temperature

Abstract

Close coupling of Iberian hydroclimate and North Atlantic sea surface temperature (SST) during recent glacial periods has been identified through the analysis of marine sediment and pollen grains co-deposited on the Portuguese continental margin. While offering precisely correlatable records, these time series have lacked a directly-dated, site-specific record of continental Iberian climate spanning multiple glacial cycles as a point of comparison. Here we present a high-resolution, multi-proxy (growth dynamics and $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^{234}\text{U}$ values) stalagmite-based, composite record of hydroclimate from two caves in western Portugal across the majority of the last two glacial cycles (~230 ka). At orbital and millennial scales, stalagmite-based proxies for hydroclimate covaried with SST, with elevated $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^{234}\text{U}$ values and/or growth hiatuses indicating reduced effective moisture coincident with periods of lowered SST during major ice-rafted debris events, in agreement with changes in palynological reconstructions of continental climate. While in many cases the Portuguese stalagmite record can be scaled to SST, in some intervals the magnitudes of stalagmite isotopic shifts, and possibly hydroclimate, appear to have been decoupled from SST.

1. Introduction

The Portuguese continental margin is an important location for understanding variations in paleoceanographic conditions over orbital and millennial-scales (Hodell et al., 2013; Voelker and de Abreu, 2011). Here, marine sediments record basin-wide oceanographic signals while co-deposited pollen grains track coeval vegetation changes occurring across Iberia. Integrated analysis of these proxies has revealed a close coupling of North Atlantic SST, regional climate, and Iberian ecosystems during the last three glacial cycles, including changes in vegetation dynamics (Sánchez Goñi et al., 2002; Tzedakis et al., 2004; Roucoux et al., 2006; Martrat et al., 2007; Naughton et al., 2007; Sánchez Goñi et al., 2008), atmospheric circulation (Sánchez Goñi et al., 2013), and fire frequency (Daniau et al., 2007). One commonly applied palynological metric is the abundance of temperate tree pollen, which rises during warm and wet conditions associated both with interglacials and Greenland interstadials, concomitant with shifts in Iberian margin SST (Sánchez Goñi et al., 2002; Tzedakis et al., 2004; Combourieu-Nebout et al., 2009; Fletcher et al., 2010; Chabaud et al., 2014). However, the nature of such land-sea connections is partially obscured by the size of catchments from which the pollen are derived, with some

reaching into central Iberia and spanning a range of environmental settings subject to varying climatic influences (Martin-Vide and Lopez-Bustins, 2006; Naughton et al., 2007) (Fig. 1).

Testing the links between terrestrial and marine systems benefits from continental climate archives that provide precisely-dated and high resolution rainfall-sensitive time series spanning tens of millennia, but such records remain rare in Iberia, particularly near the west Iberian margin (Fletcher et al., 2010; Moreno et al., 2012; Stoll et al., 2013). Here we present a composite stalagmite record of four proxies for hydroclimate – growth dynamics and $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^{234}\text{U}$ values – spanning the majority of the last and penultimate glacial cycles (~230 ka) at two cave sites in western Portugal. These time series offers a rare, site-specific continental record capable of examining the coherence of SST controls on Iberian climate and ecosystem dynamics across glacial and interglacial periods. The new record provides a continental perspective of hydroclimate dynamics linked to regional oceanographic conditions.

2. Samples and Regional Setting

2.1 Environmental Setting

We report the analysis of five stalagmites (BG41, BG66, BG67, BG611, BG6LR) from Buraca Gloriosa (BG; 39°32'N, 08°47'W; 420 m a.s.l.) and one stalagmite (GCL6) from Gruta do Casal da Lebre (GCL; 39°18'N, 9°16'W; 130 m a.s.l.), two caves in western Portugal (Fig. 1). Environmental conditions in BG and GCL are well suited for speleothem paleoclimate reconstruction (see below). BG and GCL are located within the Meso-Mediterranean bioclimatic zone that dominates much of Iberia (Fig. 1). This region is characterized by strong seasonality, with warm, dry summers and cool, wet winters (Fig. 2) associated with the winter westerlies (Blanco Castro et al., 1997). In contrast, the Atlantic zone, north of the Douro River, is cooler, wetter, and less strongly seasonal. In the Pleistocene, the transition between these zones likely shifted southward with Mediterranean-type vegetation restricted to refugia (Rey Benayas and Scheiner, 2002).

Over interannual scales, the hydroclimate of Iberia is tightly coupled with the winter North Atlantic Oscillation (NAO) (Fig. 3), an atmospheric dipole that strongly influences precipitation across much of western Europe and that more broadly reflects the strength and positioning of the Azores high pressure system, which steers storm tracks contained within the westerlies into or north of Iberia (e.g., Trigo et al, 2002; Paredes et al., 2006; Trouet et al., 2009;

Cortesi et al., 2014). The NAO is typically measured as the NAO index, which is calculated using atmospheric pressure differences between Iceland and Lisbon (or the Azores) (Barnston and Livezey, 1987). The nature of the influence of the NAO varies across Iberia, but it is strongly correlated to rainfall in western Portugal (Fig. 3), with a positive NAO index associated with a steeper pressure gradient and elevated Iberian aridity. Iberian precipitation has also been linked closely to SST in regions ranging from the western North Atlantic to the Iberian margin (Lorenzo et al., 2010) where ocean circulation is dominated by the southward-flowing Portugal Current and the near-coastal and north-flowing Iberian Poleward Current, two systems that transport pollen from river mouths along the continental shelf (Fig. 1).

2.2 Cave Settings

Buraca Gloriosa cave is located near the town of Alvados, 30 km from the Atlantic Ocean, and within middle Jurassic limestones of the Estremadura Limestone Massif (Rodrigues and Fonseca, 2010), a topographically distinct region in central Portugal (Fig. 1). The ~35 m-long cave is accessed through a single, small (~0.5 m²) entrance at the top of a collapse at the base of a 30 m-high escarpment (Fig. 4). The cave is well decorated although little active growth is occurring today. Vegetation above the cave is primarily shrubs, small trees, and mosses, hosted by a thin (< 10 cm) and highly organic soil layer.

Gruta do Casal da Lebre is located ~5 km from the coastal town of Peniche in upper Jurassic limestones. The cave is 130 m long and contains a single, one m² entrance that opens onto a 7 m vertical shaft (Fig. 4). This entrance has been closed with a solid metal door in recent decades in order limit access to the cave, and this modification likely has reduced air exchange in the GCL relative to its original state. Like BG, GCL hosts little active calcite deposition, but contains numerous fossil stalagmites and stalactites. The vegetation over the cave has been replaced in recent decades by stands of eucalyptus that grow in thin (<1-5 cm), clay-rich soils.

2.3 Pollen Sources

Pollen deposited on the west Iberian margin are sourced primarily from vegetation inhabiting the watersheds of the major west-flowing stream systems draining Portugal and Spain, which are (from north to south) the Douro, Tagus, and Sado rivers. The areas encompassed by these streams are large (79,000, 81,000, and 7,650 km², respectively) and span a variety of

elevations. The Tagus and Sado are primarily responsible for pollen deposited southwest of Portugal, while the Douro plays an important role in delivering pollen to the more northwesterly sites (Fig. 1). Prevailing wind patterns likely prevent substantial transport of pollen from Iberia to the western Portuguese margin (Naughton et al., 2007). The pollen data presented here were measured in three closely spaced cores from the southwest Iberian margin (MD01-2443: 250-194 ka (Roucoux et al, 2006; Tzedakis et al., 2004); MD01-2444: 193-136 ka (Margari et al., 2010; Margari et al., 2014); MD95-2042: 141-1 ka (Sánchez Goñi et al., 2008; Sánchez Goñi et al., 2013) (Fig. 1) and are integrated here into a single time series.

3. Materials and Methods

3.1 Environmental Monitoring

Environmental conditions were measured at both cave sites over a multi-year period, with data measured in two-hour intervals near the areas where the stalagmites were deposited. Temperature and relative humidity were obtained using HOBO U23 automated sensors while barometric pressure was recorded with HOBO U20L loggers. Drip rates were monitored at BG with Stalagmate acoustic drip counters (Collister and Matthey, 2008), which were installed at the rear of the cave.

3.2 Uranium-Series Dating

Stalagmite chronologies were constructed with a total of 72 ^{230}Th dates obtained at the University of New Mexico (Table 1) using the methods of Asmerom et al. (2010). For dating of stalagmite carbonate, powders ranging from 100-200 mg were transferred into 30 ml Teflon beakers, weighed, dissolved in 15N nitric acid, and then spiked with a mixed ^{229}Th - ^{233}U - ^{236}U tracer and processed using column chemistry methods. U and Th fractions were dissolved in 5 ml of 3% nitric acid and transferred to analysis tubes for measurement on a Thermo Neptune MC-ICP-MS. U and Th isotopic ratios were aspirated into the Neptune using a Cetac Aridus II low flow desolvating nebulizer and run as static routines. All isotopes of interest were measured in Faraday cups, except for ^{234}U and ^{230}Th , which were measured in the secondary electron multiplier (SEM). Gains between the SEM and the Faraday cups were determined using standard solutions of NBL-112 for U and an in-house ^{230}Th - ^{229}Th standard for Th that was measured after

every fifth sample; chemistry blanks reveal U and Th blanks below 20 pg. Ages are reported using two standard deviation errors and are relative to the year AD 1950.

For BG stalagmites, corrections were made for unsupported ^{230}Th using a $^{230}\text{Th}/^{232}\text{Th}$ ratio of 13.5 ppm ($\pm 50\%$), a value determined from isotopic analysis of cave dripwater. To obtain this value, 108 ml of dripwater were transferred into six 30 ml Teflon beakers. These beakers were fluxed in 6N HCl for an hour, rinsed, and heated gently on a hotplate until approximately 1-2 ml of fluid remained in each. All solutions were then combined into a single 30 ml Teflon beaker, spiked with the same tracer described above (which contains HF), fluxed, and then taken to complete dryness. The resulting precipitate was dissolved with 15N HNO₃, dried down, and dissolved again in 7N nitric acid, and processed with the same column chemistry methods used for the stalagmite samples. We lack independent constraints on the initial Th ratio for the GCL stalagmite, and thus apply the default value of 4.4 ppm ($\pm 50\%$). This difference in the initial Th ratio impacts the corrected ages of GCL6 by 0.5-3.0 kyr, and thus does not meaningfully impact our interpretations.

Age models were developed via multiple polynomial interpolations between dated intervals using the COPRA age modeling software (Breitenbach et al., 2012) (Fig. 5). Aside from providing age models, COPRA also yields mean modeled stable isotope values and confidence intervals (Supp. Fig. S1 and S2). Here we rely primarily here on the original $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values because COPRA-derived median values reflect statistically robust variations, but reduce to some degree the range of isotopic variability. For COPRA, a dummy age was included in the age model for BG41 in order to extrapolate below the hiatus, which is only possible with at least two dated points. The value of this dummy age was based on the assumption that it maintains a stratigraphically correct slope (i.e. higher sections of the stalagmite represent younger material). The dummy age was applied a conservative error, meaning that it was as large as possible without causing stratigraphic inversion with respect to the bounding ages.

3.3 Stable Isotope Ratios

A total of 1,510 stable isotope analyses were performed on calcite samples milled from the central axis of each stalagmite. After milling, powders were weighed ($\sim 200\text{ }\mu\text{g}$) and transferred to reaction vessels that were flushed with ultra-pure helium. Samples were then digested using $>100\%$ H₃PO₄ and equilibrated overnight (~ 16 hours) at 34°C before being

analyzed. Isotopic ratios were measured using a GasBench II with a CombiPal autosampler coupled to a Thermo Finnigan Delta Plus XL mass spectrometer at Iowa State University. A combination of internal and external standards was run after every fifth sample, as well as before and after each batch, in order to ensure reproducibility. Oxygen and carbon isotope ratios are presented in parts per mil (‰) relative to the Vienna Pee Dee Belemnite carbonate standard (VPDB). Average precision for both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses is better than $\pm 0.1\text{‰}$ (1σ).

For isotopic analyses of soil organic matter and vegetation collected from above the caves, samples were dried, crushed, and transferred to tin boats. Carbon isotopic ratios were measured using a Thermo Finnigan Delta Plus XL mass spectrometer in continuous flow mode coupled with a Costech Elemental Analyzer. Caffeine (IAEA-600), cellulose (IAEA-CH-3), and acetanilide (laboratory standard) isotopic standards yielded an average analytical uncertainty for carbon of $\pm 0.09\text{‰}$ 1σ (VPDB). Dripwater samples were measured using a Picarro L2130-i Isotopic Liquid Water Analyzer, with autosampler and ChemCorrect software. Each sample was measured six times, with only the last three injections used to determine isotopic values in order to minimize memory effects. Three reference standards (VSMOW, IAEA-OH-2, IAEA-OH-3) were used for regression-based isotopic corrections and to assign the data to the appropriate isotopic scale. Reference standards were measured at least once every five samples. The average analytical uncertainty for $\delta^{18}\text{O}$ measurements was $\pm 0.1\text{‰}$ 1σ (VSMOW).

3.4 Stalagmite Mineralogy and Fabrics

The calcite comprising the BG samples ranges across a variety of fabrics including a faster-growing, white, fibrous form and slower-growing, dense, clear structure (Fig. 6; Supp. Fig. S3). In some areas of two samples - BG6LR and BG67 - sharp changes between the two forms within the same growth horizons mark intervals of recrystallization. BG6LR, which grew discontinuously over much of the last glacial cycle, suffered from alteration of early and middle Holocene material, which was therefore excluded from this analysis. BG67 is characterized primarily by fibrous calcite that has been recrystallized to clear, dense calcite in a narrow band descending through its core. U/Th dates from the fibrous calcite on the margins of the growth surface reveal open system behavior and thus this portion of BG67 was excluded from discussion. A small amount of recrystallization is evident in portions of GCL6 but the consistency of U/Th dates, and the trends in stable isotopes suggest that this sample retains

reliable paleoclimatic information. Growth position changed at numerous times in several of these stalagmites, and our sampling strategy accounted for these changes so as to consistently collect samples for stable isotopic analysis from the top surface (cap) of each stalagmite rather than the margins.

4. Results

4.1 Environmental Monitoring

Temperature and relative humidity collected inside both caves document environmental conditions over a four-year period. Relative humidity remained stable at ~100% in both caves. Temperatures, while different at the two sites, exhibited similar seasonal variability that approximates the mean average temperature of the region ($14.2 \pm 0.4^\circ\text{C}$ at BG and $16.2 \pm 0.3^\circ\text{C}$ at GCL for August 2012-January 2018) (Fig. 7).

Dripwater was collected at BG both over the course of minutes during site visits on four separate occasions (November 2014, October 2015, March 2016, January 2018) and as months-long integrated samples. A total of 25 dripwater samples were analyzed for stable isotopic values. Dripwater $\delta^{18}\text{O}$ values range from -2.4‰ to -4.6‰, with a mean of $-3.8 \pm 0.8\text{‰}$ (Supp Table 1), although as the timing of site visits varied, this value clearly is impacted by seasonal controls on precipitation (and thus infiltration) oxygen isotope values. Drip rates were measured for much of the period spanning June 2014 to January 2018 (for a total of ~36 months) and exhibit seasonal variations tied to the winter wet and summer dry seasons, as well as individual rain events (Fig. 7).

4.2 U-Th Dates and Age Models

^{234}U - ^{230}Th dating of BG and GCL stalagmites reveals growth across approximately three quarters of the last 230 ka, with periods of deposition interrupted by numerous hiatuses of varying length, with the longest gaps from 160-147, 97-87, 72-60, 41-36, 32-30, and 17-15 ka (Fig. 5 and 6). These features, coupled with repeated changes in growth direction, complicate construction of a chronology in some intervals. Macroscopic petrographic discontinuities suggest the presence of several short-lived hiatuses, but these were included as gaps in the age models only where U/Th dates reveal an identifiable temporal offset. For example, the marine isotope stage (MIS) 6/5e boundary recorded by stalagmite BG67 is marked by both a change in drip

position and a sharp transition from dense, clear calcite to a white, fibrous form. Taken together, it is clear that a hiatus of some duration occurred at this time. However, these isotope data are presented as being uninterrupted given the continuity of $\delta^{18}\text{O}$ values and no U/Th evidence for a long-lived hiatus (Fig. 6).

4.3 Assessing Environmental Signals in Speleothem Isotopic Ratios

We used two approaches to assess the fidelity of BG/GCL carbon and oxygen isotopes as records of past environmental variability. First, Hendy Tests, in which stalagmite isotopic ratios must satisfy two criteria in order to be considered as having crystallized near isotopic equilibrium with cave dripwater (Hendy, 1971), were performed for each stalagmite. The first half of the Hendy Test involves analysis of multiple isotopic analyses performed on samples drilled at increasing distance from the central growth axis along the same series of growth layers. The conceptual justification for this approach is that dripwater, and thus calcite, $\delta^{18}\text{O}$ values should remain constant down the stalagmite flanks because ^{16}O preferentially lost to CO_2 outgassing is replenished by CO_2 hydration and hydroxylation reactions. Progressive ^{18}O enrichment associated with kinetic effects tied to Rayleigh distillation suggests isotopic disequilibrium. No such consistent trends toward elevated oxygen isotopic ratios are found (Fig. 8), and thus the BG/GCL stalagmites appear to satisfy the first criterion of the Hendy Test.

The second portion of the Hendy Test is based on the degree of covariation of carbon and oxygen isotopic ratios. Oxygen isotopic ratios of speleothem calcite reflect those of infiltrating fluids, which are generally close to the $\delta^{18}\text{O}$ values of meteoric precipitation, and which, in many locations, are linked to climate (air temperature, moisture source, seasonality of precipitation, or rainfall amount). Oxygen isotopic ratios in stalagmites primarily reflect the $\delta^{18}\text{O}$ value of effective precipitation, as only an extremely small proportion of oxygen in dripwater is contributed by dissolution of CO_2 or bedrock carbonate (Lachniet, 2009). Interpreting changes in oxygen isotope composition at BG/GCL during intervals of profound climatic change such as marked the last glacial period is complicated by the multiple factors that influenced $\delta^{18}\text{O}$ values of precipitation at these sites, including shifts in moisture source. The potential exists for rainfall in Iberia to be derived from atmospheric moisture sources that change on synoptic/seasonal scales (Moreno et al., 2014; Gimeno et al., 2010; Gimeno et al., 2012) as well as in response to changing glacial boundary conditions (Florineth and Schlüchter, 2000; Kuhlemann et al., 2008;

Luetscher et al., 2016). In addition, strong but opposite correlations exist in modern precipitation between rainwater $\delta^{18}\text{O}$ values and (i) the regional air temperature ($r=+0.8$) and (ii) rainfall amount ($r=-0.8$), both of which are related to the strong seasonality of precipitation associated with Meso-Mediterranean climates (IPMA, 2016).

Stalagmite $\delta^{13}\text{C}$ values reflect two primary inputs: CO_2 derived from the atmosphere and/or soil zone and bicarbonate derived from dissolution of bedrock carbonate. Speleothem $\delta^{13}\text{C}$ values reflect the type (C_3 vs C_4) and density of vegetation over the cave, both of which are impacted by changes in air temperature and/or precipitation. The average $\delta^{13}\text{C}$ value of biogenic CO_2 in the soil zone is tied to the ratio of plants utilizing the C_3 (average $\delta^{13}\text{C}$ -26‰) versus C_4 (average $\delta^{13}\text{C}$ -14‰) photosynthetic pathways (Deines, 1980; von Fischer et al., 2008). Similarly, vegetation density and soil respiration rates over the cave impact the relative contribution of atmospheric CO_2 (pre-Industrial $\delta^{13}\text{C}$ -6‰ to -7‰; Francey et al., 1999) as compared to soil-derived CO_2 (Hellstrom and McCulloch, 2000; Genty et al., 2003). Phanerozoic bedrock $\delta^{13}\text{C}$ values range from -4‰ to +8‰ (Saltzman and Thomas, 2012), but these values are static and do not contribute to temporal variability in stalagmite carbon isotopic ratios.

Superimposed on these inputs are secondary effects capable of influencing the $\delta^{13}\text{C}$ values of dripwater in the epikarst or cave. When voids in the bedrock are not fully saturated, CO_2 degassing from infiltrated water may occur in the epikarst. This preferential loss of $^{12}\text{CO}_2$ (that may result in crystallization of calcium carbonate – so-called prior calcite precipitation) enriches the residual solution in ^{13}C , a signal that can be transferred into underlying stalagmites (Baker et al., 1997). Once the solution enters the cave, equilibrium fractionation between dissolved carbon species may be disrupted owing to issues surrounding CO_2 -degassing under low drip rate conditions (Breitenbach et al., 2015) or by disequilibrium processes occurring during carbonate crystallization (Mickler et al., 2004; Fairchild et al., 2006). Importantly, $\delta^{13}\text{C}$ reflect local infiltration rather than (pan-)regional atmospheric conditions as in the case of $\delta^{18}\text{O}$. This difference between both proxies offers the opportunity to investigate environmental changes at different spatial scales.

Correlations between carbon and oxygen isotope ratios are presented in Figure 8. Three stalagmites – BG6LR, BG66, and BG67 – show strong correlations between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ ($r^2=0.6$), while the other three samples lack significant correlation. If one considers the second

criterion of the Hendy Test, the nature of equilibrium crystallization in stalagmites BG6LR, BG66, and BG67 would be considered suspect. It must be noted, however, that the reliability of the Hendy Test has been questioned because (1) equilibrium may be maintained in some portions of a stalagmite but not others, (2) growth layers thin progressively down the sides of the stalagmite, making it difficult to restrict samples to the same material, and (3) equilibrium covariation of carbon and oxygen isotope ratios may result as the direct or indirect result of climatic variability (Dorale and Liu, 2009; Lechleitner et al., 2017). We therefore interpret both isotope ratios and their covariation as environmental signals.

An additional test of equilibrium crystallization in the modern system can be constructed by comparing modeled stalagmite isotopic values to recently deposited calcite. The carbon isotopic composition of speleothem calcite is the result of a complex series of reactions that have been addressed in a number of studies (Hendy, 1971; Mühlinghaus et al., 2007; Dreybodd, 2008). For $\delta^{13}\text{C}$ in BG stalagmites, we use the equations of Li et al. (2014), which factor in the two primary sources of carbon – soil CO_2 and bedrock carbonate – the proportion of carbon derived from each source, and temperature-induced fractionation of carbon isotopes between dissolved carbon species:

$$\delta^{13}\text{C}_{\text{calcite}} = f_1 * [\delta^{13}\text{C}_{\text{ls}} - (\delta^{13}\text{C}_{\text{CO}_2(\text{g})} + 9.48 \times 10^3 / T - 23.89)] + \delta^{13}\text{C}_{\text{CO}_2(\text{g})} + 9.48 \times 10^3 / T + 0.049T - 37.72$$

where: f_1 = fraction of bicarbonate from limestone

ls = limestone

T = temperature ($^{\circ}\text{K}$)

We assume the most straightforward and simple situation: the system remains closed to soil CO_2 and bedrock carbonate contributes 50% of carbon to dripwater bicarbonate ($f_1=0.5$). We apply the average cave temperature of 14.4°C and the measured $\delta^{13}\text{C}$ values of BG bedrock and the overlying vegetation/soil of $+3 \pm 1\text{‰}$ and $-28 \pm 1\text{‰}$, respectively. This approach, while certainly overly simplified for the BG system, yields modeled stalagmite $\delta^{13}\text{C}$ values of $-7.7 \pm 1\text{‰}$, similar to calcite crystallized on two glass slides installed at the site of two actively growing stalagmites in the loft area of BG, which yielded $\delta^{13}\text{C}$ values of $-8.4 \pm 1.2\text{‰}$.

Oxygen isotopic ratios were modeled using the paleotemperature equation of Kim and O'Neil (1997), which requires measurements of cave temperature and dripwater $\delta^{18}\text{O}$ values. The modeled $\delta^{18}\text{O}$ value of $-3.1 \pm 1.0\text{‰}$ is nearly identical to the glass plate calcite value of $-3.0 \pm 0.6\text{‰}$. It should be noted, however, that assessing equilibrium crystallization in modern calcite/dripwater pairs at BG is complicated by the low temporal resolution associated with integrated, months-long dripwater samples, variable timing of dripwater collecting trips, and any seasonal biases in calcite crystallization that at present remain poorly constrained.

Replication between stalagmites of similar age is arguably the single most reliable method for evaluating the impacts of climate versus secondary influences, including evaporation and kinetic effects (Denniston et al., 1999; Mickler et al., 2004), on stalagmite isotopic ratios (Dorale and Liu, 2009; Denniston et al., 2013). When presented as an integrated data set, the BG/GCL stalagmite carbon and oxygen isotopic time series spans the majority of the last 230 ka (Fig. 9), although stalagmites spanning the same periods of time are restricted to 187-185, 111-104, 83-81, 78-73, and 58-53 ka. Because these intervals are short, and because the temporal resolution varies substantially between stalagmites, replication tests based on these intervals are of limited utility. Within the age uncertainties, $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values and trends are similar, suggesting that oxygen and carbon isotopic ratios track environmental, rather than drip-specific, variables. The three exceptions in which coeval samples do not replicate well are: $\delta^{13}\text{C}$ values offset by 3‰ from 83-81 ka and by 4‰ from 58-53 ka, and $\delta^{18}\text{O}$ values offset by 1‰ from 111-104 ka (Fig. 9; Supp. Fig. S4).

4.4 Hydroclimate Proxies

4.4.1 Carbon Isotopes

Interpreting speleothem $\delta^{13}\text{C}$ variability in a climatic context requires understanding, or at least constraining, the origins of these isotopic shifts. Terrestrial deposits preserving pollen spectra spanning substantial portions of the last glacial cycle from western Iberia are rare (Gómez-Orellana et al., 2008; Fletcher et al., 2010; Moreno et al., 2012), and thus pollen in marine sediments represents a particularly important continental climate record. Pollen samples obtained from the Iberian margin contain small percentages of *Poaceae*, the family including the majority of C_4 plants, demonstrating a persistent and overwhelming majority of C_3 (largely shrub and arboreal) vegetation throughout the last glacial cycle including between Greenland stadials

(GS) and interstadials (GI) and across Heinrich stadials (HS) (d'Errico and Sánchez Goñi, 2003; Tzedakis et al., 2004; Desprat et al., 2006; Sánchez Goñi et al., 2008; Sánchez Goñi et al., 2013; Margari et al., 2014). In the absence of changes in vegetation type, shifts in the source of carbon found in cave dripwater therefore likely originated with the density of vegetation and/or soil respiration rates (Genty et al., 2003). Reductions in these values are generally associated with decreases in temperature and/or increases in aridity, such as have been inferred from Iberian pollen spectra to have characterized Iberia during GS, HS, and glacial maxima (Sánchez Goñi et al., 2008; Margari et al., 2014). Complementing these effects are increases in the contribution of bedrock carbon, as well as prior calcite precipitation, reflecting a combination of longer residence times of infiltrating solutions and desaturation of voids in the epikarst above the cave, both of which are consistent with more arid climates (Baker et al., 1997; Genty et al., 2003). Thus, we interpret the carbon isotopic values of the BG/GCL record as primarily a local (hydro)climate proxy, with higher $\delta^{13}\text{C}$ values indicative of a cooler, drier climate. Integrating the GCL6 $\delta^{13}\text{C}$ record into the BG time series is complicated by the slightly different bedrock $\delta^{13}\text{C}$ values of the host rocks (Supp. Table 1) and what may have been distinct vegetation types and cave hydrologies at each cave when GCL6 was being deposited (187-160 ka). However, as previously discussed, the similar $\delta^{13}\text{C}$ values during their period of overlap (187-185 ka) suggests that the two records can be consolidated.

4.4.2 Oxygen Isotopes

The origins of BG/GCL isotopic variability appear more complex for oxygen than for carbon. Like $\delta^{13}\text{C}$ values, local $\delta^{18}\text{O}$ minima mark interstadials and interglacials. Analysis of modern precipitation data reveals equally strong, albeit inverse, correlations between precipitation $\delta^{18}\text{O}$ and both amount ($r=-0.8$) and air temperature ($r=+0.8$) effects, likely owing to the dominance of cool season precipitation in annual water budgets (IAEA/WMO, 2016) (Fig. 2). Based on these relationships, it remains possible that changes in air temperature, overall precipitation, and/or precipitation seasonality could impact the $\delta^{18}\text{O}$ values of effective moisture. That air temperature is likely not a prominent driver of oxygen isotopic variability is supported by two observations, however. First, the slope of the air temperature/ $\delta^{18}\text{O}$ relationship ($+0.2\text{‰}/^{\circ}\text{C}$) is nearly identical, but opposite in sign, to the calcite-water temperature dependence of oxygen isotopic fractionation ($-0.2\text{‰}/^{\circ}\text{C}$) (Kim and O'Neil, 1997). In the simplest sense,

therefore, a 1°C increase in mean annual air temperature (and thus also cave temperature) would increase precipitation $\delta^{18}\text{O}$ values by approximately the same amount that the water temperature effect would lower stalagmite calcite $\delta^{18}\text{O}$ values. In this simplified scenario, the net effect is a stalagmite record that is negligibly influenced by temperature changes alone. Secondly, the observed shift toward lower stalagmite $\delta^{18}\text{O}$ values during interstadials and interglacials, periods of elevated mean annual temperature, demonstrates that the observed positive correlation between precipitation $\delta^{18}\text{O}$ and air temperature is not a dominant feature over millennial time scales. For example, the 3.5‰ decrease in $\delta^{18}\text{O}$ values between MIS 6 and MIS 5e (136-128 ka) (Fig. 9) can be only partially accounted for by the ~1‰ ice volume-related decrease in North Atlantic surface water $\delta^{18}\text{O}$ values (Schrag et al., 1996). Other factors such as kinetics associated with humidity and wind speed at the point of evaporation (Grootes et al., 1993), temperature and source of atmospheric moisture (Herbert et al., 2001), and cloud evolutionary pathways (Rozanski and Araguás, 1995) need also be considered but cannot account for the entirety of this shift. Because of the narrow continental shelf in central Portugal, the LGM shoreline was located close to the modern shoreline, thereby minimizing continental effects, and the magnitude of the impacts of wind speed and ocean temperature do not appear sufficient to account for the observed stalagmite $\delta^{18}\text{O}$ variability. Thus, the decrease in stalagmite $\delta^{18}\text{O}$ between the penultimate glacial and last interglacial suggests that stalagmite oxygen isotope ratios are primarily recording (pan-)regional hydroclimate rather than temperature.

4.4.3 $\delta^{234}\text{U}$ Values

$\delta^{234}\text{U}$ values (calculated as the difference between the age-corrected $^{234}\text{U}/^{238}\text{U}$ ratio of a sample and the secular equilibrium $^{234}\text{U}/^{238}\text{U}$ ratio) of speleothem carbonate has also been used as a proxy for paleoprecipitation (Hellstrom and McCulloch, 2000; Oster et al., 2012; Plagnes et al., 2002; Polyak et al., 2012; Zhou et al., 2005). ^{234}U exists in the stalagmite crystalline lattice due to incorporation from cave dripwater and through *in situ* production from decay of ^{238}U . Alpha recoil displaces ^{234}U from its lattice position, increasing its susceptibility to leaching by infiltrating waters, meaning that ^{234}U is selectively mobilized relative to ^{238}U in cave dripwater (Chabaux et al., 2003; Oster et al., 2012). The flux of infiltrating fluids is therefore tied to $\delta^{234}\text{U}$ values of dripwater, and thus stalagmite carbonate such that decreases in effective precipitation

and/or bedrock dissolution rate, both of which are tied to increased aridity, are associated with elevated speleothem $\delta^{234}\text{U}$ values (Hellstrom and McCulloch, 2000; Plagnes et al., 2002; Polyak et al., 2012).

As differences in $\delta^{234}\text{U}$ values between stalagmites may arise from distinct infiltration pathways (Zhou et al., 2005), complicating the integration of $\delta^{234}\text{U}$ values from multiple stalagmites into a single, cohesive data set, we restrict our analysis to stalagmite BG6LR, which represents the longest individual stalagmite record of the BG/GCL time series. While the number of $\delta^{234}\text{U}$ measurements is small compared to stable isotopic values, the temporal density of the former is sufficient to demonstrate the utility of $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values as paleohydroclimate proxies (Fig. 9). Decreased precipitation/effective moisture is associated with elevated stalagmite $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and $\delta^{234}\text{U}$ values. The relationships between $\delta^{13}\text{C}$ and $\delta^{234}\text{U}$ values in all BG and GCL stalagmites are presented in Supp. Fig. S5.

5. Environmental Conditions at BG/GCL and Links to Iberian Margin SST

The previously discussed tests for isotopic equilibrium, including the reproducibility of carbon and oxygen isotope ratios between coeval BG and GCL stalagmites, support the notion that their $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values may be integrated into cohesive time series reflecting paleohydroclimatic conditions and used to assess links between continental climate and SST (Fig. 10). Over the last several glacial cycles, oceanographic conditions along the western Iberian margin varied at millennial and orbital time scales in close correlation with Greenland air temperature and North Atlantic conditions and circulation (Roucoux et al., 2005; Danialu et al., 2007; Sánchez Goñi et al., 2008; Darfeuille et al., 2016). Abrupt changes in SST reflect a balance between southward expansion of subpolar waters and northward migration of subtropical water masses (de Abreu et al., 2003). During the particularly cold conditions characterizing HS and GS, Iberian margin SST decreased by up to 9°C (to as much as 13°C below present values; de Abreu et al., 2003), with these changes helping to position the arctic or subarctic front at ~39°N, the same latitude as BG and GCL. These cold surface waters reduced the production and transport of atmospheric moisture to Iberia (Eynaud et al., 2009; Voelker and de Abreu, 2011), and would have thereby influenced the timing of speleothem growth and carbon and oxygen isotopic values in BG and GCL stalagmites. Indeed, the composite BG/GCL record documents coherence, at both orbital and millennial scales, between Portuguese hydroclimate, vegetation,

and Iberian margin SST during the last two glacial cycles (Fig. 10 and 11). In an attempt to quantify this covariance, we binned the SST and stalagmite stable isotope data into century-long intervals. The relatively short record of BG41 was not included, and model ages for stalagmites BG66 and GLC6 were increased by 4.0 kyr and 1.3 kyr, respectively, to improve correlation with the SST chronology. The resulting inverse correlation between SST and carbon and oxygen is strong ($r=-0.55$ and -0.52 , respectively; $p<0.0001$) (Supp. Fig. S6).

5.1 Growth Intervals

The single most fundamental prerequisite to speleothem deposition is infiltration of surface waters, and thus the timing of stalagmite growth can reflect changes in mean hydroclimatic state. Deposition of multiple BG stalagmites was punctuated by hiatuses spanning similar time intervals (although the precise ages of the onset and/or termination of the hiatuses are distinct), a relationship that suggests links to changes in hydroclimate rather than random drip site-specific variability.

Hiatuses in some BG samples coincide with HS1, HS3, HS4, and HS6, and pollen spectra independently suggest increased aridity during HS and glacial maxima. Decreases in arboreal pollen abundance and concomitant increases in drought-tolerant vegetation coincide with periods of reduced SST. Vegetation patterns during maximal IRD deposition on the Iberian margin reveal not only dramatically reduced forest cover but also a pronounced expansion of semi-desert plants (e.g. Sánchez Goñi et al., 2000; Roucoux et al., 2005; Naughton et al., 2009). These changes mark the long hiatus between HS7 and HS6 (71-59 ka), which overlaps with the some of the coldest SST of the last 70 ka as reconstructed using U_{37}^k at core MD95-2042 (Darfeuil et al., 2016) (Fig. 10; Fig. 12). An absence in BG stalagmite deposition from ~160-149 ka occurs at the same time as massive seasonal discharges from the Fleuve Manche river and the coldest continental climates and SST (157-154 ka) of the last 230 ka, as determined from pollen and foraminifera from core MD01-2444 (Margari et al., 2014; Fig. 1).

Whether hiatuses in BG speleothem deposition are a result of pronounced reductions in precipitation, an extension of below freezing temperatures that limited infiltration (Vaks et al., 2013; Fankhauser et al., 2016), or variations in infiltration pathway/drip position is ambiguous. Pollen transfer functions from MD95-2042 suggest winter temperatures dropped below 0°C during HS and annual precipitation was reduced by up to 50% (from 800 mm to 500-400 mm

during HS3, HS4, and HS5) (Sánchez Goñi et al., 2002). Applying this temperature reconstruction to western Portugal is complicated, however, by the broad area across which these pollen were sourced. Permafrost reconstructions (Vandenberghe et al., 2014) of Iberia argue against the hypothesis that continuous sub-zero temperatures inhibited infiltration and stalagmite growth. We thus suggest that the hiatuses observed at BG and GCL were driven largely by reductions in precipitation.

Other western European cave records also share similar growth histories. For example, stalagmites from Villars Cave, southwestern France (Genty et al., 2003; Genty et al., 2010; Wainer et al., 2011), and from multiple caves in northern Spain (Stoll et al., 2013) (Fig. 1) are also punctuated by hiatuses during HS. For example, at or near HS7, stalagmite hiatuses were formed at Villars Cave (78-76 ka), in northern Spain (~75 k), and BG (80-78 ka). No stalagmite deposition has been identified at BG from 71-60 ka or Villars cave from 67-62 ka, a period that includes HS6. Finally, HS1 is marked by a hiatus in northern Spain (18-15.5 ka) and at BG (17-15 ka). While the timing of these hiatuses is not identical, and not all hiatuses at Villars Cave and the Spanish caves overlap with those at BG, the substantial degree of overlap suggests a common origin. Stoll et al. (2013) noted that stalagmite deposition and/or elevated growth rates in northern Spain stalagmites occurred during periods of high Northern Hemisphere summer insolation or during GI, while hiatuses occurred during periods of low insolation and low SST (<13.7°C). The BG record supports this interpretation that growth interruptions are most likely related to reductions in effective moisture tied to SST controls on regional atmospheric moisture availability.

5.2 BG/GCL Stable Isotopic and $\delta^{234}\text{U}$ Variability

Stalagmite $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values covary with changes in SST at orbital time scales. The offset between interglacial and glacial isotopic values averages ~3‰ for $\delta^{18}\text{O}$ and ~7‰ for $\delta^{13}\text{C}$ values and largely tracks changes in NH summer insolation (Fig. 10). Stalagmite $\delta^{234}\text{U}$ values also preserve these changes in aridity. Millennial-scale changes are also recorded in stalagmite carbon isotope ratios, with shifts of 3-7‰ associated with GI/GS transitions, and oxygen isotopic changes of ~1-2‰. The large swing in $\delta^{18}\text{O}$ values during the transition from GI-1 to the Younger Dryas (YD) (~5‰ from 14.0-13.5 ka) is anomalous. Given that the change in $\delta^{13}\text{C}$ values at this time (6‰) is consistent with other GI transitions, the hydroclimatic implications of

this interval require additional study. Similarly, oxygen and carbon isotopic variability is pronounced during the late Holocene portion of the BG record. The origin of this high variability is unclear although it could simply represent the considerably faster Holocene stalagmite growth rates, and thus reduced time averaging in stable isotope samples, relative to the Pleistocene sections, or possibly external factors such as a change in cave ventilation that increased evaporation may be involved. Replication of the Holocene portion of this record currently underway will help address this question (Thatcher et al., 2018).

Where growth is continuous during HS, the link between stalagmite isotopic variations and SST changes is clearly visible (Fig. 11). Prominent positive carbon isotopic excursions define the YD, HS2, HS5, HS6, and HS8, consistent with diminished concentrations of arboreal pollen in cores from the Iberian margin, and serve to document particularly cold and dry conditions at these times (Sánchez Goñi et al., 2000; Roucoux et al., 2006; Sánchez Goñi et al., 2008). Reduced stalagmite $\delta^{13}\text{C}$ values mark periods of enhanced effective moisture from 170-160 and 145-135 ka, tracking peaks in temperate tree pollen and alkenone-based SST. The BG records reveals a pronounced increase in stalagmite $\delta^{13}\text{C}$ values during the YD, at odds with the plateau in SST observed in some Portuguese coastal margin sediments at this time. However, a higher resolution SST record reveals a pronounced drop in SST (Rodrigues et al., 2010), well matched with the BG isotopic profile and the stalagmite record from Villars Cave.

Hydroclimatic shifts associated with GS and GI are most clearly expressed during MIS 5a and 5b in the BG carbon isotope record (Fig. 11). Other European stalagmite records have identified GI/GS events from the last glacial period (Genty et al., 2003; Spötl et al., 2006; Boch et al., 2011; Moseley et al., 2014) (Fig. 10), but the level of resolution recorded in the BG/GCL time series has not been clearly identified previously in western Iberia. A carbon isotope time series (albeit with low temporal resolution) of a flowstone from southeastern Spain does not present clear evidence of either GI or most HS during the last glacial cycle, although it does contain a clear expression of HS11 (Hodge et al., 2008) (Fig. 1). And while some Iberian lakes and peat bogs document environmental changes concurrent with HS, no single record, including one of the longest - the 50 ka time series from the Fuentillejo maar, south-central Spain - contains a consistent signal for all HS (Vegas et al., 2010; Moreno et al., 2012) (Fig. 1). GS/GI oscillations during MIS 3 are not clearly defined in BG stalagmites, likely owing to insufficient

temporal resolution, although the BG records does share a resemblance to reconstructed SST variability (Fig. 11).

Whether the apparent inconsistent linkages between Iberian margin SST and Iberian hydroclimate are due to the limitations of these proxies, region-specific responses to SST variations, or a changing influence of SST on precipitation is unclear. However, other points of divergence between SST and the BG/GCL records exist. For example, some marine cores reveal a prominent spike in forest taxa occurring at the start of interglacials, decreasing thereafter for the next 5-10 kyr (Tzedakis et al, 2004; Desprat et al., 2007) (Fig. 10). This early interglacial peak is a common feature in several time series including the Antarctic δD (Petit et al., 1999) and CH_4 records (Loulergue et al., 2008), and in stalagmite isotopic ratios from the eastern Mediterranean (Bar-Matthews et al., 2003) and southern France (Couchoud et al., 2009). The BG/GCL $\delta^{13}C$ and $\delta^{18}O$ records lack this feature, although the previously discussed issues surrounding the continuity of the MIS6/5e transition may complicate identifying it.

Stalagmite $\delta^{13}C$ and $\delta^{18}O$ values are lower during GI 20-22 (MIS 5a/4; 84-72 ka) than in either the Holocene or MIS 5e (Fig. 10 and 12), and BG6LR $\delta^{234}U$ values support this observation. This interval is of particular interest given that Atlantic forest pollen, which has been used as a proxy for air temperature, was decoupled from SST across northwestern Iberia during cold events (C18-C20) (Rousseau et al., 2006; Rasmussen et al., 2014). This decoupling is interpreted as reflective of a weakened control of SST on Iberian atmospheric temperature that, in turn, enhanced transport of atmospheric vapor to the high latitudes, amplifying production of ice sheets in the early stages of the last glacial cycle (Sánchez Goñi et al., 2013). This process has also been demonstrated for an earlier interglacial (MIS 19; Sánchez Goñi et al., 2016). Other offsets include (1) the gradual change in BG $\delta^{13}C$ and $\delta^{18}O$ values across the MIS 8/7 boundary, in contrast to the sharp rise in SST at this time; (2) the anomalously large $\delta^{13}C$ response to ice rafting event C24 (111-108 ka), and (3) the persistence of low $\delta^{13}C$ values as SST decreased from 205-187 ka (Fig. 11 and 12).

The mechanism linking SST and Iberian hydroclimate over millennial time scales remains unclear. The NAO exerts a strong control over Iberian precipitation, and previous studies have suggested that GS and GI (Moreno et al., 2002; Sánchez Goñi et al., 2002; Danianu et al., 2007) and HS (Naughton et al., 2009) were characterized by distinct NAO modes. The dynamics of the NAO and Azores High pressure system are not well understood prior to the

historical era (Trouet et al., 2009), and the BG/GCL record cannot address this question independently. However, rainfall variability in eastern Iberia is less closely tied to the NAO than is western Iberia and instead reflects other climatic phenomena including the El Niño-Southern Oscillation (Rodó et al., 1997), helping to produce an east-west precipitation gradient. Additional high-resolution speleothem records from central and eastern Iberia could therefore provide a more robust test of the underlying drivers of millennial-scale hydroclimatic changes during recent glacial periods.

6. Conclusions

The discontinuous BG/GCL speleothem composite record demonstrates that the hydroclimate and vegetation dynamics in west-central Portugal tracked Iberian margin SST over orbital and millennial scales during the past two glacial cycles. Enhanced aridity characterized HS, as evidenced by elevated carbon and oxygen isotopic ratios and/or hiatuses in stalagmite growth, consistent with other regional stalagmite time series. GI/GS variability expressed in the Iberian margin SST record and in co-deposited pollen spectra are also present in the BG/GCL time series, and are particularly well defined in MIS 5a and 5b. Understanding differences between the structures of the stalagmite and SST records during some time intervals will require development of speleothem records from central and southern Iberia.

Acknowledgements

This work was supported by the Center for Global and Regional Environmental Research and Cornell College (to R.F.D.), and the U.S. National Science Foundation (grant BCS-1118155 to J.A.H., BCS-1118183 to M.M.B., and AGS-135539 to C.C.U.). Field sampling performed under the auspices of IGESPAR (to J.A.H.) and Associação de Estudos Subterrâneos e Defesa do Ambiente. Brandon Zinsious and Stephen Rasin contributed to fieldwork at BG, and Zachary LaPointe assisted with radioisotopic analyses; Suzanne Ankerstjerne performed stable isotope measurements. 950

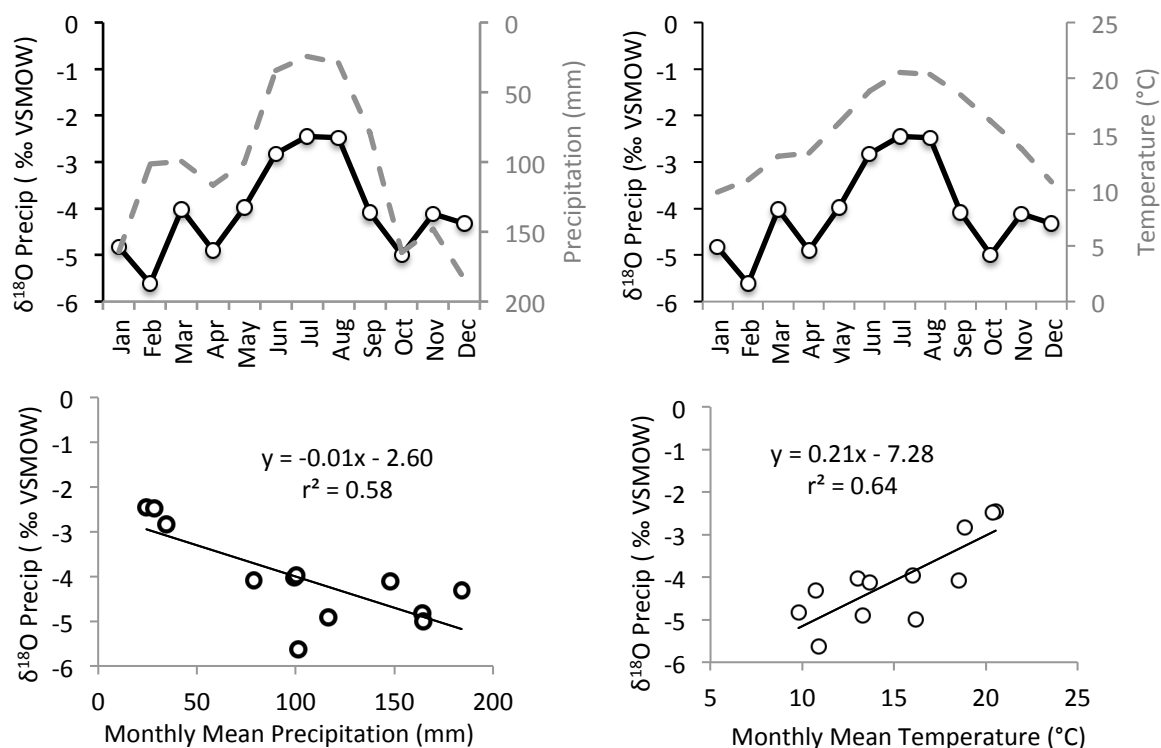

Figure 2. Oxygen isotopic composition of precipitation versus rainfall amount (lefthand panels) and air temperature (righthand panels). Data collected at IAEA/GNIP site in Porto, Portugal (see Fig. 1 for location) for 1988-2004. Oxygen isotope data represent multi-year averages of monthly means. Note that righthand y-axis in upper left panel is inverted in order to illustrate inverse nature of rainfall and precipitation oxygen isotopic composition.

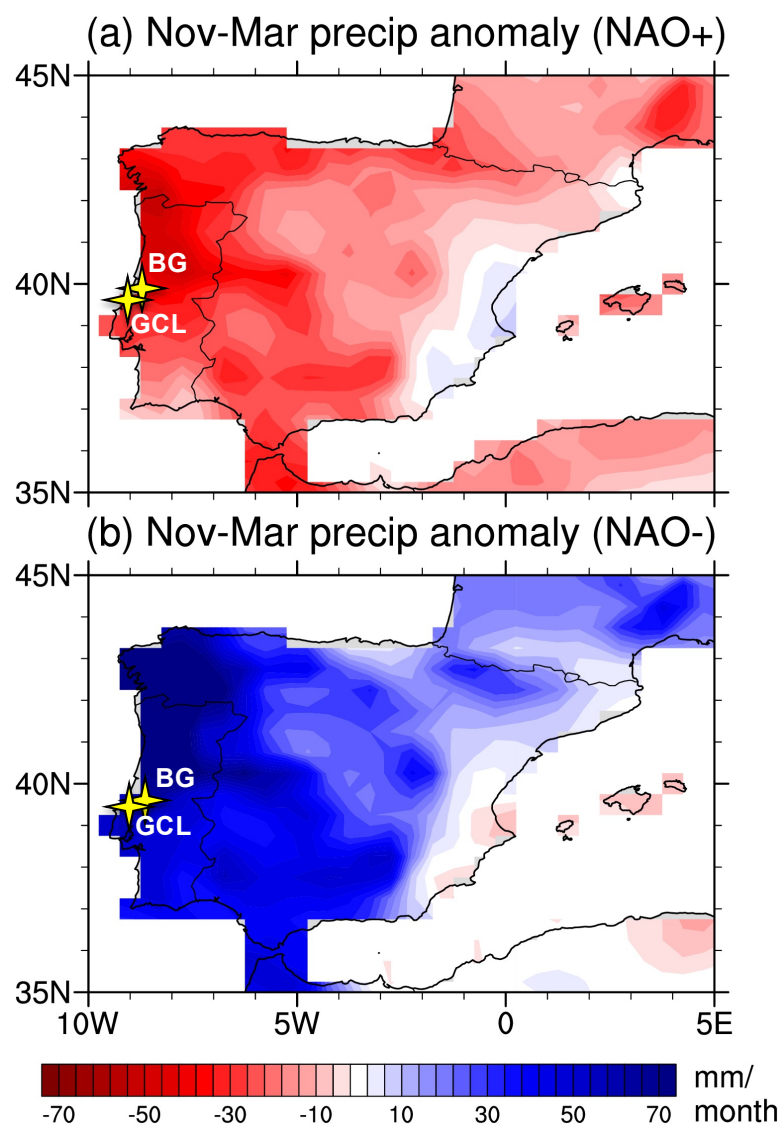

Figure 3. Iberian rainfall anomalies associated with the North Atlantic Oscillation.

Composites of November-March precipitation anomalies (mm/month) during (a) positive and (b) negative NAO winters for the period 1901-2012. Positive/negative NAO winters were determined using the December-March Hurrell principal component-based NAO index (CDG, 2018) as those winters with NAO values in the highest/lowest decile of all winters. The PC-based NAO index represents the time series of the leading Empirical Orthogonal Function of SLP anomalies over the Atlantic sector, 20°-80°N, 90°W-40°E. Precipitation anomalies are based on the GPCC precipitation, version 7, at 0.5° spatial resolution (Schneider et al. 2014). Yellow stars denote cave sites in this study: BG = Buraca Gloriosa; GCL = Gruta do Casal da Lebre.

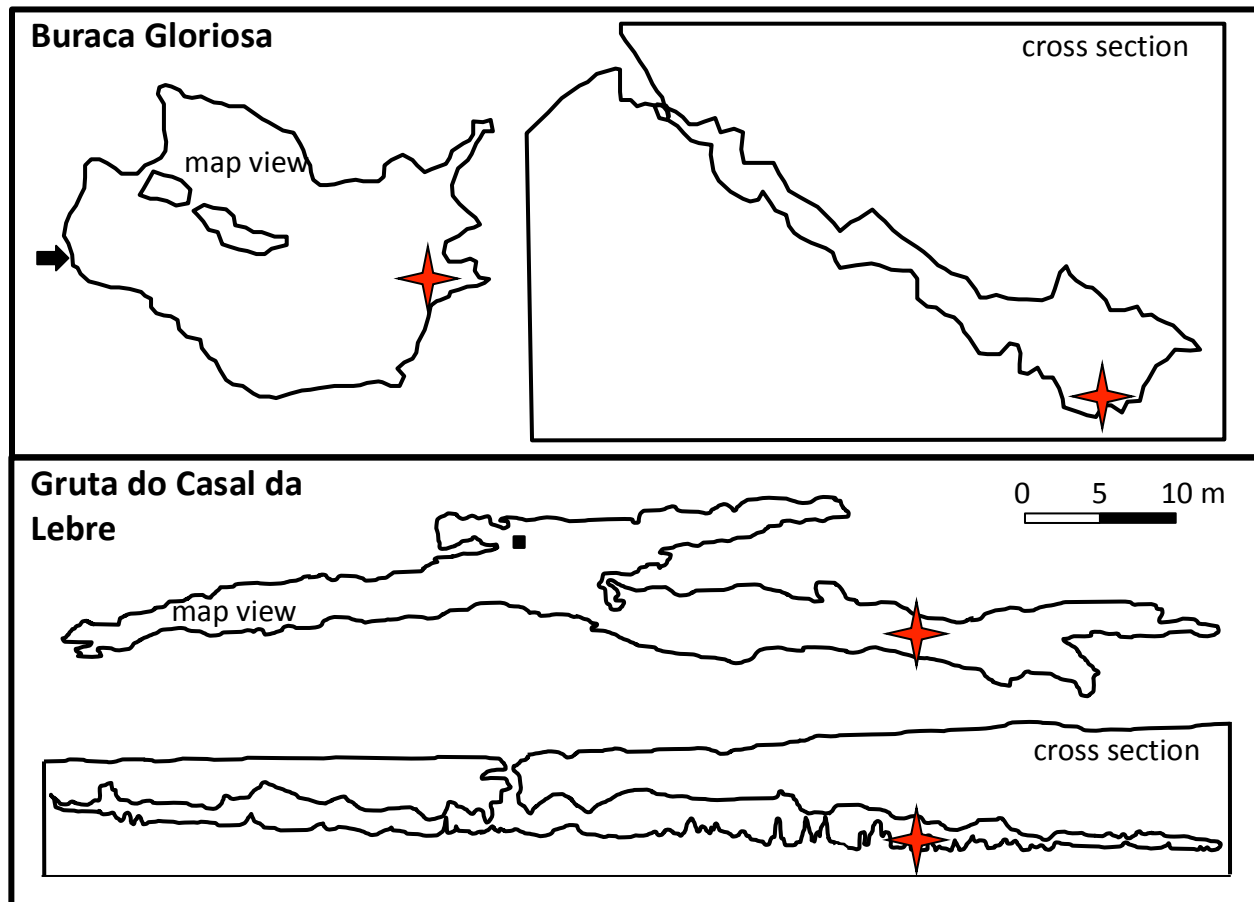

Figure 4. Profile and map views of Buraca Gloriosa (top) and Gruta do Casal da Lebre (bottom). Entrance denoted by arrow (top panel) and filled square (bottom panel). Red stars denote locations of stalagmites used in this study.

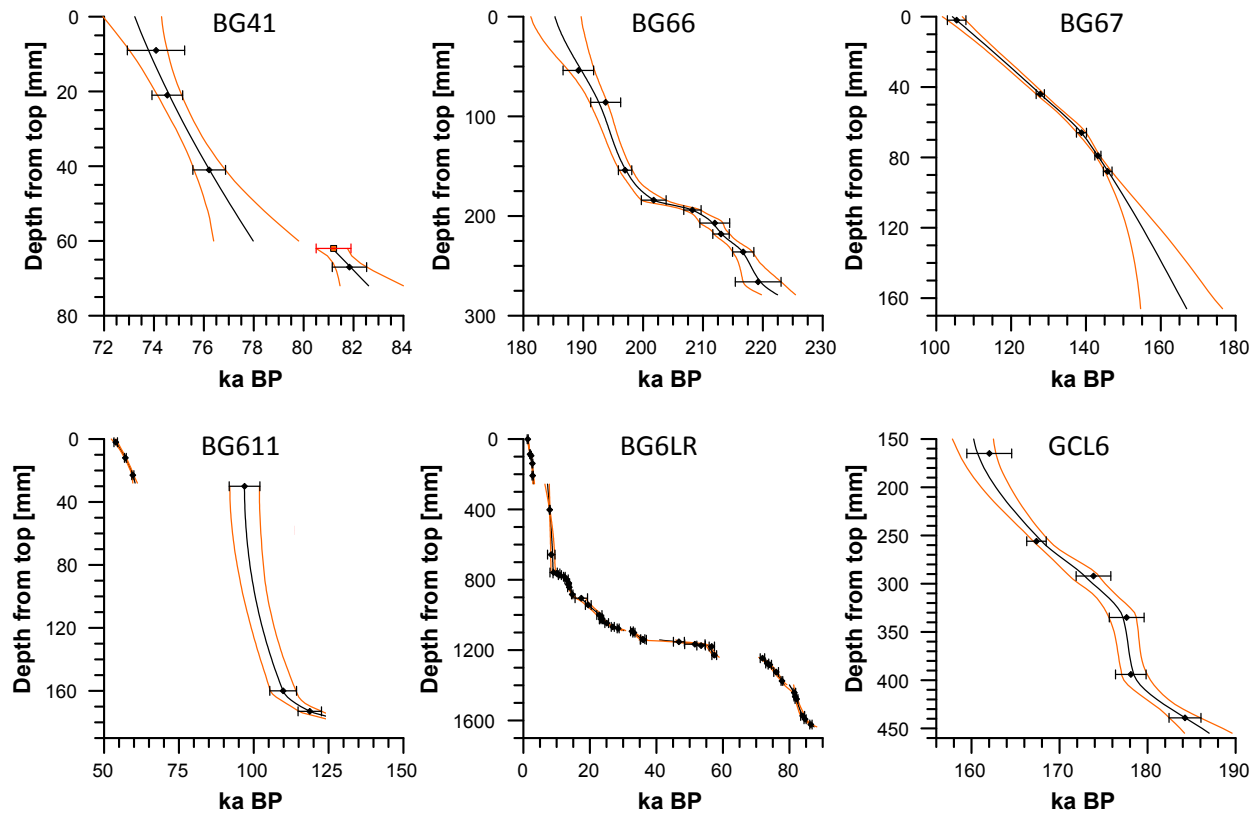

Figure 5. COPRA-derived age models for BG/GCL stalagmites. Black lines represent mean of calculated age models while red lines denote 95% confidence intervals. See Table 1 for specific ages and isotopic ratios. Orange square represents a “dummy age” that was included in order to extrapolate below the hiatus, which is only possible with at least two dated points. The bottom of BG611 was based on linear extrapolation through dated intervals.

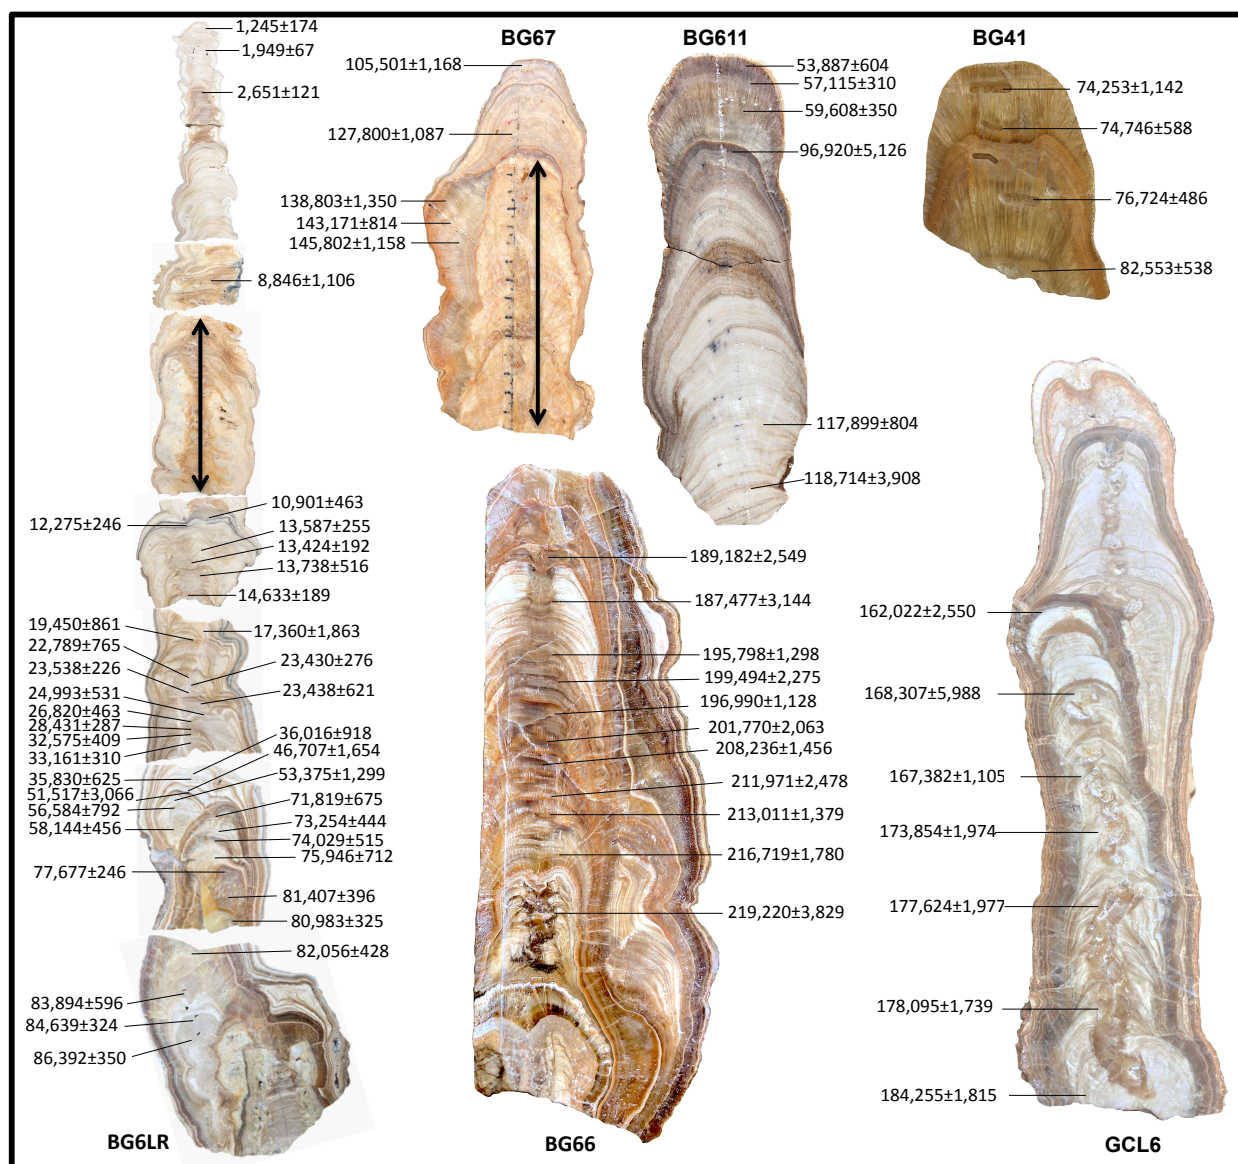

Figure 6. BG/GCL stalagmites and U/Th ages. Black arrows represent intervals excluded from this study due to evidence of open system behavior.

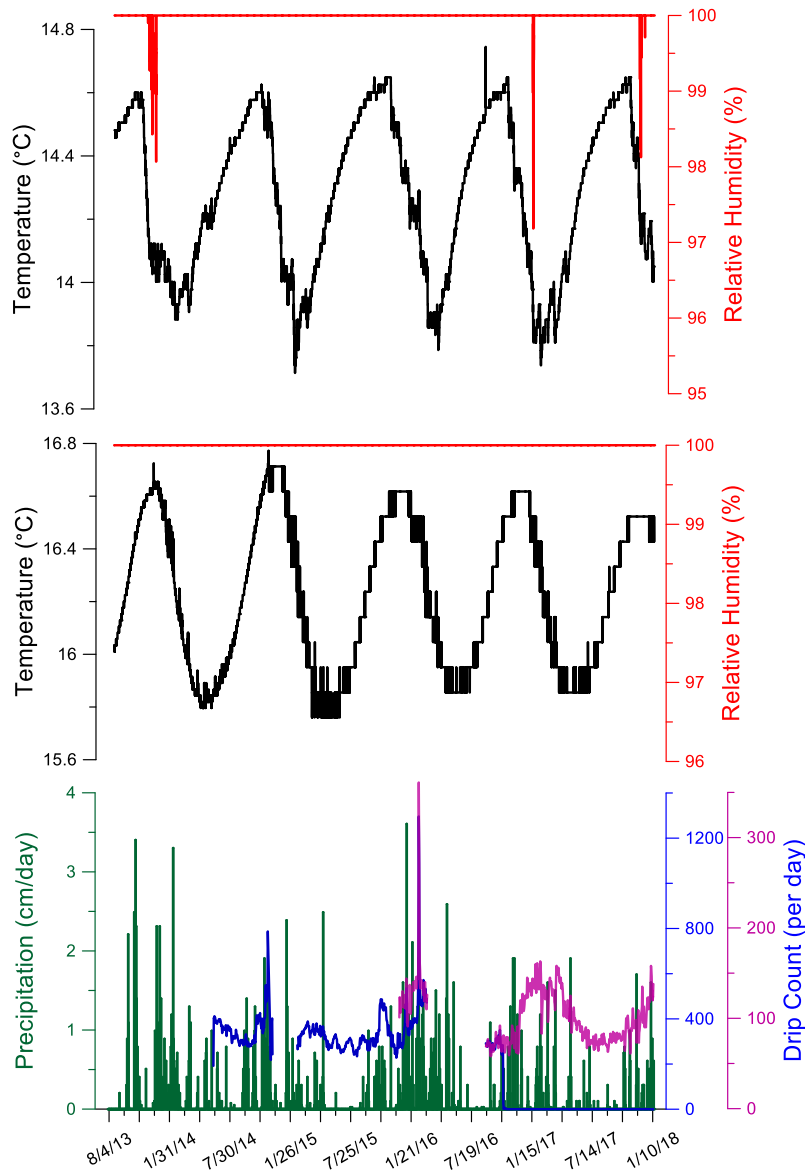

Figure 7. Temperature and relative humidity variations from (top) Buraca Gloriosa and (middle) GCL. Drip rate from Buraca Gloriosa and precipitation variability (bottom) from Monte Real, Portugal (35 km from BG). Temperature sensor in GCL was changed in November 2014 and the sensitivity of the new instrument varies slightly from the original.

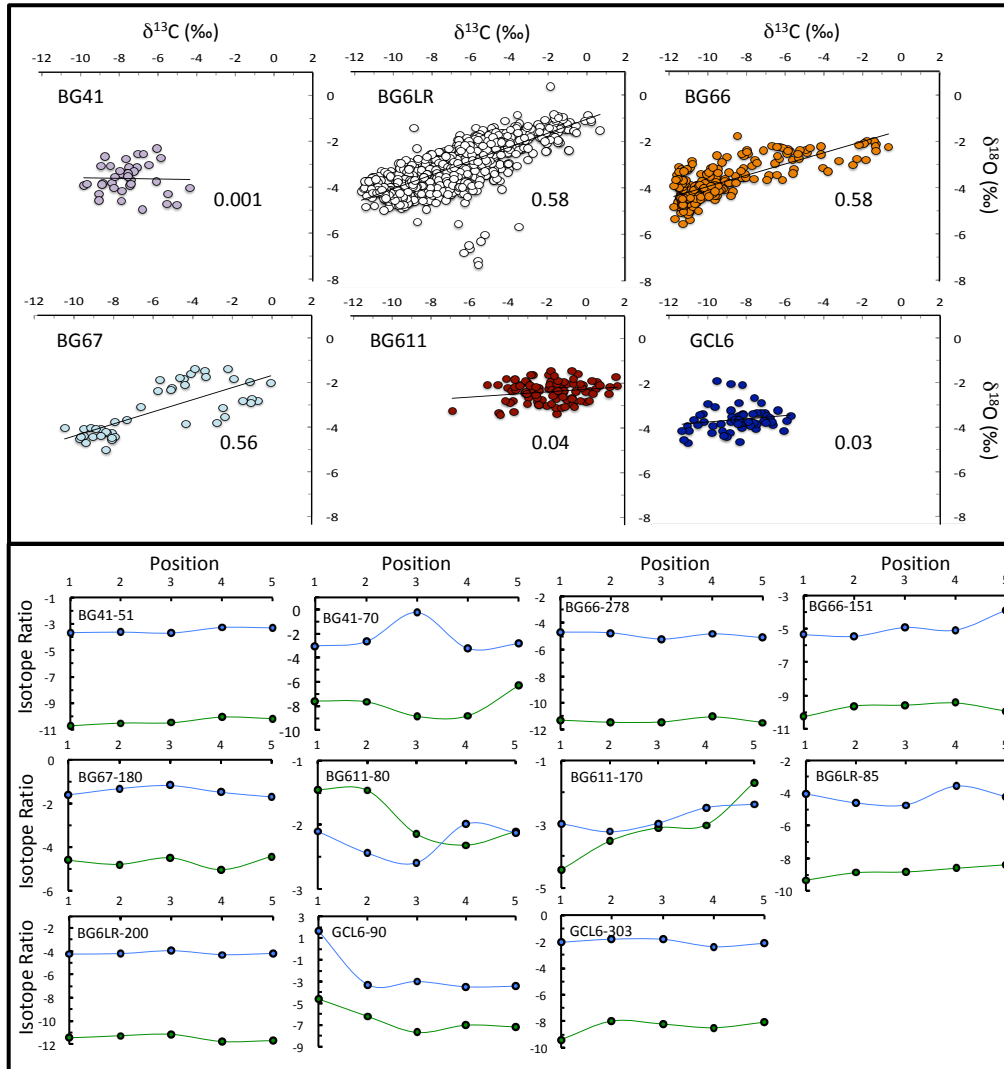

Figure 8. Hendy Tests of BG/GCL stalagmites. Top: Covariance plots of carbon and oxygen isotopic ratios. Correlation coefficients (r^2 values) are listed for each plot. High positive correlations have been identified as an indicator of non-equilibrium crystallization. Bottom: Oxygen (blue) and carbon (green) isotopic variations along the same growth layers with distance (listed in the upper left corner of each panel) from the stalagmite central growth axis. Progressive increases in $\delta^{18}\text{O}$ values have been interpreted to reflect disequilibrium crystallization. Limitations of the Hendy Tests are discussed in text.

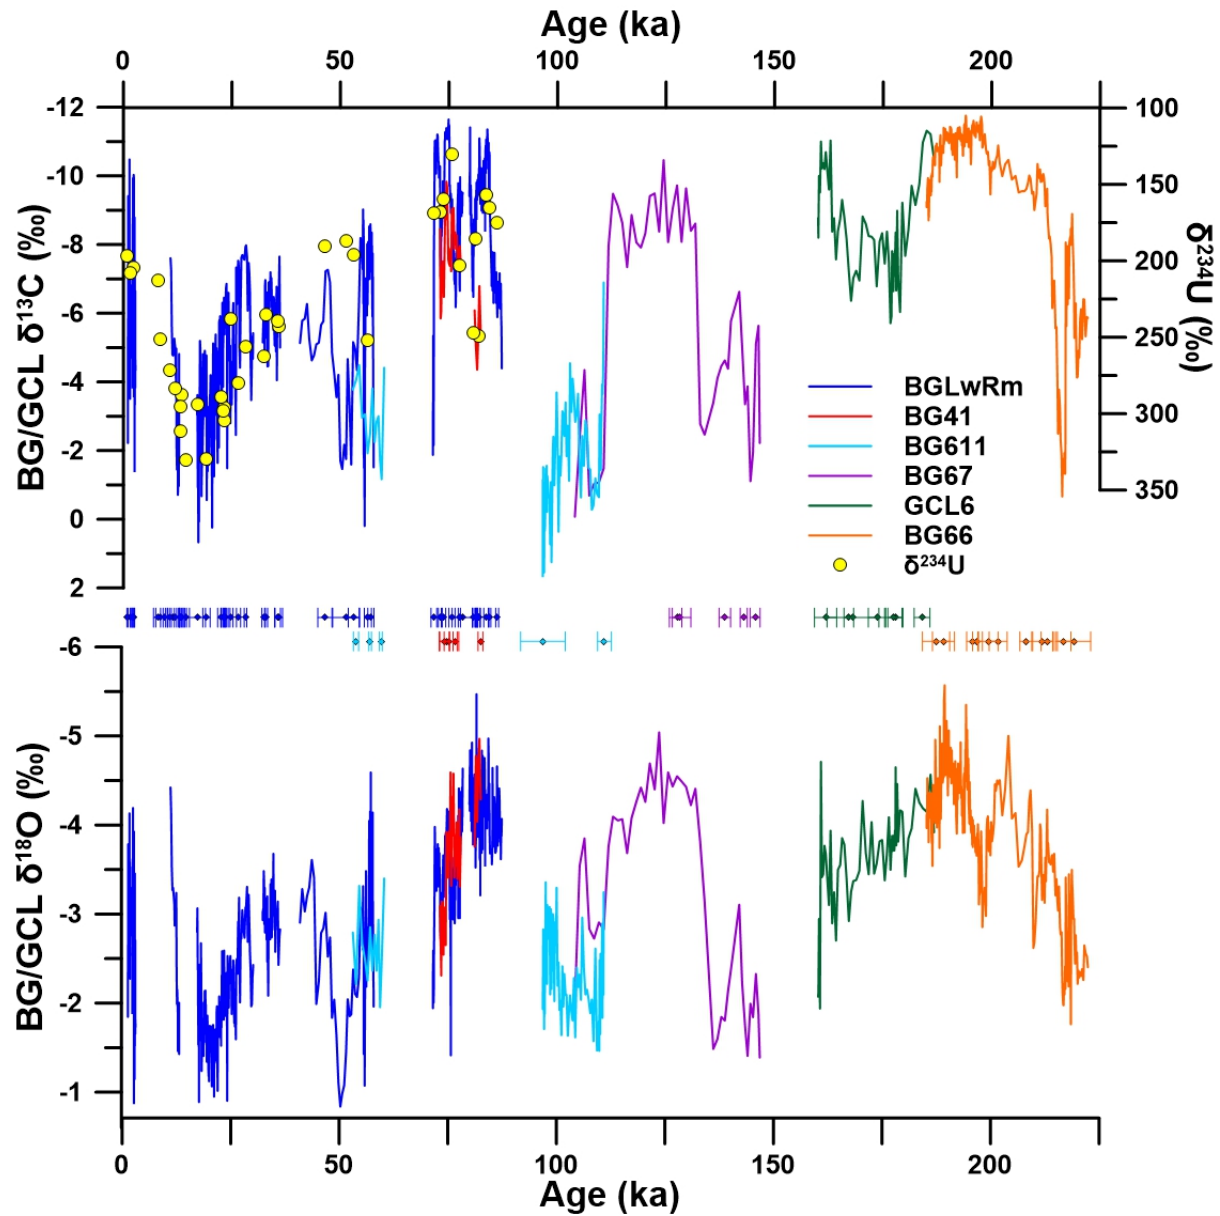

Figure 9. BG/GCL stalagmite isotopic time series. Carbon (top) and oxygen (bottom) isotopes, with each stalagmite presented in a different color. $\delta^{234}\text{U}$ values (yellow circles) for BG6LR are plotted against carbon isotope ratios (plots showing the $\delta^{234}\text{U}$ and $\delta^{13}\text{C}$ values of the other stalagmites are presented in the Supplemental Material). U/Th ages (with 2 s.d. errors) are also shown.

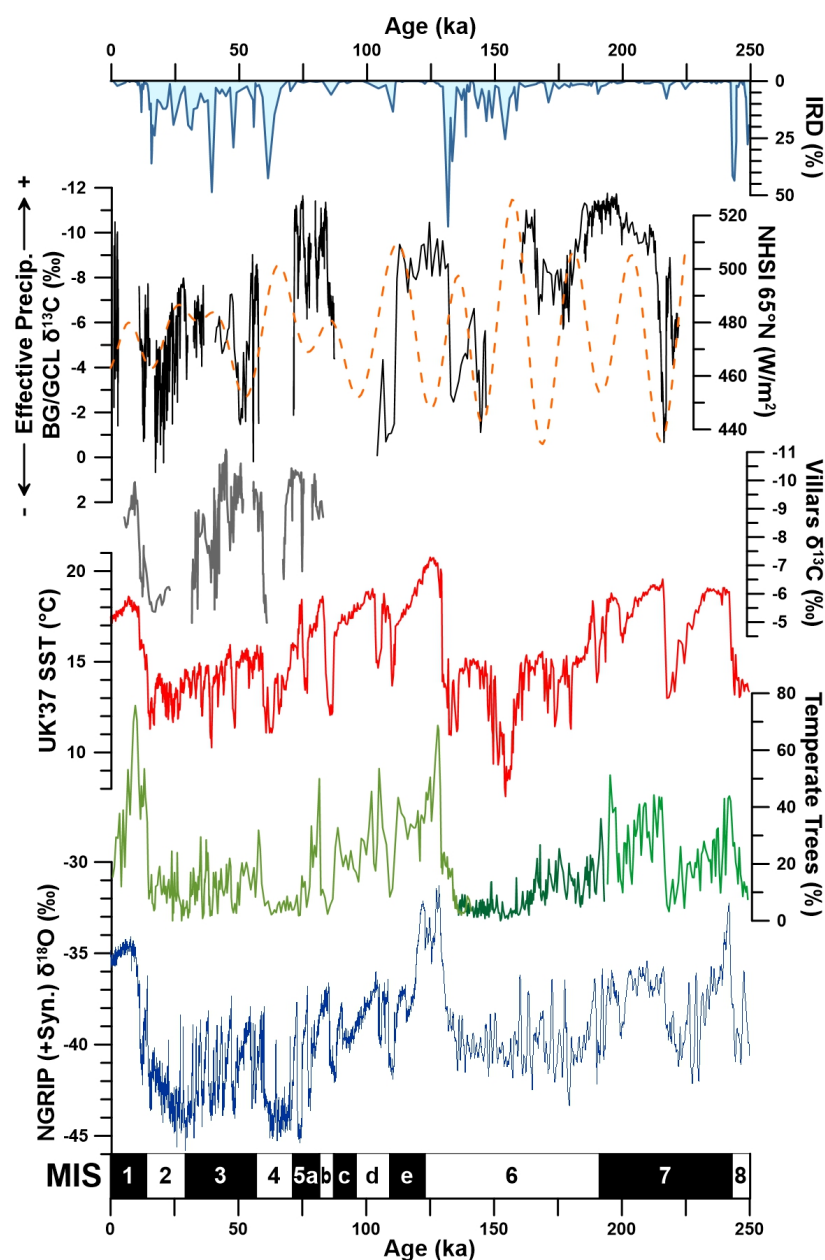

Figure 10. Comparison of Portuguese stalagmite hydroclimate proxies with regional and global climate records from the last two glacial cycles (A) Ice-rafted debris abundance from North Atlantic ODP Site 980 (McManus et al., 1999 using Hulu cave time scale as presented in Barker et al., 2011); (B) composite BG/GCL stalagmite carbon isotopic time series with NH summer insolation (Berger and Loutre, 1991); (C) Carbon isotopic time series from Villars Cave, southern France (Genty et al., 2003; Genty et al., 2006); (D) Alkenone-based Iberian margin SST reconstruction (core MD01-2443; Martrat et al., 2007); (E) Temperate forest pollen abundance from three closely spaced cores (MD01-2443: 250-194 ka (Roucoux et al., 2006; Tzedakis et al., 2004); MD01-2444: 194-136 ka (Margari et al., 2010; Margari et al., 2014); MD95-2042: 136-1 ka (Sánchez Goñi et al., 2008; Sánchez Goñi et al., 2013)); (F) NGRIP (0-122 ka) (North Greenland Ice Core Project members, 2004) and synthetic Greenland oxygen isotopic record (Barker et al., 2011) and (G) marine isotope stages.

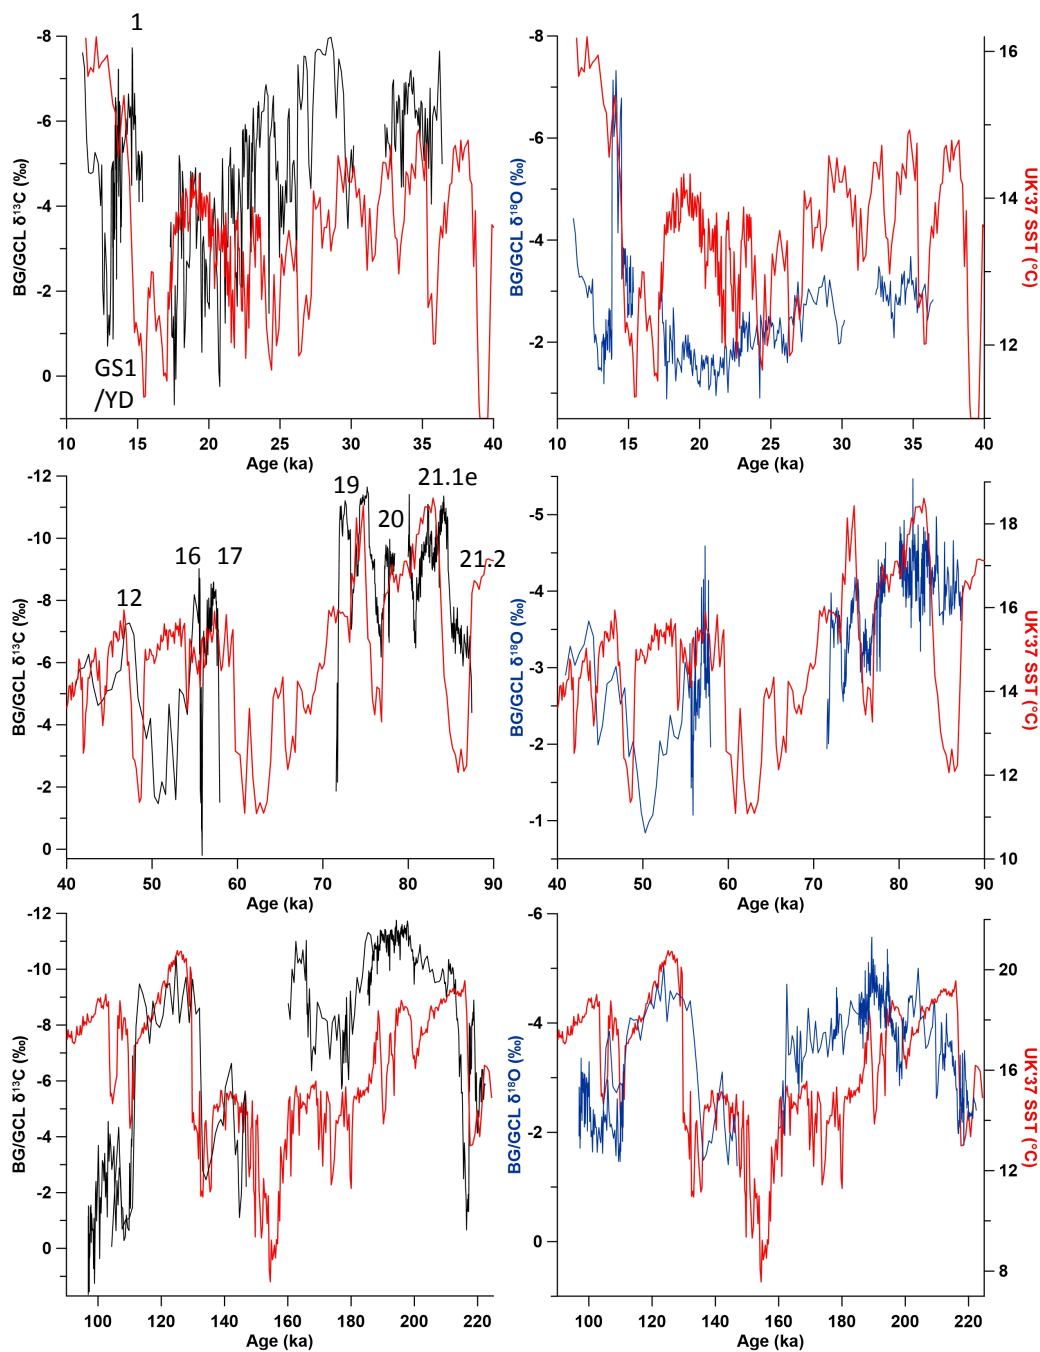

Figure 11. Iberian margin SST (red) and stalagmite carbon (black) and oxygen (blue) isotopes. Numbers denote select GI events using stratigraphic nomenclature of Rasmussen et al. (2014).

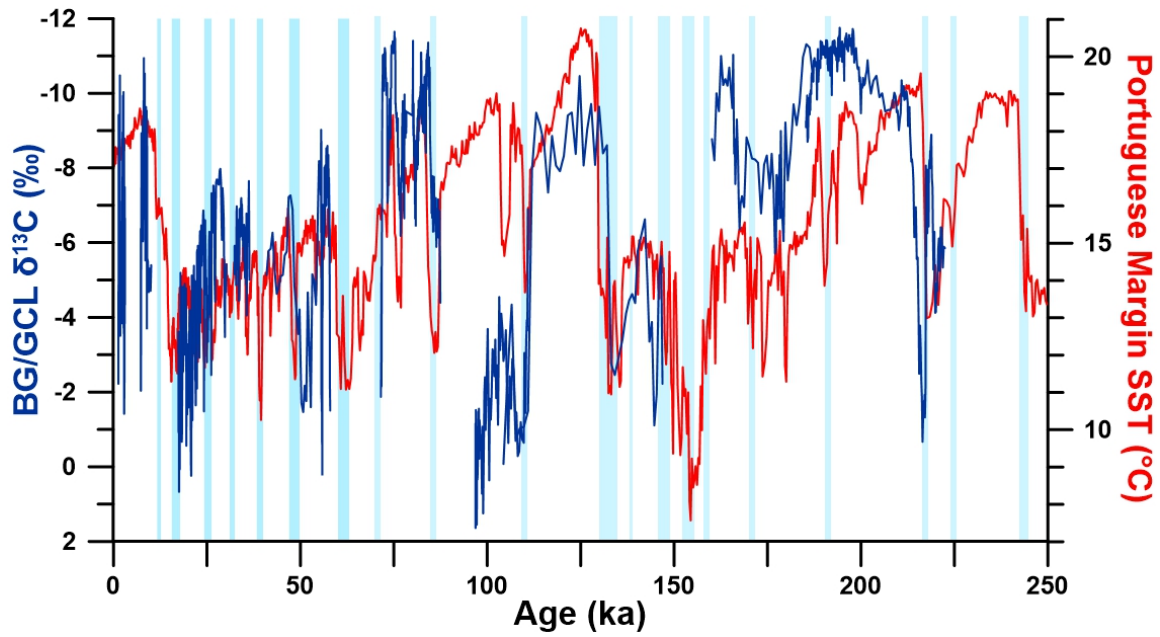

Figure 12. BG/GCL stalagmite carbon isotopic time series and Iberian margin SST. Light blue vertical rectangles denote North Atlantic cold events (some of which are labeled). Several interruptions in stalagmite growth coincide, within the errors of the stalagmite chronologies, with periods of depressed SST.

Table 1. U/Th Isotopic Ratios and ²³⁰Th Ages

| Stalagmite | Distance to Top (mm) ^a | ²³⁸ U (ng/g) | ²³² Th (pg/g) | $\delta^{234}\text{U}^b$ (corr'd) | Error ^c | ²³⁰ Th/ ²³⁸ U (activity) | Error | ²³⁰ Th/ ²³² Th (ppm) | Error | Uncorrected Age (yr BP) ^d | Error (yr) | Corrected Age (yr BP) ^e | Error (yr) |

^a Distances are relative to the base of the stalagmite; negative distances reflect measurements on basal portions obtained in subsequent field seasons.^b $\delta^{234}\text{U}_{\text{meas'd}} = [({}^{234}\text{U}/{}^{238}\text{U})_{\text{meas'd}}/({}^{234}\text{U}/{}^{238}\text{U})_{\text{eq}} - 1] \times 10^3$, where $({}^{234}\text{U}/{}^{238}\text{U})_{\text{eq}}$ is secular equilibrium activity ratio: $\lambda_{238}/\lambda_{234} = 1.0$. Values reported as permil.^c Errors are at the 2 σ level.^d Present is defined as the year AD 1950.^e Initial ${}^{230}\text{Th}/{}^{232}\text{Th}$ atomic ratio of $13.5 \times 10^{-6} \pm 6.75 \times 10^{-6}$ used to correct for unsupported ${}^{230}\text{Th}$. BG stalagmites use $4.4 \times 10^{-6} \pm 2.2 \times 10^{-6}$.
