP.

3.3 Comparison of decadal variability

3.3.1 Annual

5 Figure 4a compares decadal moving averages for each long-term precipitation series. Strong agreement between all series is evident. In the pre-1766 record, EWR reveals the lowest decadal mean annual totals, consistent with concerns that EWR underestimates early totals (Jones and Briffa, 2006). In the IoI_1711 annual series the most recent decade (2006-2015) is the wettest. Indeed, the last 50 years has seen the most persistent period of decadal mean annual totals above the 1900-1950 mean. The driest decade in the IoI_1711 annual series was 1740-1749. The 1740s was also notably dry in the other long series covering this period. For instance, the 1740s was the driest decade on record for Spalding and second driest for Kew 10 (after 1893-1902). Although the 1740s were notably dry in the Hoofddorp series, decades commencing from the 1790s through to the early 1800s were even drier. Figure 4b plots the early annual totals from Cork taken by Dr T. Tuckey relative to the raw IoI_1711 annual totals. These data confirm that the 1740s were notably dry. In both series, 1740 was the driest year of the decade, followed by 1747. Indeed, in the entire IoI_1711 series, 1740 is the second driest year after 1788.

15 3.3.2 Winter (DJF)

Winters [DJF] are named by the year in which December falls, so that winter 1712, for example, comprises December 1712 together with January and February of 1713. Figure 5 plots decadal mean totals for all winter series standardised to the period 1900-1950. Consistency of all precipitation series (Figure 5a) from about 1790 onwards is noted. Prior to this there is divergence between the available precipitation series. Evident also is the long-term increasing trend in winter decadal mean 20 precipitation totals across all series. Despite this increasing trend, the decade 1730-1739 was the wettest in the IoI_1711 winter record. Other long-term UK precipitation series that extend back this far do not show a remarkably wet decade. However, the 1730s are well known for their exceptional warmth within the CET record, which we also note shows strong coherence with IoI_1711 throughout the record (Figure 5b). Additionally, the highest decadal value in the WI winter series is found for the 1730s and the winter L-NAO is in positive mode at this time also.

25

Table 5 provides the seasonal summaries of Rutty (1770) during the 1730s. Evident for winter is the description of each year as open (frost free) and warm. In 1733 reference is made to primroses and violets blooming at Christmas. The only frosty winter is noted in 1739. While winter 1730 is noted as dry, each subsequent winter in the decade (with the exception of 1737 and 1739) is described as wet, wet and windy, or wet and stormy, which is consistent with strong westerly flow. While a 30 number of independent series support the view that winters in the 1730s were remarkably wet in the IoI_1711 series, confidence is low in the winter decadal means from 1740 to 1785. Within the context of the entire series these decadal means

are exceptionally low with little evidence for such dry winter conditions in other long precipitation series. We note that decadal means in the CET record are cold during this time, which is consistent with a negative winter NAO and WI. While dry conditions would be expected under such winter dynamics, the deviation between CET and IoI_1711 decadal means is largest during this period. At this time, the record of Jenkinson et al. (1979) is dependent almost entirely on qualitative information from weather diaries. Despite being biased too dry, it is likely that the decade 1777-1786 was at least among the driest decades in the winter series. This is consistent with the driest winter decade in EWP (1776-1785) and Carlisle (1776-1785). The years 1781-1790 are also the driest winter decade in the Oxford record. From 1790 onwards confidence in the IoI_1711 winter record is strengthened by the high degree of consistency with all other series.

3.3.3 Spring

The pre-1850 IoI_1711 record shows substantial decadal variability (Figure 6). In IoI_1711 the wettest spring decade occurs at the beginning of the series (1715-1724), while the driest is 1831-1840. The latter is consistent with EWP (driest spring decade 1833-1842) and with Oxford (third driest decade 1831-1840). Figure 6a shows strong agreement in decadal totals throughout the record from 1740 across all precipitation series. Prior to the 1740s there are few sources for comparison. Nonetheless, there is good coherence between Spalding, EWR and IoI_1711 during this period. Strong agreement is also evident between the WI and IoI_1711. A positive WI index is commensurate with wet spring conditions during the earliest decades of the 1700s, at the turn of the 20th Century (1895-1910), during the 1950s and 1960s, and the last quarter of the 21st Century (from the mid-1970s). Conversely, a predominance of negative NAO conditions during 1715-1724 is inconsistent with reconstructed exceptionally wet spring conditions, although we note that negative NAO conditions can result in diverse climate patterns. Neither the PL index nor L-SLP series contain sufficient data for the period to place much confidence in the comparator series. Throughout the latter half of the 1700s spring decadal means are almost consistently below the 1900-1950 mean, consistent with persistent negative NAO conditions and negative WI for the period.

3.3.4 Summer

The main feature of the pre-1850 record is the persistence of wet summers throughout much of the latter half of the 18th Century (Figure 7). The 1750s (1750-1759) is the wettest IoI_1711 decade. Decadal mean totals for this period are also notably wet in other long-term precipitation series. For instance, 1767-1776 is wettest in the Kew series (although it should be noted that the period is not as wet and is less protracted at Kew relative to other long-term series). The years 1755-1764 mark the wettest summer decade in the Hoofddorp series. The mid-1750s were also exceptionally wet at Spalding, however, the 1870s were marginally wetter.

Figures 7b and 7c plot IoI_1711 summer decadal means for L-SLP alongside indicators of westerly flow (L-NAO, PL index and WI). The wet 1750s coincides with record low MSLP at London. Much of the latter half of the 18th Century is associated with strong westerly airflow, with a persistently positive summer NAO and markedly positive values for the PL index.

Unfortunately, the summer WI has a lot of missing data for this period. Table 6 shows the seasonal summaries provided by Rutty (1770) for the 1750s; with the exception of 1759 all are described as wet. Figure 7d compares IoI_1711 with Kew, Spalding and the Rinne et al. (2013) tree ring reconstructions for southern England for the months MJJA. The tree ring reconstructions are consistent with Kew in terms of the wetness of the period, although later decades are wetter (e.g. decades commencing 1836 and 1877), suggesting that southern England, while wet throughout the latter half of the 18th Century, was not as wet as other parts of the BI. The driest summer decade of the IoI_1711 series is recorded for 1968-1977.

3.3.5 Autumn

Autumn decadal means show strong coherence across all long-term precipitation series (Figure 8). Of note is the large decadal variability in autumn series prior to 1900, with high decadal mean totals prominent during 1750-1870. The wettest decade in the IoI_1711 autumn series is 1770-1779, which partly overlaps with the wettest at Carlisle (1766-1775), Oxford (1767-1776) and Spalding (1768-1777). The driest autumn decade in the IoI_1711 series is 1745-1754, which matches closely with Kew (1745-1754), Spalding (1748-1757) and the early EWR series (1748-1757). In autumn, there is a strong negative correlation with L-SLP ($r = -0.65$), with decadal totals for 1745-1754 commensurate with wet autumn conditions of the 1760s and 1770s. Furthermore, the driest autumn decade (1745-1754) coincides with anomalously high values for L-SLP at this time, adding confidence to this finding.

3.4 Monotonic trends in the IoI_1711 series

Trends in annual and seasonal totals for the IoI_1711 series were assessed for all possible start and end dates with a minimum record length of 30 years (Figure 9). The annual series shows a significant increasing trend, but only since 2000. Largest MK Zs values in the annual series are found for tests commencing before 1850. In winter, exceptionally large values are apparent for tests commencing prior to 1790. Significant increasing trends are also found for series commencing between 1790 and 1850. However, trends commencing post 1850 are insignificant, with weak increasing and decreasing trends apparent.

Trends in spring are marked by variability, with a lack of persistence in either trend magnitude or direction. Largest MK Zs values are found for tests commencing in the 1760s and 1770s. Series beginning after 1850 show weak increasing and decreasing trends. In summer, significant decreasing trends are found for series commencing before 1900. The most notable decreasing trends are found for series starting in the mid-1700s, consistent with wet summers during this period. It is evident that outside of the 1700s decreasing trends have only emerged as significant since the 1970s. For trends commencing post 1950 (the period of record with most digital data), significant increasing trends are found. These are likely an artefact of the short record and highlight that even 60 years of data can reveal trends unrepresentative of longer records. Finally, autumn is marked by weak and variable trends. Significant increasing trends are evident for tests commencing in the late 19th to early 20th Century, but do not persist.

4. Discussion

This paper develops a 305-year continuous rainfall series for the Island of Ireland that extends back to the late Maunder Minimum. The series was derived by merging previously unpublished work by Jenkinson et al. (1979) with the more recently derived and quality assured IoI rainfall of Noone et al. (2016). Given the variety of sources used (both observations and documentary sources), the changing number of contributing sources and stations, changing measurement apparatus and techniques, together with the difficulty in penetrating the full details of methods used by Jenkinson et al. (1979), the pre-1850 record must be treated with caution. For example, rain gauges in use during the 1700s and early 1800s were experimental and largely unrecognisable by modern standards. The gauge used by Thomas Neve in Derry is described as being 12 inches in diameter and fixed to the ridge of his house, draining through a funnel and tin pipe into a loft and collected by a large glass bottle (Dixon, 1959). Obviously such gauges would be prone to considerable under catch. Indeed, it was not until the pioneering work of G.J. Symons, documented in the British Rainfall series from 1860, that more widespread use of standardised gauges increases (Pedgley, 2002). Additionally, it is unclear whether Jenkinson et al. (1979) made allowances for the adoption of the Gregorian calendar, which resulted in an advance of 11 days in September 1752. Jones and Briffa (2006) state, in relation to EWR, that the lack of any major seasonal cycle in precipitation over the region minimises cause for concern over the calendar adjustment. Moreover, much of the IoI_1711 series during the 1700s is derived from weather diaries. While translating qualitative descriptions of weather into quantitative estimates of rainfall is useful for exploring variability, the actual rainfall totals must be treated as highly uncertain. Nonetheless, comparison with other long records helps to build confidence in the early record and identify aspects that need further investigation. Remarkably, for both spring and autumn, decadal mean totals from IoI_1711 show strong coherence with other long-term series throughout the full period of record. Thus, the following paragraphs distil confidence and directions for future work for the winter and summer series.

Confidence is low in the winter IoI_1711 series prior to 1790 when conditions are likely overly dry for the period 1740 to 1790. Much of this part of the record is informed by qualitative descriptions in weather diaries or data from the UK used to represent Irish rainfall. While confidence in actual rainfall totals is low, it is likely that much of this period was indeed very dry. Jones and Briffa (2006) highlight the exceptional cold and dryness of the early 1740s for the British-Irish Isles, with the impacts on Irish society and ‘The Forgotten Famine’ well documented by Dickson (1997) and Engler et al. (2013). The 1740s are noted as exceptionally dry in the IoI_1711 winter and annual series, while 1740 stands out as exceptionally dry in the early annual totals from Cork taken by Dr. Timothy Tucker.

The weather diary of Joshua Wight from Cork offers further insight into conditions of the 1750s. In his analysis of that diary, Tyrell (1995) notes the severe cold of winters during the years 1753-1756, and in particular the notably low frequency of wet days during the winter of 1754-1755, citing a higher frequency of northerly and easterly winds during the winter half year

(October to March) for this period, typically associated with fewer wet days and longer dry spells. Tyrell (1995) also notes the middle and high latitudes were strongly affected by volcanic activity during the 1750s, with Lamb's dust veil index for these latitudes peaking between 1753 and 1756, following the eruption of Katla in 1755-1756 (Tyrell, 1995).

5 While the 1740s are the driest decade in the IoI_1711 annual series, the years 1777-1786 mark the driest winter decade. Similar years are also driest in a number of long-term precipitation records in the UK (e.g. EWP (1776-1785), Carlisle (1776-1785), Oxford (1781-1790)). Additionally, this period is marked by relatively low values of the Westerly Index, strongly negative phase of the NAO Index and exceptional cold in the CET record, thus favouring reduced rainfall. The period is also coincident with the Laki eruption of 1783-1784, with winters following the eruption being amongst the most
10 severe on record in Europe and North America (Thordarson and Self, 2003). Rather than volcanic forcing, some have argued that the exceptional conditions of these years was due to natural variability related primarily to a combined negative phase of the NAO and an El Niño-Southern Oscillation (ENSO) warm event – similar to conditions during the cold and snowy European winter of 2009-10 (D'Arrigo et al., 2011). Still others have argued that a combination of volcanic forcing and natural variability may have played a role (Schmidt et al., 2012). Winter 1784-85 and 1785-86 both rank among the ten
15 driest winters in the entire IoI_1711 record and are also notable in the EWP series (1784-855 ranks in the top ten driest winters, with 1785-86 ranked as 13th driest for the period 1766-2016).

Within the IoI_1711 winter series the 1730s are identified as the wettest decade in the entire 305-year series. Rather than an individual year in the 1730s standing out as remarkable, the decade is notable for persistently wet conditions. Confidence in
20 the 1730s being exceptionally wet is heightened given concurrent and almost unprecedented warmth in the CET (Jones and Briffa, 2006), glacial advance throughout Scandinavia (Nesje et al., 2008), and notably enhanced westerly air flow (Bariopedro et al. 2015), all consistent with a wintertime NAO-type forcing. After 1790, when early Irish observations become available, IoI_1711 shows improved consistency with other long-term observational and proxy records. Indeed, when the Pettit and SNHT tests are applied to the winter series commencing in 1790, the step change previously identified in
25 1864 is no longer evident, pointing to the increase in available data and the overly dry nature of the pre-1790 record as the cause of the identified break. Rather, an upward step change is identified in 1909 (p-value = 0.002), with the same year associated with an upward step change in EWP (1766-2016) (p-value < 0.001). Consistency across both series suggests that this change point is due to climatic variability.

30 While summer decadal mean totals show strong coherence with other long-term records, a break in the mean is revealed in 1855. This break point towards the middle of the series likely reflects real climate non-stationarity; with exceptionally wet summers of the mid to late 1700s and very dry summers of the 1970s near the end of the record. However, it is also possible that the break is associated with increased data availability as George J. Symons formalised an early rainfall network for the island. The exceptional summer wetness of the IoI_1711 series in the mid-1700s is supported by oxygen isotope tree-ring

reconstructions for southern England (Rinne et al., 2013). The period is also noted as exceptionally wet in tree-ring reconstructions (based on tree-ring widths) by Wilson et al. (2013) who note the mid-1700s as among the five wettest 20-year periods since 950 AD for the months March-July in southern-central England. The Old World Drought Atlas (Cook et al., 2015) also identifies the mid-1700s as notably wet in the context of the last 1000 years. Relative to other long-term precipitation observations (e.g. at Kew), this wet period seems to be greater in magnitude and duration in the IoI_1711 series. In his analysis of Joshua Wight's diary, Tyrell (1995) highlights that summers of the mid-1750s were wetter than recent years, noting in particular that the number of wet days reported for summer 1756 were significantly higher than the average for the modern regime. Multiple lines of evidence thus add confidence to the very wet summers of this period in the IoI_1711 series.

10

The IoI_1711 series considerably extends our understanding of the rainfall regime of Ireland. Monotonic trends derived for the IoI_1711 series reveal large variability in both magnitude and direction, depending on the period of record assessed. Winter records commencing before the 1850s show statistically significant (0.05 level) increasing trends. Tests commencing between 1850 and 1900 show non-significant increasing trends. Non-significant decreasing trends are evident for tests commencing after 1900. It is thus evident that the finding of statistically significant increasing trends in winter rainfall is dependent on cold and dry conditions in the pre-1850 record. This is also the case for EWP (not shown). The early records in both IoI_1711 and EWP draw upon descriptions from weather diaries and early and experimental rain gauges that may be prone to undercatch, particularly during cold, snowy conditions. It is therefore possible that biases in measurement during cold conditions affect the magnitude and significance of trends in winter rainfall in long-term rainfall series. We intend to explore this potential temperature-dependent bias and potential influences on winter rainfall trends using physically-based models in a future study. Summer rainfall reveals statistically significant (0.05 level) decreasing trends, but only for tests commencing before the 1900s. Trends expressed in records that represent the typical availability of digitised data (i.e. 1940s onwards) reveal results that are unrepresentative of the long-term, thus illustrating; i) the importance of long records (Burt et al., 2016), and; ii) that monotonic linear trend models are insufficient as a descriptor of IoI rainfall change.

25

Finally, a novel aspect of this work has been the use of multiple long-term observational and proxy sources to help assess confidence in the early IoI_1711 series. A key challenge was identifying where circularity exists in comparing with other sources. This challenge was compounded by a lack of transparency on sources used in early records – particularly the EWR series used to calibrate the Jenkinson et al. (1979) data, and indeed the lack of detail on how exactly the Jenkinson series was calibrated. Such issues highlight the importance of carefully documenting data sources in the development of regional series. Unfortunately, this was not a strength of early attempts at developing regional rainfall series. Independent quality-assured series such as the CET, WI, L-SLP and the PL-index thus provide invaluable datasets for building confidence in long precipitation records in the region.

30

5. Conclusion

The IoI_1711 series presents valuable insights into the long-term rainfall regime of Ireland from the late Maunder Minimum to present. In particular, the series offers an opportunity to further investigate the effects of multiple different forcings (volcanic, solar, greenhouse gases) on the rainfall climatology of a sentinel location in Europe. Our analysis shows that decadal variability may be substantially larger than available digital records suggest. For spring, summer and autumn, strong coherence with other long-term observational and proxy series increases confidence in the derived record. The most recent decade (2006-2015) is identified as the wettest in the 300-year annual series. While confidence in the winter series is reduced prior to 1790, the early record presents compelling evidence of exceptionally dry (1777-1786) and wet (1730s) winters. The long record reveals statistically significant increasing trends in winter rainfall and statistically significant decreasing trends in summer rainfall. However, we caution that the former may be influenced by temperature-related biases in the early record. In all seasons, trends derived from the period with the most widely available digital records (i.e. 1940s onwards) are not representative of long-term trends. The continuous 305-year series developed here has many potential uses. These include a more comprehensive description of multi-decadal and multi-centennial rainfall variability in Ireland, contextualising contemporary weather extremes, and inferring the underlying drivers of climate variability and change in the region. In closing, priorities for future work to address uncertainties in the pre-1850 record include:

- Statistical and dynamical reconstruction of winter rainfall in the IoI_1711 and other long-term regional series using available independent observational sources and dynamical climate models. The Westerly Index, London Sea Level Pressure and the Central England Temperature Record show utility for this purpose given their strong correlation with regional winter rainfall.
- Unfortunately, oxygen isotope-based tree ring reconstructions for IoI are not yet available. Here we used reconstructions from southern England. A pilot study by Vallack et al. (2016) confirms the potential of developing a composite summer precipitation reconstruction from oak tree cores (*Quercus robur* and *Quercus petraea* L.) in Ireland. It is important that this work be pursued to interrogate the exceptionally wet summers of the mid-1700s identified here.
- Ireland has a rich history of weather observing, but much of the early data remains held in paper records. Future work should prioritise the digitisation of these data (e.g. Ryan et al. 2017) to maximise the utility of early observational records. There are also additional weather diaries held by Met Éireann that could help shed further light on the rainfall of the 1700s.

Acknowledgements

We thank Prof. Phil Jones for providing the EWR series, Prof. Dennis Wheeler for providing the Westerly Index and to Dr. Katja Rinne-Garmston for providing her tree precipitation reconstruction. C.M. was funded by the Irish Environmental
5 Protection Agency under grant no. 2014-CCRP-MS.16.

Years	Source	Description of the data	Reference
1711-1725	Derry, NW Ireland	Monthly and annual totals extracted from the weather diary of Thomas Neve.	Dixon (1959)
1711-1715	Crosby, NW England	Monthly and annual totals extracted from Nicholas Blundell's Diurnal. ⁽¹⁾	Blundell (1968,1970,1972)
1716-1717	Crosby, NW England	Monthly and annual totals extracted from Nicholas Blundell's Diurnal. ⁽¹⁾	Blundell (1968,1970,1972)
1718-1727	London, SE England	Monthly and annual totals extracted from Nicholas Blundell's Diurnal. ⁽¹⁾	Blundell (1968,1970,1972)
1726-1727	Antrim, NE Ireland	Monthly and annual totals.	Met Office
1716-1765	Dublin, E Ireland	Brief monthly and seasonal summaries extracted from a chronological history of the weather in Dublin 1716-65. ⁽²⁾	Rutty (1770)
1757-1839	NW England	Monthly and annual totals. Regional series used as a single Ireland station.	Met Office
1792-1839	SW Scotland	Monthly and annual totals. Regional series used as a single Ireland station.	Met Office
1757-1977	Scotland	Monthly and annual totals. For completeness data was combined with the Glasspoole series from 1868 onwards.	Met Office/Glasspoole (1925)
1792-1839	Dublin, E Ireland	Monthly and annual totals. Supplemented by MS data available from the Met Office.	Dixon (1953)
1813-1830	Kilkenny, SE Ireland	Monthly and annual totals.	Met Office
1823-1824	Dublin, E Ireland	Monthly and annual totals.	Met Office
1795-1801	Derry, NW Ireland	Monthly and annual totals.	Met Office
1814-1815	Belfast, NE Ireland	Monthly and annual totals.	Met Office
1818-1977	Belfast, NE Ireland	Monthly and annual totals.	Met Office
1836-1977	Armagh, NE Ireland	Monthly and annual totals.	Met Office
1825-1832	Cork, S Ireland	Monthly and annual totals.	Met Office
1836-1977	Cork, S Ireland	Monthly and annual totals.	Met Office
1833-1977	Sligo, NW Ireland	Monthly and annual totals.	Met Office
1840-1977	Ireland	Monthly and annual totals. Combined with the Glasspoole series from 1881 onwards.	Met Office/Glasspoole (1925)
1940-1945	United Kingdom	Annual rainfall maps (with percentage isopleths)	Met Office
1946-1948	Ireland	Annual rainfall maps (with percentage isopleths)	Irish Meteorological Service
1940-1948	Ireland	Monthly and annual totals recorded at ten long-term stations throughout Ireland (listed below*).	Tabony (1980)
1949-1977	Ireland	Monthly and annual totals recorded at various stations throughout Ireland.	Irish Meteorological Service

Table 1 Description of the data used to produce the Jenkinson series of monthly and annual rainfall, 1711-1977. Derived values were subsequently converted to internal percentages of the annual rainfall for each station. For both ⁽¹⁾ and ⁽²⁾ this was achieved using a ranking method to classify rainfall amounts (e.g. wet/dry). The frequency of the ranked events for each month was recorded. Using a comparable period of reference, internal percentages (per ‰) were assigned to the rankings to determine internal percentages for each year. *Markree, Valentia, Shannon, Birr, Dublin, Cork, Waterford, Armagh, Londonderry, Belfast

Cork Annual Totals (Cork) measured by Dr. T. Tuckey	1738-1748	Wakefield (1812)
A chronological history of the weather in Dublin 1716-1765 and associated pressure measurements for Dublin*	1716-1765	Dr. John Ruttly (1770); Dixon, F.E. (1962)

Table 2 List of data sources used for comparison with the reconstructed IoI_1711 series. Given are the full data set name and its abbreviation as used in the text and subsequent figures, the years for which data are available and the primary references for each dataset. An asterisk identifies series that are likely to be have a risk of circularity.

Region	Station	Observer	Years
Devon/Cornwall	Plymoth	Dr. J. Huxham	1725-1752
Devon/Cornwall	Penzance	Rev. W. Borlase	1759-1772
London	Crane Court	Mr F. Hauksbee	1725-1733 & 1744-1781
London	Tonbridge	Mr. J. Hooker	1734-1764
London	Lambeth	MS. Of G.J. Symons	1765-1769
London	Gravesend	Mr. J Hooker	1728-1733
East Anglia	Norwich	Mr. W. Arderon	1750-1762
East Midlands	Southwick (Oundle)	Mr. G. Lynn	1726-1741
East Midlands	Lyndon (Rutland)	Mr. T. Barker	1737-1798
Yorkshire	Hallifax	Dr. Nettleton	1725-1727
Yorkshire	Darlington	Mr. Forth	1734-1742
Yorkshire	Pickering	T. Robinson	1736-1749
Yorkshire	Malton	NA	1736-1741
Carlisle	Carlisle	Dr. J Carlyle	1757-1783
Notts and Derby	Chatsworth	Lord G. Cavendish	1761-1813
Liverpool Area	Hulme, Manchester	Mr. G. Lloyd	1765-1769

Table 3 List of rainfall stations recording in the UK for the years prior to the commencement of the contemporary EWP series (i.e. pre 1766) which would have been available to Nicholas and Glasspoole (1931) in constructing the EWR series. Stations are taken from those listed in Craddock (1976).

Year	Seasonal Summary
1730	The spring variable. Summer wet. Autumn variable. Winter open, mild and comparatively dry.
1731	A dry and cold spring, but concluded hot. A hot and dry summer. Autumn variable and sometimes windy. Winter wet and warm.
1732	Variable weather in the spring, the last month rainy. Summer moderately fair and dry. Autumn wet and windy. A wet, windy, stormy and warm winter.
1733	A very dry spring. A dry summer but ended wet and windy. A wet and windy autumn. A wet windy and very warm winter, as so in England. The primroses and violets were blooming at Christmas.
1734	The two first moths of spring very warm (and so for England) but followed by a cold and nipping May, which hurted the fruits and burnt the grass. A wet summer: much straw and little grain: grass plentiful in the uplands. Autumn variable. A wet, windy and generally mild winter. N.B. the state of the weather in England from Short's Chronological History of the Weather and Seasons agrees very nearly to ours. " From September 28th 1731, to June 12th 1734 it was mostly droughty, no general or great floods or rains, and the springs failed in most places: then June 12th 1734, began the long wet season, and continued mostly to February 2nd 1736, viz a year and eight months, after two years and nine months drought"
1735	Of the spring the two first months were pretty open; the succeeded by a cold and dry May. The summer cold and wet like winter. Autumn wet. Winter open. Abundance of moisture through the three seasons of summer, autumn and winter.
1736	This summer was as remarkable for heat as the preceding one had been for coldness and moisture. A mild spring for the most part, though not without some frost and changeable weather. One of the hottest summers that has been remembered. Autumn moderately fair and mild. Winter very open, wet and windy: little frost.
1737	Spring warm, and May excessively hot. Summer mostly fair, but great changes as to the temperature of the air. Some days excessively hot, others very cold, and August a winter like month. Autumn fair and mild. Winter open.
1738	Spring seasonable. Summer cold and wet, except July which was hot and dry. Autumn for the most part wet. Winter wet and stormy.
1739	Spring mostly cold. Summer very wet. Autumn variable. Winter frosty, after a long series of open winters.

Table 5 Seasonal weather summaries for each year in the 1730s derived from the weather diary of Dr John Rutty (1770).

Year	Seasonal Summary
1750	Spring cold, dry, and backward. Summer (excepting a few excessively hot days) cold, moist, and winter-like. Autumn variable, mild at the beginning, frosty after. Winter (except December, which was warm) exhibited a good deal of frost and snow.
1751	Spring cold. Summer wet. Autumn variable. Winter hazy and cloudy, little frost.
1752	Spring cold and dry, excepting a moist May. Summer extremely wet. Autumn moderate and dry. Winter frosty, with snow and frequent rains.
1753	Spring seasonable, excepting a wet March. Summer wet, not above one half summer-like. Autumn fair and dry, ending frosty. Winter rainy, and great floods with frosts interposed.
1754	Spring partly temperate, partly cold. Summer wet. Autumn fair and summer-like. Winter frosty.
1755	Spring wet. Summer wet. Autumn wet, except October. Winter wet.
1756	Spring variable, a cold and moist April. Summer very wet. Autumn variable. Winter frosty.
1757	Spring cold and backward. Summer generally cloudy and wet, except June, and a few days in July and August. Autumn mostly dry and summer like. Winter mostly mild and open.
1758	Spring cold and dry. Summer rainy for the most part. Autumn mostly dry and fair. Winter mild.
1759	The spring mostly fair and dry. The summer mostly fair, dry and warm. The autumn mostly fair and moderate. The winter variable, but more inclined to moisture.

Table 6 Seasonal weather summaries for each year in the 1750s taken from the weather diary of Dr John Rutt (1770).

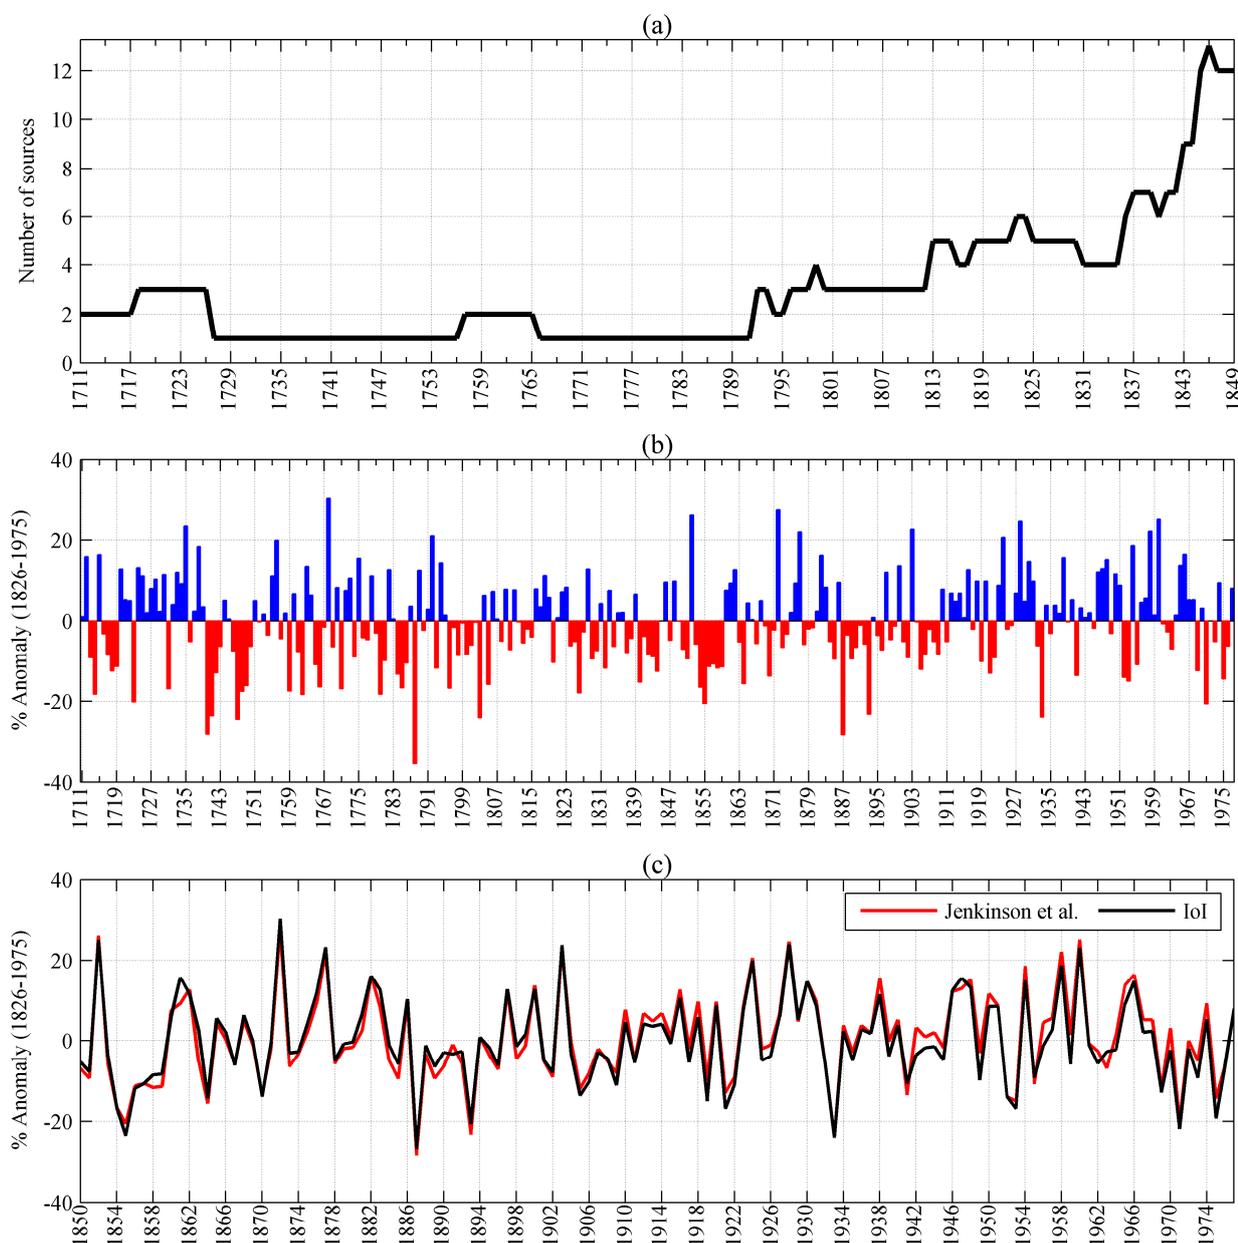

Figure 1 a). The number of constituent sources used to compile the Jenkinson data for the years 1711-1849; b). percentage annual rainfall anomalies (relative to the normal period 1826-1975) contained in Jenkinson et al. (1979) and c). comparison of b). with anomalies from IoI_1850 for years 1850-1977 (anomalies from 1850-1975 mean representing closest approximation of the Jenkinson et al. (1979) normal).

5

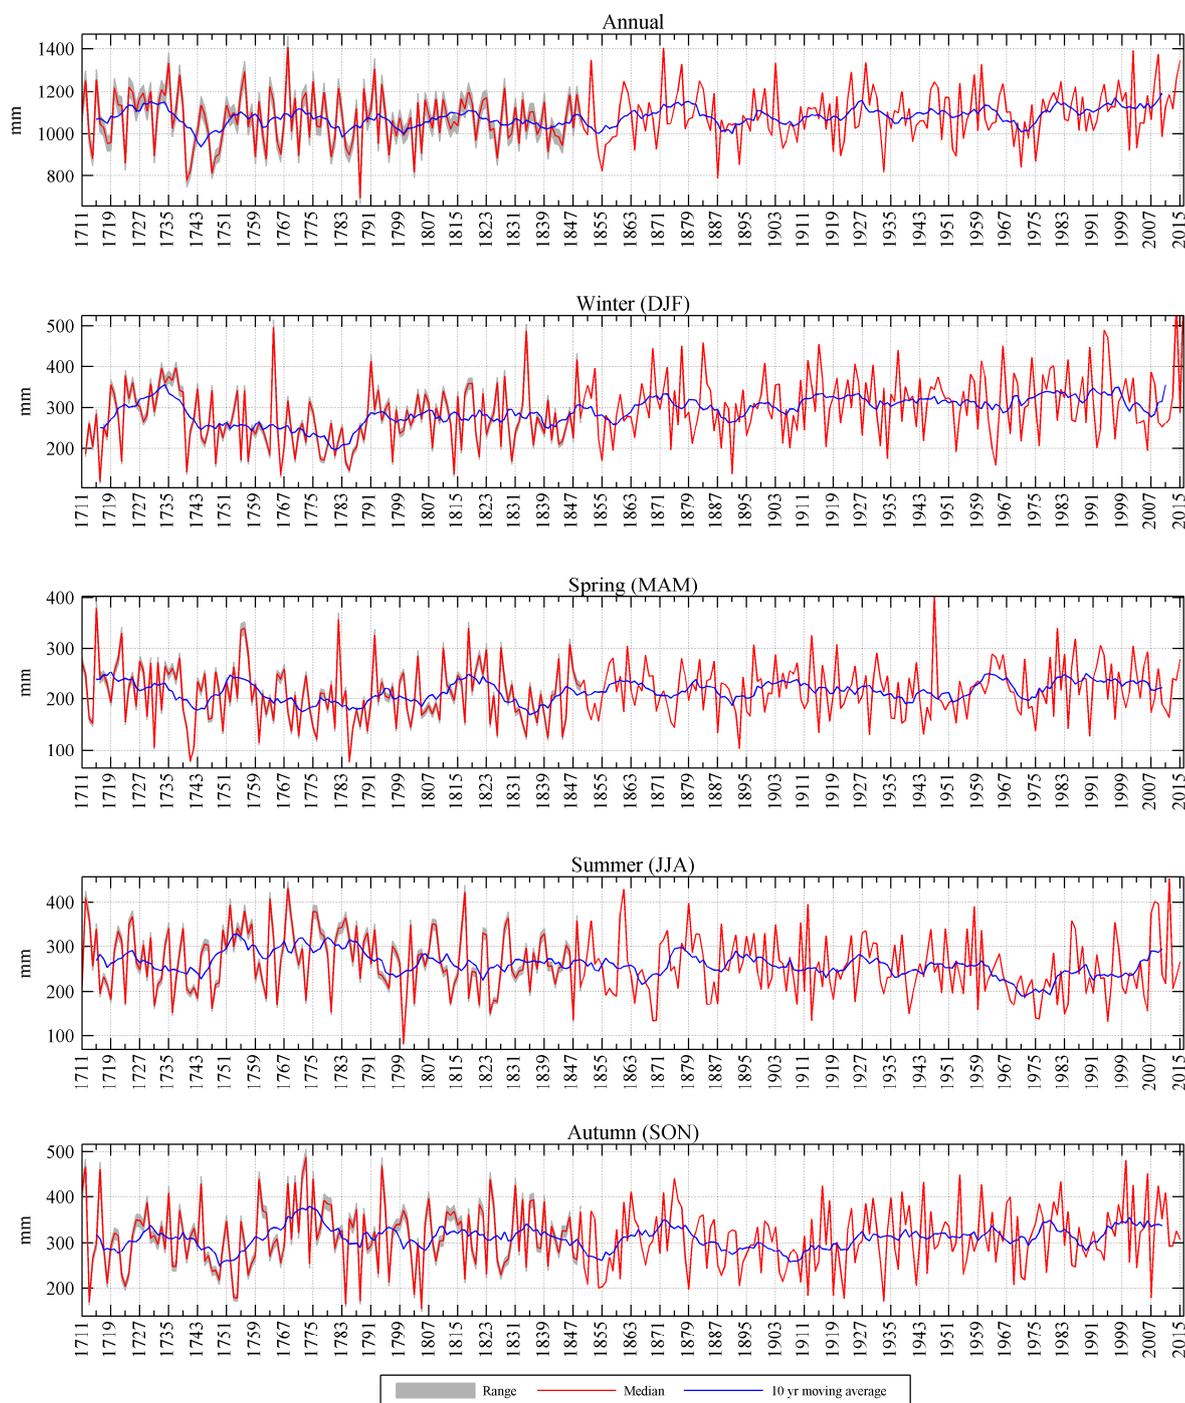

Figure 2 Reconstructed IoI_1711 precipitation series showing annual and seasonal totals. The grey shading shows the uncertainty in the reconstruction from resampling of the baseline used to derive AAR. The red line (used in subsequent analysis) is the median of the 1000 resamples. From 1850 onwards the data is the IoI_1850 series produced by Noone et al. (2016). The blue line represents a 10-year moving average.
