Subject	Submission of manuscript to Climate of the Past

Dear Professor Thornalley, Dear editor,

Please find enclosed our final revised manuscript, entitled "**Oligocene–Miocene paleoceanography off the Wilkes Land margin (East Antarctica) based on organic-walled dinoflagellate cysts**" (cp-2017-148). Our contribution is part of a set of three companion manuscripts submitted to your journal: Hartman et al. cp-2017-153 and Salabarnada et al. CP-2017-152.

We were very pleased to see three reviewers critically assessed our submission. All three were very positive about our manuscript, and raised some critical points of discussion and suggestions. We used these reviews to revise our manuscript accordingly, which results in a much clearer and better structured presentation of our results and interpretation.

Specifically, we adjusted the comparison of our dinocyst assemblage data with lithologic interpretations made in the companion paper Salabarnada et al. who in their revision added detailed lithologic descriptions for the Miocene part of the succession. This enabled us to extend our lithology-dinocyst assemblage comparison into the Miocene, as was specifically suggested by two of the reviewers. This makes our exercise much clearer to the reader, while reinforcing the conclusions made in our first submission, notably that we see profound differences in dinocyst assemblages in independently interpreted interglacial sediments compared to glacial sediments, reflecting profound ice-proximal oceanographic changes associated to astronomically-paced glacial-interglacial changes.

We also added a section reviewing the evidence for *Selenopemphix antarctica* as indicator for sea-ice conditions, as was specifically suggested by reviewer 2.

The final version of the manuscript contains 7 figures, 2 tables and about 6500 words.

In anticipation of your reply,

Best regards, also on behalf of my co-authors,

Peter K. Bijl

22 **Abstract**

23 Next to atmospheric CO₂ concentrations, ice-proximal oceanographic
24 conditions are a critical factor for the stability of Antarctic marine-terminating
25 ice sheets. The Oligocene and Miocene epochs (~34–5 Ma ago) were time
26 intervals with atmospheric CO₂ concentrations between those of present-day
27 and those expected for the near future. As such, these past analogues may
28 provide insights into ice-sheet volume stability under warmer-than-present-
29 day climates. We present organic-walled dinoflagellate cyst (dinocyst)
30 assemblages from chronostratigraphically well-constrained Oligocene to mid-
31 Miocene sediments from Integrated Ocean Drilling Program Expedition (IODP)
32 Site U1356. Situated offshore the Wilkes Land continental margin, East
33 Antarctica, the sediments from Site U1356 have archived the dynamics of an ice
34 sheet that is today mostly grounded below sea level. We interpret dinocyst
35 assemblages in terms of paleoceanographic change on different time scales, i.e.,
36 with regard to both glacial-interglacial and long-term variability. Our record
37 shows that a sea-ice related dinocyst species, *Selenopemphix antarctica*, occurs
38 only for the first 1.5 Ma of the early Oligocene, following the onset of full
39 continental glaciation on Antarctica, and after the mid-Miocene Climatic
40 Optimum. Dinocysts suggest a weaker-than-modern sea-ice season for the
41 remainder of the Oligocene and Miocene. The assemblages generally bear
42 strong similarity to present-day open-ocean, high-nutrient settings north of the
43 sea-ice edge, with episodic dominance of temperate species similar to those
44 found in the present-day subtropical front. Oligotrophic and temperate surface
45 waters prevailed over the site notably during interglacial times, suggesting that

46 **the positions of the (subpolar) oceanic frontal systems have varied in**
47 **concordance with Oligocene-Miocene glacial-interglacial climate variability.**

48

49 **1. Introduction**

50 The proportion of the East Antarctic ice sheet that is presently grounded below sea
51 level is much larger than originally interpreted (Fretwell et al., 2013). This implies
52 that a larger part of the continental ice sheet is sensitive to basal melting by warm
53 waters than previously thought (Shepherd et al., 2012; Rignot et al., 2013; Wouters et
54 al., 2015), and that a higher amplitude and faster rate of sea-level rise is to be
55 expected under future climate warming than previously acknowledged (IPCC, 2013).
56 Studying the amount and variability of Antarctic ice volume in periods with high
57 atmospheric CO₂ concentrations (*p*CO₂) provides additional insight into ice/ocean
58 feedback processes. Foster and Rohling (2013) compared sea-level and atmospheric
59 *p*CO₂ concentrations on geological timescales. Their study suggests that global ice
60 sheets were rather insensitive to climate change when atmospheric *p*CO₂ ranged
61 between 400 and 650 parts per million in volume (ppmv). During the Oligocene and
62 Miocene, atmospheric *p*CO₂ ranged between 400 and 650 ppmv (Foster et al., 2012;
63 Badger et al., 2013; Greenop et al., 2014). Crucially, similar *p*CO₂ levels are expected
64 for the near future given unabated carbon emissions (IPCC, 2013), implying that
65 global ice volume may not change much under these *p*CO₂ scenarios.

66 In contrast to the invariant global ice volume inferred by Foster and Rohling
67 (2013), a strong (up to 1 per mille; ‰) variability is preserved in deep-sea benthic
68 foraminiferal oxygen isotope (hereafter benthic δ¹⁸O) data (Pälike et al., 2006;
69 Beddow et al., 2016; Holbourn et al., 2007; Liebrand et al., 2011; 2017). These

70 benthic $\delta^{18}\text{O}$ data reflect changes in continental ice volume (primarily on Antarctica)
71 and deep-sea temperature. The latter is strongly coupled to polar surface-water
72 temperature, as deep-water formation was predominantly at high latitudes at that
73 time (Herold et al., 2011). High-amplitude variations in benthic $\delta^{18}\text{O}$ thus suggest
74 either (i) strong climate dynamics in the high latitudes with relatively minor ice-
75 volume change (which would be in accordance with numerical modelling
76 experiments (Barker et al., 1999) and the interpretation of Foster and Rohling
77 (2013)), or (ii) strong fluctuations in Antarctic ice volume, with relatively subdued
78 temperature variability (which would be in accordance with indications for unstable
79 Antarctic ice sheets under warmer-than-present climates (Cook et al., 2013; Greenop
80 et al., 2014; Rovere et al., 2014; Sangiorgi et al., 2018). If one assumes a present-day
81 $\delta^{18}\text{O}$ composition (-42‰ versus standard mean ocean water (SMOW)) for Oligocene–
82 Miocene Antarctic ice-sheets and modern deep-water temperature (2.5°C), the
83 benthic $\delta^{18}\text{O}$ fluctuations during the Oligocene–Miocene suggest long-term ice-sheet
84 variability to have fluctuated considerably (Liebrand et al., 2017). Similarly strong
85 fluctuations were observed in sedimentary records from the Gippsland Basin,
86 southeast Australia (Gallagher et al., 2013). Meanwhile, deep-sea temperatures have
87 fluctuated considerably as well during the Oligocene and Miocene (Lear et al., 2004),
88 which is further evident from ice-free geologic episodes (Zachos et al., 2008).
89 Therefore, a combination of deep-sea temperature and ice-volume changes is likely
90 represented in these records. Further ice-proximal reconstructions of climate, ice-
91 sheet and oceanographic conditions are required to provide an independent
92 assessment of the stability of ice sheets under these higher-than present-day $p\text{CO}_2$
93 concentrations.

94 While Oligocene–Miocene climates may bear analogy to our future in terms of
95 $p\text{CO}_2$ concentrations, the uncertainties and differences in Antarctic paleotopography
96 must be considered in any such comparison, as this factor critically determines the
97 proportion of marine-based *versus* land-based ice. An Antarctic continent with low
98 topography would result in more ice sheets being potentially sensitive to basal melt
99 and as such a higher sensitivity of these ice sheets to climate change. Moreover, the
100 fundamentally different paleogeographic configuration of the Southern Ocean during
101 that time as compared to today should also be considered (Figure 1). The
102 development and strength of the Antarctic Circumpolar Current (ACC) connecting the
103 Atlantic, Indian and Pacific Ocean basins (Barker and Thomas, 2004; Olbers et al.,
104 2004) depend on the basin configuration (i.e., the width and depth of the gateways as
105 well as the position of the landmasses). The exact timing when the ACC reached its
106 modern-day strength is still uncertain, ranging from the middle Eocene (41 Ma) to as
107 young as Miocene (23 Ma; Scher and Martin, 2004; Hill et al., 2013; Scher et al., 2015).
108 Whether and, if so, how the development of the ACC has influenced latitudinal heat
109 transport, ice-ocean interactions and the stability of Antarctic continental ice has
110 remained poorly understood.

111 To directly assess the role of ice-proximal oceanography on ice-sheet stability
112 during the Oligocene–Miocene, ice-proximal proxy-records are required. Several
113 ocean drilling expeditions have been undertaken in the past to provide insight in the
114 history of the Antarctic ice sheets (Barrett, 1989; Wise and Schlich, 1992; Barker et
115 al., 1998; Robert et al., 1998; Wilson et al., 2000; Cooper and O'Brien, 2004; Exon et
116 al., 2004; Harwood et al., 2006; Escutia and Brinkhuis, 2014). For some of the
117 retrieved sedimentary archives, age control was particularly challenging due to the

118 paucity of useful means to calibrate them to the international time scale. As a
119 consequence, the full use of these archives for the generation of paleoceanographic
120 proxy records and ice-sheet reconstructions has remained limited.

121 In 2010, Integrated Ocean Drilling Program (IODP) Expedition 318 drilled an
122 inshore-to-offshore transect off Wilkes Land (Fig. 1a), a sector of East Antarctica that
123 is interpreted to be highly sensitive to continental ice-sheet melt (Escutia et al.,
124 2011). The sediments recovered from IODP Site U1356 are from the continental rise
125 of this margin (Escutia et al., 2011) and hence contain a mixture of shelf-derived
126 material and pelagic sedimentation. Dinocyst events in this record have been recently
127 tied to the international time scale through integration with calcareous nannofossil,
128 diatom and magnetostratigraphic data (Bijl et al., 2018). By Southern Ocean
129 standards, the resulting stratigraphic age frame for the Oligocene–Miocene record of
130 Site U1356 (Fig. 2; Table 1) is of high resolution. In this paper, we investigate the
131 dinocyst assemblages from this succession by utilizing the strong relationships
132 between dinocyst assemblage composition and surface-water conditions of today's
133 Southern Ocean (Prebble et al., 2013). We reconstruct the oceanographic regimes
134 during the Oligocene and mid-Miocene, and evaluate their implications. We further
135 compare the palynological data with lithological observations and their
136 interpretations from Salabarnada et al. (submitted, this volume). Pairing the
137 sedimentological interpretations and biomarker-derived absolute sea-surface
138 temperature (SST) reconstructions from Site U1356 (Hartman et al., submitted, this
139 volume) with our dinocyst assemblage data, we reconstruct the paleoceanographic
140 conditions off Wilkes Land and assess their variability both on glacial-interglacial and
141 longer-term times scales.

142

143 **2. Material**

144 2.1 Site description for IODP Hole U1356A

145 Samples were taken from IODP Hole U1356A, the only hole from Site U1356, cored on
146 the continental rise of the Wilkes Land margin, East Antarctica (Figure 1a; present
147 coordinates 63°18.6' S, 135°59.9' E; Escutia et al., 2011). The paleolatitude calculator
148 of van Hinsbergen et al. (2015) was used to reconstruct the paleolatitudinal history of
149 the site (Figure 1, between -59.8±4.8°S and -61.5±3.3° S between 34 Ma and 13 Ma,
150 respectively). Hole U1356A reaches a depth of 1006.4 m into the seabed (Escutia et
151 al., 2011). Oligocene to upper Miocene sediments were recovered between 890 and 3
152 mbsf (meters below sea floor, Figure 2; Tauxe et al., 2012; revised according to Bijl et
153 al., 2018). The uppermost 95 meters of the hole were poorly recovered; sediments
154 consisted of unconsolidated mud strongly disturbed by rotary drilling (Escutia et al.,
155 2011). Hence, we focused our investigation on the interval between Cores 11R to 95R
156 Section 3 (95.4–894 mbsf; 10.8–33.6 Ma; Figure 2).

157

158 2.2 Lithology in IODP Hole U1356A

159 In the interval between 95.4 and 894 mbsf, nine lithologic units have been recognized
160 during shipboard analysis (Figure 2; Escutia et al., 2011). Salabarnada et al.
161 (submitted, this volume) present a detailed lithologic column of the Oligocene and
162 Miocene sediments. The lithologic facies described in Salabarnada et al. (submitted,
163 this volume) will help us compare paleoceanographic differences between climatic
164 extremes. Salabarnada et al. (submitted this volume) distinguished various lithologies
165 along with interpretations of their depositional settings which can be summarized as:

166 1) laminated silty clay sediments (interpreted as glacial deposits; hereafter Fg), 2)
167 bioturbated siltstones and claystones that in some intervals are carbonate-cemented
168 (interpreted as interglacial deposits, hereafter Fi), and 3) perturbed mass transport
169 deposits (MTDs): slumps and debris flows. We refer to Salabarnada et al. (submitted
170 this volume; Fig S2) for a detailed description of these facies, and to the
171 supplementary datasets on pangaea for more detailed separation of our palynological
172 results per facies type.

173

174 2.3 Bio-magnetostratigraphic age model for IODP Hole U1356A

175 Stratigraphic constraints for the Oligocene–Miocene succession from IODP Hole
176 U1356A are provided through calcareous nannoplankton, radiolarian, diatom and
177 sparse palynological biostratigraphy, complemented by magnetostratigraphy (Tauxe
178 et al., 2012). Bijl et al. (2018) and Crampton et al. (2016) have updated the existing
179 age model for Site U1356 for the Oligocene and Miocene parts of the succession,
180 respectively. In their efforts, they recalibrated the tie points to the international time
181 scale of Gradstein et al. (2012). We here follow their revision of the age model (Table
182 1). We infer ages by linear interpolation between tie points (Figure 2; Table 1).

183

184 2.4 Depositional setting at IODP Site U1356

185 The depositional setting at Site U1356 changed from a shallow mid-continental shelf
186 in the early Eocene (Bijl et al., 2013a) to a deep continental rise environment by the
187 Oligocene (Houben et al., 2013) due to subsidence of the Wilkes Land margin (e.g.,
188 Close et al., 2009). Regional correlation of the facies at Hole U1356A via seismic
189 profiles suggests a mix of distal-submarine fan and hemipelagic sedimentation during

190 the early Oligocene, grading into channel-levee deposits in the later Oligocene
191 (Escutia et al., 2011). The boundary between these two different depositional settings
192 is at ~650 mbsf; there, sedimentation rates increase, and the documentation of mass-
193 transport deposits from this depth upwards suggests shelf-derived erosion events on
194 the Wilkes Land continental slope (Escutia et al., 2011).

195

196 **3. Methods**

197 3.1 Palynological sample processing

198 The sample processing and analytical protocols as followed in this study are in
199 accordance with standard procedures and have been previously described by Bijl et
200 al. (2013b; 2018). The 25 species of dinocysts new to science, which are formally (2
201 species) and informally (23 species) described in Bijl et al. (2018), fit into known and
202 extant genera, and therefore could be confidently included in the ecological groups as
203 described below. We refer to Bijl et al. (2018) for an extensive overview (including
204 plates) of the dinocyst species encountered.

205

206 3.2 Ecological grouping of dinocyst taxa

207 Bijl et al. (2018) provided additional statistical evidence to distinguish in situ
208 dinocysts from those that are reworked from older strata. In this paper, we follow the
209 interpretations of Bijl et al. (2018) and divide the dinocyst species into a reworked
210 and an in situ group (Table 2). To use the in situ dinocyst assemblages for
211 oceanographic reconstructions, we rely on the observation that many taxa in the
212 fossil assemblages have morphologically closely related modern counterparts. This
213 approach takes advantage of studies on the present-day relationship between

214 Southern Ocean microplankton in general and dinoflagellate cysts in particular and
215 their surface-water characteristics (e.g., Eynaud et al., 1999; Esper and Zonneveld,
216 2002, 2007; Prebble et al., 2013). We assign Oligocene–Miocene dinocyst taxa to
217 present-day eco-groups interpreted from the clusters identified by Prebble et al.
218 (2013), which appear to be closely related to the oceanic frontal systems in the
219 Southern Ocean (Figure 3). Supporting evidence for the ecologic affinities of the
220 dinocyst groups comes from empirical data, such as correlation of abundances with
221 other sediment properties or proxies (Sluijs et al., 2005; Egger et al., 2018), for
222 instance with regard to the affinities of *Nematosphaeropsis labyrinthus*,
223 *Operculodinium* spp., *Pyxidinosia* sp. (this includes *Corrudinium* spp. and
224 *Cerebrocysta* spp.) and *Impagidinium* spp. There is further abundant evidence, both
225 empirically (e.g., Sluijs et al., 2003; Houben et al., 2013) and from modern
226 observations (Zonneveld et al., 2013; Prebble et al., 2013; Eynaud et al., 1999), that
227 links the abundance of protoperidinioid dinocysts to high surface-water productivity.
228 The arguably most important inference from the surface-sediment sample study of
229 Prebble et al. (2013) is that *Selenopemphix antarctica* is common to dominant (10–
230 90%) south of the Antarctic polar front (AAPF). In particular, the Antarctic
231 continental shelf exhibits a consistently high relative abundance of *Selenopemphix*
232 *antarctica*. In addition to the surface samples of Prebble et al. (2013), this is also
233 evident at the Wilkes Land margin proper (IODP Site U1357; Hartman, Bijl and
234 Sangiorgi, pers. obs.), at Prydz Bay (Storkey, 2006), in the Weddell (Harland and
235 Pudsey, 1999) and Ross Seas (Hartman, Bijl and Sangiorgi, pers. obs), and in the
236 southern Indian Ocean (Marret and de Vernal, 1997): samples all contain very
237 abundant to dominant (>50 to 90%) *S. antarctica*. The dominance of this species

238 becomes even stronger when considering that assemblages in these surface samples
239 often include cysts that are not easily preserved in older sediments such as that of
240 *Polarella glacialis*. Leaving these dinocyst out of the dinocyst sum increases the
241 relative abundance of *Selenopemphix antarctica* in surface samples. Notably, surface-
242 sediment samples outside of the AAPF never have dominant (~90%) *Selenopemphix*
243 *antarctica* (Prebble et al., 2013). Another important observation is that the surface-
244 sediment samples south of the AAPF are generally devoid of gonyaulacean dinocysts,
245 with the exception of two species of *Impagidinium* (i.e., *I. pallidum* and *I. sphaericum*)
246 that may occur, although neither abundantly (Prebble et al., 2013) nor exclusively
247 (e.g., Zevenboom, 1995; Zonneveld et al., 2013), in ice-proximal locations. Abundant
248 *Nematosphaeropsis labyrinthus* occurs exclusively in regions outside of the
249 Subantarctic Front, and particularly near the Subtropical Front. Thus, we conclude
250 from the available literature a dominance of *S. antarctica* south of the AAPF, a
251 dominance of other protoperidinioid dinocysts at and north of the AAPF, mixed
252 protoperidinioid and gonyaulacoid dinocysts (with a notable occurrence of
253 *Nematosphaeropsis labyrinthus* at the sub-Antarctic front (SAF), and mixed
254 gonyaulacoid dinocysts at and outside of the subtropical front (STF). These trends
255 represent a north-south transition from sea-ice-influenced to cold upwelling/high
256 nutrient to warm-temperate/lower nutrient conditions, respectively. We use these
257 affinities to reconstruct past oceanographic conditions at the Wilkes Land continental
258 margin.

259

260 **4. Results**

261 4.1 Palynological groups

262 In our palynological analysis we separated palynomorph groups into four categories:
263 reworked dinocysts (following Bijl et al. (2018); Table 2), in situ dinocysts, acritarchs,
264 and terrestrial palynomorphs. Our palynological slides further contain a varying
265 amount of pyritized diatoms and a minor component of amorphous organic matter,
266 which is not further considered in this study. The relative and absolute abundances of
267 the four palynomorph groups vary considerably throughout the studied interval
268 (Figure 4). Reworked dinocysts are ubiquitous throughout the record, and are
269 particularly abundant in the lowermost 40 meters of the Oligocene and in the Upper
270 Oligocene. In situ dinocysts dominate mid-Oligocene and mid-Miocene palynomorph
271 assemblages. Chorate, sphaeromorph and *Cymatiosphaera*-like acritarchs (which are
272 not further taxonomically subdivided) dominate the assemblage in the Upper
273 Oligocene and into the mid-Miocene, while terrestrial palynomorphs (which are
274 considered in situ and not reworked from older strata (Strother et al., 2017)) are a
275 constant minor (a few % of the total palynomorph assemblage) component of the
276 total palynomorph assemblage (Fig. 4). The terrestrial palynomorphs and the
277 paleoclimatic and paleoecological interpretations derived from them will be
278 presented in another study.

279

280 4.2 In situ dinocyst assemblages

281 Throughout the Oligocene, in situ dinocyst assemblages are dominated by
282 protoperidinioid dinocysts, notably *Brigantedinium* spp., *Lejeunecysta* spp., *Malvinia*
283 *escutiana*, and *Selenopemphix* spp. (Figure 4), all of which are cysts of heterotrophic
284 dinoflagellates (e.g., Esper and Zonneveld, 2007). Among these protoperidinioid
285 cysts, *S. antarctica* is frequently present (up to 39% of the in situ assemblage), but

286 only between 33.6 and 32.1 Ma (earliest Oligocene) and after 14.2 Ma (i.e., during and
287 after the mid-Miocene climatic transition; Fig. 5). The remainder of the record is
288 almost entirely devoid of *S. antarctica*. This is much in contrast to the dinocyst
289 assemblages nearby Site U1356 today, which are dominated by this taxon (Prebble et
290 al., 2013). Instead of *S. antarctica*, other protoperidinioid dinocysts dominate during
291 the Oligocene and Miocene, such as *Brigantedinium* spp., several *Lejeunecysta* species
292 and *Selenopemphix nephroides*, which have close affinities to high-nutrient conditions
293 in general (e.g., Harland et al., 1999; Zonneveld et al., 2013), but are not specifically
294 restricted to sea-ice-proximity or the Southern Ocean. Today, these three genera
295 dominate dinocyst assemblages in high-nutrient settings at or outside of the AAPF
296 (Prebble et al., 2013). A varying abundance of protoperidinioid dinocysts could not be
297 placed with confidence into established protoperidinioid dinocyst genera. These are
298 grouped under ‘protoperidinioid spp. pars’ (Figure 4; Bijl et al., 2018) and are here
299 assumed to exhibit the same heterotrophic life-style as the other protoperidinioid
300 dinocyst genera.

301 Next to protoperidinioid dinocysts, gonyaulacoid dinocysts also occur in relatively
302 high abundances throughout the record from Site U1356. They comprise both known
303 and previously unknown (Bijl et al., 2018) species of *Batiacashaera*, *Pyxidinopsis*,
304 *Corrudinium*, *Cerebrocysta*, *Nematosphaeropsis*, *Impagidinium*, *Operculodinium*, and
305 *Spiniferites* (Fig. 4; 5). The ‘others’ group represents exclusively gonyaulacoid species
306 such as *Invertocysta tabulata* and *Gelatia inflata*. Except for the extinct genera
307 *Batiacasphaera* and *Cerebrocysta* and some genera in the ‘others’ group, all the other
308 genera are still extant and represent phototrophic dinoflagellates (Zonneveld et al.,
309 2013). Their abundance is at the expense of the assumed heterotrophic

310 protoperidinioid dinocysts. A marked increase in abundance of gonyaulacoid cysts is
311 associated with the mid-Miocene Climate Optimum (MMCO between ~17 and 15 Ma;
312 Fig. 4, 5; Sangiorgi et al., 2018). Of the gonyaulacoid taxa, *Nematosphaeropsis*
313 *labyrinthus* is associated with frontal systems of the present-day Southern Ocean
314 (Prebble et al., 2013) and of the North Atlantic Ocean (Boessenkool et al., 2001;
315 Zonneveld et al., 2013).

316

317 4.3 Comparison between palynological data and lithological facies

318 The Oligocene-Miocene sediments from Site U1356 comprise distinctive alternations
319 of lithologic facies throughout the section (Salabarnada et al., submitted, this volume;
320 Figure S2). Laminated (Fg) and bioturbated sediments, that are in some intervals are
321 carbonate-rich (Fi) alternate on orbital time scales and this pattern is in some
322 intervals disrupted by slumps and/or debris flows. We here evaluate and compare
323 the palynological content of each of these facies both in terms of absolute and relative
324 abundance of the main palynomorph groups: reworked dinocysts, in situ dinocysts,
325 acritarchs and terrestrial palynomorphs, and relative abundance of in situ dinocyst
326 eco-groups.

327

328 4.3.1 Palynomorph groups and lithology

329 There are distinct differences in the relative and absolute abundances of the
330 palynomorph groups between the different lithologies (Figure 6). The highest relative
331 and absolute abundances of reworked dinocysts occur in the slump and Fi facies (Fig.
332 6), particularly those of early Oligocene age (EOT slumps and bioturbated siltstones
333 in Supplementary datasets), in line with observations of Houben et al. (2013).

334 Reworking is a minor component of the palynomorph assemblage in the other
335 lithologies for most samples, with a higher absolute abundance in Fi deposits than in
336 glacial deposits. This suggests that submarine erosion of Eocene continental shelf
337 material was particularly prominent during interglacial times, when arguably sea
338 level along the Wilkes Land margin was lower (Stocchi et al., 2013). The relative and
339 absolute abundance of *in-situ* dinocysts is highest in the interglacial and glacial
340 deposits and the slumps (Figure 6). Acritarchs reach highest relative and absolute
341 abundances in Fi facies and in the debris flows (Figure 6). Terrestrial palynomorphs
342 are most abundant in the lower Oligocene slumps and Fi sediments (Supplementary
343 tables) but have low relative abundance in all lithologies (Figure 6).

344

345 4.3.2 In situ dinocyst eco-groups and their abundance per facies

346 The in situ dinocyst eco-groups are also compared with the lithological facies (Figure
347 7). The Fg glacial facies contains generally more peridinioid (heterotrophic)
348 dinocysts, while the Fi interglacial facies contains more gonyaulacoid (oligotrophic)
349 dinocysts, but more information is to be seen when focussing on the individual eco-
350 groups. The abundance of *Selenopemphix antarctica* is low throughout the record (0–
351 5%), with the exception of the interval post-dating the MMCO and the lowermost
352 Oligocene, where the taxon reaches occasionally more than 20% (Figs. 4, 5). *S.*
353 *antarctica* reaches highest abundances in the slump facies and Fg and is less
354 abundant in the other lithologies (Figure 7). *Selenopemphix* spp. reaches highest
355 relative abundances in the Fg facies. *Lejeunecysta* spp. and *Protoperidinium* spp. pars.
356 show no noticeable variance in relative abundance in any of the lithologies.
357 *Brigantedinium* spp. is clearly higher abundant in the Fg facies than in the Fi facies.

358 *Malvinia escutiana* abundances seem to be higher in Fi than in Fg (Figure 7), although
359 this species has a stratigraphic occurrence that is limited to the early Oligocene (Bijl
360 et al., 2018). *Nematosphaeropsis labyrinthus*, *Pyxidinosia* spp., *Operculodinium* spp.,
361 and *Impagidinium* spp. reach higher relative abundances in Fi than in Fg facies,
362 whereas the abundance of *Batiacasphaera* spp. seems invariant to facies.

363

364 **5. Discussion**

365 5.1 Paleoceanographic interpretation of the dinocyst assemblages

366 The composition of the dinoflagellate cyst assemblages in the Wilkes Land record
367 reflect changes in surface-ocean nutrients, sea- surface temperature conditions and
368 paleoceanographic features. We will discuss these implications in the following.

369

370 5.1.1 Surface-ocean nutrient conditions

371 The general dominance of heterotrophic dinocysts in the Oligocene–Miocene
372 assemblages indicates overall high nutrient levels in the surface waters. Given the
373 offshore geographic setting, we therefore infer that surface waters at Site U1356
374 experienced upwelling associated to the AAPF during most of the Oligocene and
375 Miocene. We can exclude the possibility that nutrients were brought to the site via
376 river runoff given the anticipated small catchment area that experienced liquid
377 precipitation in the Wilkes Land hinterland, the low amounts of terrestrially-derived
378 (amorphous) organic matter in the palynological residues and relatively low
379 branched over isoprenoid tetraether (BIT) index values (Hartman et al., submitted
380 this volume) that indicates predominantly marine organic matter. The exception may

381 be the mid-Miocene climatic Optimum (Sangiorgi et al., 2018) when considerable soil-
382 derived organic matter reached the site.

383 The occasionally abundant gonyaulacoid cyst taxa encountered in our record
384 suggest that at times surface waters were much less nutrient-rich supported the
385 growth of oligotrophic dinoflagellates. Notably, these taxa are typical for outer-shelf
386 to oceanic or outer neritic settings (e.g., Sluijs et al., 2005; Zonneveld et al., 2013;
387 Prebble et al., 2013), which makes it unlikely that they were reworked from the
388 continental shelf. Indeed, they show low relative abundances in the perturbed
389 deposits (Figure 7). Although the members of these genera have relatively long
390 stratigraphic ranges extending back into the Eocene, most of the species encountered
391 at Site U1356 are not present in Eocene continental shelf sediments in the region
392 (e.g., Wrenn and Hart, 1988; Levy and Harwood, 2000; Brinkhuis et al., 2003a, b; Bijl
393 et al., 2011; 2013a, b). This makes it unlikely that they are reworked from Eocene
394 strata. In addition, statistical analysis also yields that these species are part of the in
395 situ assemblage (Bijl et al., 2018). These different lines of evidence lead us to
396 interpret them as part of the in situ pelagic assemblage in our study, which allows us
397 to interpret their paleoceanographic implications based on their modern affinities.
398 The absence of these taxa in modern surface waters south of the AAPF is probably
399 caused by a combination of different factors: It can be connected to low sea-surface
400 temperatures and an isolation by strong eastward currents, but also the abundance
401 and seasonally concentrated availability of nutrients, all of which make the proximal
402 surface waters off Antarctica a highly specialistic niche unfavourable for these
403 species. Apparently, surface-water conditions during the Oligocene and Miocene were

404 such that these oligotrophic species could at times proliferate so close to the Antarctic
405 margin.

406

407 5.1.2 Sea-surface temperature

408 The best modern analogues for the dinocyst assemblages in our record are to be
409 sought off the southern margins of New Zealand and Tasmania (as inferred from
410 Prebble et al., 2013; Figure 2). Today, these regions feature a mix between
411 protoperidinioid dinocysts along with gonyaulacoid dinocyst genera such as
412 *Nematosphaeropsis*, *Operculodinium* and *Impagidinium*. These assemblages prevail in
413 surface waters with mean annual temperatures of 8–17°C (Prebble et al., 2013) and
414 therefore suggest relatively warm surface water temperatures close to the Wilkes
415 Land margin. In support of this, a bayesian approach on the TEX₈₆ index values at Site
416 U1356 (presented in Sangiorgi et al., 2018; Hartman et al., submitted, this volume)
417 also suggests the Southern Ocean mid-latitudes as a modern-analogue region and
418 reconstructs a paleotemperature range of 8–20°C for the Oligocene–Miocene at Site
419 U1356, with values in excess of 24°C for the late Oligocene (Hartman et al., submitted,
420 this volume). Further, supporting evidence for temperate Oligocene–Miocene surface
421 waters comes from the abundance of nannofossils encountered in the sediments
422 (Escutia et al., 2011; Salabarnada et al., submitted this volume). Today, carbonate-
423 producing plankton is rare in high-latitude surface waters south of the AAPF (Eynaud
424 et al., 1999). Moreover, the remains of the few pelagic carbonate-producing
425 organisms living at high latitudes rarely reach the ocean floor because of strong
426 upwelling of relatively CO₂-rich, corrosive waters (e.g., Olbers et al., 2004). Hence, the
427 presence of carbonate-rich intervals during the Oligocene–Miocene at Site U1356

428 along with the encountered oligotrophic, temperate dinocysts suggests
429 fundamentally warmer surface-water conditions than today.

430

431 5.1.3 Surface paleoceanography

432 The strong similarity of Oligocene–Miocene dinocyst assemblages at Site U1356 with
433 those today occurring much further north (i.e., around Tasmania and Southern New
434 Zealand (Prebble et al., 2013) suggests a fundamentally different *modus operandi* of
435 Southern Ocean surface oceanography. The strict latitudinal separation of dinocyst
436 assemblages in the Southern Ocean today (Prebble et al., 2013) is likely due to
437 different surface water masses present across the oceanic fronts where strong wind-
438 driven divergence around 60° S (known as the Antarctic Divergence; e.g., Olbers et al.,
439 2004), strong sea-ice season and/or the vigorous Antarctic Circumpolar Current are
440 in place. The strength and position of the AAPF during the Oligocene–Miocene is not
441 well understood. Climate model (GCM) experiments under Miocene boundary
442 conditions suggest that west and east wind drifts prevailed south and north of 60°S,
443 respectively (Herold et al., 2011). This wind orientation determined the average
444 position of the Antarctic Divergence at 60°S during the Oligocene and Miocene,
445 similar to today. This suggests that Site U1356 was likely directly overlain by the
446 AAPF. However, the significantly warmer, more oligotrophic dinocyst assemblages off
447 Wilkes Land throughout the Oligocene–Miocene argue against proximity to the AAPF.
448 The position of the AAPF relative to that of Site U1356 strongly determines the
449 likelihood of southward transport of low-latitude waters towards the site. A
450 southward position of the AAPF relative to Site U1356 would greatly enhance the
451 possibility for a southward migration of temperate surface water masses towards the

452 site. A northward position of the AAPF relative to the site would make such a
453 latitudinal migration much more difficult. The presence of carbonate in these deep
454 marine sediments also suggests that upwelling of corrosive waters through the
455 (proto-)Antarctic Divergence was either much reduced or located elsewhere.
456 Therefore, we deduce that the occurrence of the oligotrophic, temperate dinocysts is
457 an evidence for a southward position of the AAPF relative to the position of Site
458 U1356. This would allow a higher connectivity between the site and the lower
459 latitudes, and promote preservation of carbonate on the sea floor. Also, such an
460 oceanographic setting would be in line with reduced sea ice along the Wilkes Land
461 margin.

462 The separate averaging of dinocyst assemblages for glacial and interglacial
463 facies from Site U1356 (Figure 7) allows us to reconstruct glacial-interglacial changes
464 in surface-water conditions throughout the Oligocene. First of all, our observations
465 suggest that Oligocene glacial-interglacial cycles were connected to substantial
466 paleoceanographic dynamics off Wilkes Land. In agreement with the 2–3 °C SST
467 variability as documented for this site during glacial-interglacial cycles (Hartman et
468 al., submitted, this volume), dinocyst assemblages contain more oligotrophic,
469 temperate dinocysts during interglacial times compared to glacial times when more
470 eutrophic, colder dinocysts proliferated (Fig. 7). This could be the result of a slight
471 latitudinal movement of oceanic frontal systems (notably the AAPF) as it has been
472 reconstructed for the Southern Ocean fronts during the most recent glacial to
473 interglacial transition (e.g., Bard and Rickaby, 2009; Kohfeld, et al., 2013; Xiao et al.,
474 2016). In such a scenario, the AAPF would reach a southern position during
475 interglacials, allowing for temperate oligotrophic surface waters to reach the site,

476 while it would migrate northward over Site U1356 during glacials, thereby causing
477 cold, high-nutrient surface-water conditions and obstructing low-latitude influence.

478

479 5.2 Implications for Oligocene–Miocene ocean circulation

480 At Site U1356, dinocyst assemblages bear similarities to present-day proximal-
481 Antarctic assemblages (Prebble et al., 2013) only in the lowermost Oligocene and in
482 strata deposited after the mid-Miocene Climate Optimum (after 14.2 Ma); in
483 particular, they are characterized by high abundances (up to 39%) of *Selenopemphix*
484 *antarctica*. Even in those intervals, however, the relative abundances of *S. antarctica*
485 do not reach present-day values at the same site (Prebble et al., 2013). The absence of
486 a strong shift towards modern-day-like assemblages in our record can be interpreted
487 to reflect a weaker-than-present ACC. This interpretation is in line with numerical
488 models (Herold et al., 2012; Hill et al., 2013). The ACC itself represents an important
489 barrier for latitudinal surface-water transport towards the Antarctic margin, in
490 addition to the Antarctic Divergence (Olbers et al., 2004). Our data suggest an
491 increase in the influence of oligotrophic dinocysts at the Antarctic margin during the
492 late Oligocene and during the MMCO, which argues against the installation of a
493 vigorous ACC at 30 Ma as recently inferred by Scher et al. (2015): No particular
494 change in sea-surface conditions emerges from our dinoflagellate cyst data around 30
495 Ma, and there is no major change in the benthic $\delta^{18}\text{O}$ data either (Figure 5). Instead, if
496 the Tasmanian Gateway had opened to an extent that allowed ACC development
497 (Scher et al., 2015), the ACC must have been much weaker throughout the Oligocene
498 and Miocene than at present, which has also emerged from modelling experiments
499 (Hill et al., 2013). The strongly different dinocyst assemblages compared to present-

500 day nearby Site U1356 throughout our record imply that a strong coherent ACC was
501 not installed until after the mid-Miocene Climatic Transition (MMCT; 11 Ma). This is
502 consistent with inferences from the lithology at the same site (Salabarnada et al.,
503 submitted, this volume), suggesting a proto-ACC much weaker than at present and,
504 likewise, weaker Southern Ocean frontal systems. An alternative explanation is that
505 the ACC increased in strength during the Oligocene–Miocene, but that this
506 strengthening had no influence on the dinocyst assemblages at Site U1356. However,
507 the vigorous nature of the ACC influencing surface as well as bottom waters and
508 governing eddy water circulation in the Southern Ocean (Olbers et al., 2004) in
509 combination with the high sensitivity of dinoflagellates to changes in surface-water
510 conditions (e.g., Zonneveld et al., 2013; Prebble et al., 2013) makes such a scenario
511 very unlikely. Nevertheless, to firmly clarify whether the ACC reached its present-day
512 strength only after the MMCT (as suggested by our data), ocean-circulation modelling
513 of time slices younger than the Oligocene (Hill et al., 2013) will be required.

514 Our results also seem difficult to reconcile with indications of bottom-water
515 formation at the Wilkes Land margin, as seen from neodymium isotope analyses on
516 the same sediments (Huck et al., 2017). It could be that bottom water formation took
517 place only when surface waters cooled down in wintertime, and the organic proxies
518 are more representative of spring/summer conditions. Salabarnada et al. (this
519 volume) interpret bottom-current activity in the Oligocene at Site U1356 and suggest
520 it may be spilling over from the Ross Sea, like today. Our dinocyst results and the SST
521 reconstructions by Hartman et al. (submitted this volume) suggest that surface
522 waters at the Wilkes Land margin were too warm to allow local bottom-water

523 formation, therefore our data also supports the suggestion that bottom water along
524 the Wilkes Land margin was sourced from the Ross Sea.

525

526 5.3 Implications for ice-sheet and sea-ice variability

527 The relative abundances of the sea-ice-related *Selenopemphix antarctica* are
528 consistently lower in our record than in present-day dinocyst assemblages nearby
529 Site U1356 (Prebble et al., 2013; Figure 3). This suggests that sea-ice conditions were
530 never similar to today during the studied time interval. More specifically, our
531 dinocysts suggest the occurrence of sea ice near the site only during two time
532 intervals: The first 1.5 million years following the Oi-1 glaciation (33.6–32.1 Ma;
533 Figure 5), and during and after the mid-Miocene climatic Transition (after 14.2 Ma;
534 Figure 5). Numerical ice-sheet/sea-ice modelling (DeConto et al., 2007) has suggested
535 sea-ice to develop only if the continental ice sheets reach the coastline. Our lack of
536 sea-ice indicators during most of the Oligocene and Miocene could thus point towards
537 a much-reduced Antarctic continental ice sheet during that time. The finding of a
538 weaker sea-ice season throughout most of the Oligocene–Miocene at Site U1356 is
539 important because it suggests a decrease in the potential formation of Antarctic
540 bottom waters at this site.

541 The relative abundance of oligotrophic dinocyst taxa broadly follows long-
542 term Oligocene-Miocene benthic $\delta^{18}\text{O}$ trends (see Fig. 5): During times of low $\delta^{18}\text{O}$
543 values in deep-sea benthic foraminifera (and thus high deep-sea temperatures and/or
544 less ice volume; e.g., at 32 Ma, 24 Ma and 15 Ma; Figure 5), the abundance of
545 oligotrophic temperate dinocysts was high (Figure 5). At times of higher $\delta^{18}\text{O}$ values,
546 lower deep-sea temperatures and higher ice volume (e.g., at 33.5 Ma, 27 Ma, 23 Ma,

547 and 13 Ma; Figure 5), temperate dinocysts were reduced in abundance and high-
548 nutrient, sea-ice indicators (re)appeared. Altogether, on long time scales this pattern
549 suggests that there was a stronger influence of warm surface waters at the Wilkes
550 Land margin at times when ice sheets were smaller and climate was warmer, and less
551 influence of warm surface waters during times of larger ice sheets. Hence a
552 connection existed between ice- sheet expansion/retreat and paleoceanography.

553 Oxygen-isotope mass-balance calculations suggest that a modern-day-sized
554 Antarctic ice sheet formed at the Eocene/Oligocene boundary (DeConto et al., 2008).
555 Benthic $\delta^{18}\text{O}$ records suggest that ice sheets must have fluctuated considerably in size
556 during the subsequent Oligocene and Miocene (Liebrand et al., 2017), although this
557 inference lacks an independent assessment of the deep-sea temperature effect in
558 these $\delta^{18}\text{O}$ values. The same conclusion was reached based on detailed microfossil,
559 geochemical and facies analyses on sediments from the Gippsland Basin, southeast
560 Australia (Gallagher, et al. 2013). This study suggests that ice volume during the early
561 Oligocene varied by as much as 140–40% of its present-day size, of which the
562 maximum ice volume estimates far exceed those implied by our data. However, there
563 is consistency in the observation of considerable glacial-interglacial and long-term
564 dynamics in the ice-ocean system. This is in contrast to the heavy $\delta^{18}\text{O}$ values for
565 Oligocene benthic foraminifera from Maud Rise (ODP Site 690), which lead to suggest
566 Antarctic ice sheets were near-present-day size throughout the Oligocene
567 (Hauptvogel et al., 2017). It remains to be seen whether the variability in
568 paleoceanography as indicated by our data can be extrapolated to larger parts of the
569 Antarctic margin, including regions of deep-water formation. Given the high
570 temperatures and only weak sea-ice influence, the Wilkes Land margin was likely not

571 the primary sector of deep-water formation (see, e.g., Herold et al., 2012), although
572 there is ample evidence for bottom-current activity at the site (Salabarnada et al.,
573 submitted, this volume; Huck et al., 2017). Instead, it appears that bottom-water
574 formation during the Oligocene was taking place along the Wilkes Land coast (Huck,
575 et al. 2017). If the oceanographic and climate variability that we reconstruct offshore
576 Wilkes Land also characterises regions of deep-water formation, some (if not all) of
577 the variability both on long and on orbital time scales as documented in benthic $\delta^{18}\text{O}$
578 records would be due to changes in deep-sea temperature rather than Antarctic ice
579 volume (see also Hartman et al., submitted, this volume). Meanwhile, we find little
580 support in our study for the large (and, by implication, marine-terminating)
581 continental ice sheets in this sector of East Antarctica during the Oligocene as implied
582 by Hauptvogel et al. (2017) given the absence of dominance of sea-ice dinocysts and
583 the presence of in situ terrestrial palynomorphs (Strother et al., 2017). As an
584 alternative explanation for the difference in $\delta^{18}\text{O}$ values between Maud Rise (Site
585 690) and the equatorial Pacific (Site 1218) during the Oligocene (Hauptvogel et al.,
586 2017), we suggest that these two sedimentary archives have recorded the
587 characteristics of two different deep-water masses, with those at Maud Rise (Site
588 690) being much colder and more saline than those in the equatorial Pacific (Site
589 1218).

590

591 **6. Conclusions**

592 The dinocyst assemblages in the Oligocene–Miocene (33.6–11 Ma) of Site U1356 were
593 interpreted in terms of surface-water paleoceanography via comparison with
594 present-day dinocyst distribution patterns. Based on our results, we suggest that the

595 Oligocene–Miocene surface paleoceanography of the Southern Ocean was
596 fundamentally different from that of today. A sea-ice signal (yet still weaker than at
597 present) emerges for the Wilkes Land margin only for the first 1.5 million years of the
598 Oligocene (33.6–32.1 Ma) and during and after the mid-Miocene climatic transition
599 (after 14.2 Ma). During the remainder of the Oligocene–Miocene, surface waters off
600 Wilkes Land were warm and relatively oligotrophic; notably, they lack indications of
601 a prominent sea-ice season. Upwelling at the Antarctic Divergence was profoundly
602 weaker during Oligocene and Miocene times than at present, or significantly
603 displaced southward from its present-day position. Furthermore, the continental ice
604 sheets were much reduced at the Wilkes Land sub-glacial basin for most of the
605 Oligocene–Miocene compared to today. The influence of warm oligotrophic surface
606 waters appears strongly coupled to deep-sea $\delta^{18}\text{O}$ values, suggesting enhanced low-
607 latitude influence of surface waters during times of light $\delta^{18}\text{O}$ in the deep sea and *vice*
608 *versa*. The absence of (a trend towards a stronger) paleoceanographic isolation of the
609 Wilkes Land margin throughout the Oligocene to mid-Miocene suggests that the ACC
610 may not have attained its full, present-day strength until at least after the mid-
611 Miocene Climatic transition. Moreover, we note considerable glacial-interglacial
612 amplitude variability in this oceanographic setting. Stronger influence of oligotrophic,
613 low-latitude-derived surface waters prevailed over Site U1356 during interglacial
614 times and more eutrophic, colder waters during glacial times. This pattern may
615 suggest considerable latitudinal migration of the AAPF over the course of Oligocene
616 and Miocene glacial-interglacial cycles.

617

618 **Acknowledgements**

619 This research used data and samples from the Integrated Ocean Drilling Program
620 (IODP). IODP was sponsored by the U.S. National Science Foundation and
621 participating countries under management of Joined Oceanographic Institutions Inc.
622 PKB and FS thank NWO-NNPP grant no 866.10.110, NWO-ALW VENI grant no
623 863.13.002 for funding and Natasja Welters for technical support. JP acknowledges
624 support through the IODP priority program of the German Research Foundation
625 (DFG). CE and AS thank the Spanish Ministerio de Economía y Competitividad for
626 Grant CTM2014-60451-C2-1-P. We thank Kasia Śliwińska, Stephen Gallagher and an
627 anonymous reviewer for their constructive comments that considerably improved
628 our manuscript.

629

630 **Author contributions**

631 PKB, FS, CE, and JP designed the research. AJPH, FS and PKB carried out dinocyst
632 analyses for the earliest Oligocene, Miocene, and Oligocene-Miocene boundary
633 interval, respectively. AS and CE provided the lithological data. PKB integrated, cross-
634 validated and compiled the data, and wrote the paper with input from all co-authors.

659 Figure 4. Core recovery and lithostratigraphic facies (after Salabarnada et al., this
660 volume, and Sangiorgi et al., 2018) and lithologic units (Escutia et al., 2011),

661 chronostratigraphic epochs (E = Eocene) and stages (L = Lutetian, Burd. =
662 Burdigalian, Ser. = Serravallian, T. = Tortonian), absolute palynomorph (grey) and in
663 situ dinocyst (black) concentrations (# per gram of dry sediment, presented on a
664 logarithmic scale), palynomorph content (reworked dinocysts, in situ dinocysts,
665 acritarchs, terrestrial palynomorphs (given in percentages of total palynomorphs),
666 and relative abundance of in situ dinocyst eco-groups (in percentage of in situ
667 dinocysts) for the Oligocene–Miocene of Hole U1356A.

668

669 Figure 5. Compilation of benthic foraminiferal oxygen isotope data from Site 588
670 (Zachos et al., 2008), Site 1090 (Zachos et al., 2008) Site 1218 (Pälike et al., 2006), ,
671 Sites 1264/1265 (Liebrand et al., 2017), Site U1334 (Holbourn et al., 2015), Site
672 U1337 (Beddow et al., 2016), all calibrated to the GTS2012 time scale (Gradstein et
673 al., 2012) with in situ dinocyst assemblage data from Site U1356 (see Fig. 4 for
674 legend). For presentation of the dinocyst data (see Fig. 4 for legend), the age-depth
675 model specified in Figure 2 and Table 1 was used.

676

677 Figure 6. Comparison of absolute (left bar, in # * gr⁻¹ dry weight) and relative (right
678 bar; in % of total palynomorphs) abundances of palynomorph groups per lithology
679 for Hole U1356A. Average (black lines) and 17–83% percentile (coloured bar) of
680 absolute and relative abundances of total palynomorphs, reworked dinocysts, in situ
681 dinocysts, acritarchs, and terrestrial palynomorphs grouped for the different facies
682 (Salabarnada et al., submitted this volume).

683

684 Figure 7. Abundance/concentration of in situ eco-groups within various lithologies at
685 Hole U1356A. Average (black line) and 17–83% percentile (coloured bar) of relative
686 abundances of grouped taxa from samples from the different facies (Salabarnada et
687 al., submitted this volume).

688

689 **Table captions**

690 Table 1. Age constraints for the Oligocene–Miocene of Hole U1356A.

691 Table 2. List of assumed in situ and reworked dinoflagellate cyst taxa encountered in
692 this study. See Bijl et al. (2018) for informal species descriptions and discussion about
693 which species are considered reworked and in situ.

In situ taxa
<i>Adnatosphaeridium?</i> sp.
<i>Ataxodinium choane</i>
<i>Batiacasphaera compta</i>
<i>Batiacasphaera</i> spp. (pars.)
<i>Batiacasphaera hirsuta</i>
<i>Batiacasphaera micropapillata</i>
<i>Batiacasphaera minuta</i>
<i>Batiacasphaera sphaerica</i>
<i>Batiacasphaera</i> sp. A
<i>Batiacasphaera</i> sp. B
<i>Batiacasphaera</i> sp. C
<i>Batiacasphaera</i> sp. D
<i>Brigantedinium simplex</i>
<i>Brigantedinium pynei</i>
<i>Brigantedinium</i> sp. A
<i>Brigantedinium</i> sp. B
<i>Brigantedinium</i> sp. C
<i>Brigantedinium</i> sp. D
<i>Cerebrocysta</i> WR small
<i>Cerebrocysta delicata</i>
<i>Cerebrocysta</i> sp. A
<i>Cleistosphaeridium</i> sp. B
<i>Cleistosphaeridium</i> sp. A
<i>Cordosphaeridium minutum</i>
<i>Corrudinium labradori</i>
<i>Corrudinium</i> sp. A
<i>Cryodinium?</i> sp.
<i>Distatodinium</i> spp.
<i>Edwardsiella sexispinosa</i>
<i>Elytrocysta</i> sp. A
<i>Elytrocysta brevis</i>
<i>Gelatia inflata</i>
<i>Habibacysta?</i> spp.
<i>Homotryblum</i> spp.
<i>Hystrichokolpoma bullatum</i>
<i>Huystrichosphaeropsis obscura</i>
<i>Impagidinium</i> spp. (pars)
<i>Impagidinium aculeatum</i>
<i>Impagidinium cantabrigiense</i>
<i>Impagidinium elegans</i>
<i>Impagidinium elongatum</i>
<i>Impagidinium pacificum</i>
<i>Impagidinium pallidum</i>
<i>Impagidinium paradoxum</i>
<i>Impagidinium patulum</i>
<i>Impagidinium plicatum</i>
<i>Impagidinium velorum</i>
<i>Impagidinium victorianum</i>
<i>Impagidinium</i> sp. A
<i>Impagidinium sphaericum</i>
<i>Invertocysta tabulata</i>
<i>Islandinium</i> spp.
<i>Lejeunecysta attenuata</i>
<i>Lejeunecysta adeliense</i>
<i>Lejeunecysta fallax</i>
<i>Lejeunecysta cowei</i>
<i>Lejeunecysta acuminata</i>
<i>Lejeunecysta rotunda</i>
<i>Lejeunecysta katatonos</i>
<i>Malvinia escutiana</i>
<i>Nematosphaeropsis labyrinthus</i>
<i>Oligokolpoma galeotti</i>
<i>Operculodinium tiara</i>
<i>Operculodinium</i> sp. A
<i>Operculodinium piaseckii</i>
<i>Operculodinium janduchenei</i>
<i>Operculodinium cf eirikianum</i>
<i>Operculodinium eirikianum</i>
<i>Paleocystodinium golzowense</i>
<i>Paucisphaeridium</i> spp.
<i>Phthanoperidinium amoenum</i>
<i>Pyxidinopsis</i> spp. (pars)
<i>Pyxidinopsis</i> sp. A
<i>Pyxidinopsis</i> sp. B
<i>Pyxidinopsis</i> sp. C
<i>Pyxidinopsis</i> sp. D
<i>Pyxidinopsis vesiculata</i>
<i>Pyxidinopsis tuberculata</i>
<i>Pyxidinopsis reticulata</i>
<i>Pyxidinopsis fairhavensis</i>
<i>Reticulatosphaera actinocoronata</i>
<i>Selenopemphix antarctica</i>
<i>Selenopemphix nephroides</i>
<i>Selenopemphix dioneacysta</i>
<i>Selenopemphix</i> sp. A
<i>Selenopemphix undulata</i>
<i>Selenopemphix brinkhushi</i>
<i>Spiniferites</i> sp. B
<i>Spiniferites</i> sp. A
<i>Spiniferites</i> sp. C
<i>Stoveracysta ornata</i>
<i>Stoveracysta kakanuliensis</i>
? <i>Svalbardella</i> spp.
<i>Tectatodinium</i> spp.
<i>Unipontedinium aqueductus</i>
<i>Protoperidinioid</i> indet.
<i>Protoperidinium</i> sp. B
<i>Protoperidinium</i> sp. A
<i>Protoperidinium</i> sp. C
<i>Protoperidinium</i> sp. D

Reworked taxa
<i>Achilleodinium biformoides</i>
<i>Achomosphaera allicornu</i>
<i>Aiora fenestrata</i>
<i>Aireiana verrucosa</i>
<i>Adnatosphaeridium</i> spp.
<i>Alisocysta circumtabulata</i>
<i>Alterbidinium distinctum</i>
<i>Apectodinium</i> spp.
<i>Arachnodinium antarcticum</i>
<i>Areoligera</i> spp. (pars)
<i>Areoligera semicircularata</i>
<i>Cerebrocysta bartonensis</i>
<i>Charlesdowniea clathrata</i>
<i>Charlesdowniea edwardsii</i>
<i>Cooksonidinium capricornum</i>
<i>Cordosphaeridium fibrospinosum</i>
<i>Cordosphaeridium furniculatum</i>
<i>Corrudinium incompositum</i>
<i>Corrudinium regulare</i>
<i>Cribroperidinium</i> spp.
<i>Damassadinium crassimuratum</i>
<i>Dapsillidinium</i> spp.
