21

22 **ABSTRACT**

23 The Beaufort Gyre (BG) and the Bering Strait inflow (BSI) are important elements of
24 the Arctic Ocean circulation system and major controls on the distribution of Arctic sea

25 ice. We report records of the quartz/feldspar and chlorite/illite ratios in three sediment
26 cores from the northern Chukchi Sea providing insights into the long-term dynamics of
27 the BG circulation and the BSI during the Holocene. The quartz/feldspar ratio, a proxy
28 of the BG strength, gradually decreased during the Holocene, suggesting a long-term
29 decline in the BG strength, consistent with orbitally-controlled decrease in summer
30 insolation. We suppose that the BG rotation weakened as a result of increasing stability
31 of sea-ice cover at the margins of the Canada Basin, driven by decreasing insolation.
32 Millennial to multi-centennial variability in the quartz/feldspar ratio (the BG
33 circulation) is consistent with fluctuations in solar irradiance, suggesting that solar
34 activity affected the BG strength on these timescales. The BSI approximation by the
35 chlorite/illite record, despite a considerable geographic variability, consistently shows
36 intensified flow from the Bering Sea to the Arctic during the middle Holocene, which is
37 attributed primarily to the effect of higher atmospheric pressure over the Aleutian Basin.
38 The intensified BSI was associated with decrease in sea-ice concentrations and increase
39 in marine production, as indicated by biomarker concentrations, suggesting a major
40 influence of the BSI on sea-ice and biological conditions in the Chukchi Sea.
41 Multi-century to millennial fluctuations, presumably controlled by solar activity, were
42 also identified in a proxy-based BSI record characterized with the highest age
43 resolution.

44

45 **1. Introduction**

46 The Arctic currently faces rapid climate change caused by global warming (e.g.,
47 Screen and Simmonds, 2010; Harada, 2016). Changes in the current system of the
48 Arctic Ocean regulate the state of Arctic sea ice and are involved in global processes via

49 ice albedo feedback and the delivery of freshwater to the North Atlantic Ocean (Miller
50 et al., 2010; Screen and Simmonds, 2010). The most significant consequence of this
51 climate change during recent decades is the retreat of summer sea ice in the Pacific
52 sector of the Arctic (e.g., Shimada et al., 2006; Harada et al., 2016, and references
53 therein). Inflow of warm Pacific water through the Bering Strait (hereafter Bering Strait
54 Inflow [BSI]) is suggested to have caused catastrophic changes in sea-ice stability in the
55 western Arctic Ocean (Shimada et al., 2006). Comprehending these changes requires
56 investigation of a longer-term history of circulation in the western Arctic and its
57 relationship to atmospheric forcings. Within this context, the Chukchi Sea is a key
58 region to understand the western Arctic current system as it is located at the crossroads
59 of the BSI and the Beaufort Gyre (BG) circulation in the western Arctic Ocean (Fig. 1)
60 (e.g., Winsor and Chapman, 2004; Weingartner et al., 2005).

61 In this paper we apply mineralogical proxies of the BG and BSI to sediment cores
62 with a century-scale resolution from the northern margin of the Chukchi shelf. The
63 generated record provides new understanding of changes in the BG circulation and BSI
64 strength during most of the Holocene (last ~9 ka). We discuss the possible causes and
65 forcings of the BG and BSI variability, as well as its relationship to sea-ice history and
66 biological production in the western Arctic.

67

68 **2. Background information**

69 ***2.1. Oceanographic settings***

70 The wind-driven surface current system of the Arctic Ocean consists of the BG and
71 the Transpolar Drift (TPD) (Proshutinsky and Johnson, 1997; Rigor et al., 2002). This
72 circulation is controlled by the atmospheric system known as the Arctic Oscillation

73 (AO) (Rigor et al., 2002). When the AO is in the positive phase, the BG shrinks back
74 into the Beaufort Sea, the TPD expands to the western Arctic Ocean, and the sea-ice
75 transport from the eastern Arctic to the Atlantic Ocean is intensified. When the AO is in
76 negative phase, the BG expands, the TPD is limited to the eastern Arctic, and sea ice is
77 exported efficiently from the Canada Basin to the eastern Arctic. Thus, sea-ice
78 distribution is closely related to the current system.

79 A dramatic strengthening of the BG circulation occurred during the last two decades
80 (Shimada et al., 2006; Giles et al., 2012). This change was attributed to a recent
81 reduction in sea-ice cover along the margin of the Canada Basin, which caused a more
82 efficient transfer of the wind momentum to the ice and underlying waters in the BG
83 (Shimada et al., 2006). The delayed development of sea ice in winter enhanced the
84 western branch of the Pacific Summer Water across the Chukchi Sea. This anomalous
85 heat flux into the western part of the Canada Basin retarded sea-ice formation during
86 winter, thus, further accelerating overall sea-ice reduction.

87 The BSI, an important carrier of heat and freshwater to the Arctic, transports the
88 Pacific water to and across the Chukchi Sea, interacts with the BG circulation at the
89 Chukchi shelf margin (e.g., Shimada et al., 2006). Mooring data suggest that an increase
90 in the BSI volume by ~50% from 2001 (~0.7 Sv) to 2011 (~1.1 Sv) has driven an
91 according increase in the heat flux from $\sim 3 \times 10^{20}$ J to $\sim 5 \times 10^{20}$ J (Woodgate et al.,
92 2012). After passing the Bering Strait the BSI flows in three major branches. One
93 branch, the Alaskan Coastal Current (ACC), runs northeastward along the Alaskan coast
94 as a buoyancy-driven boundary current (Red arrow in Fig. 1; Shimada et al., 2001;
95 Pickart, 2004; Weingartner et al., 2005). The second, central branch follows a seafloor
96 depression between Herald and Hanna Shoals, then turns eastward and merges with the

97 ACC (Yellow arrow in Fig. 1; Winsor and Chapman, 2004; Weingartner et al., 2005).
98 The third branch flows northwestward, especially when easterly winds prevent the ACC
99 (Winsor and Chapman, 2004). This branch may then turn eastward along the shelf break
100 (Blue arrow in Fig. 1; Pickart et al., 2010).

101 The BSI is driven by a northward dip in sea level between the North Pacific and the
102 Arctic Ocean (Shtokman, 1957; Coachman and Aagaard, 1966). There has been a
103 long-standing debate, whether this dipping is primarily controlled by steric difference
104 (Stigebrandt, 1984) or from wind-driven circulations (Gudkovitch, 1962). Stigebrandt
105 (1984) assumed that the salinity difference between the Pacific and Atlantic Oceans
106 causes the steric height difference between the Bering Sea and the Arctic Ocean.
107 Aagaard et al. (2006) argued that the local salinity in the northern Bering Sea controlled
108 the BSI, although wind can considerably modify the BSI on a seasonal timescale. De
109 Boer and Nof (2004) proposed a model that the mean sea level difference along the
110 strait is set up by the global winds, particularly the strong Subantarctic Westerlies.

111 Recently, a conceptual model of the BSI controls has been developed based on a
112 decade of oceanographic observations (Danielson et al., 2014). According to this model,
113 storms centered over the Bering Sea excite continental shelf waves on the eastern
114 Bering shelf that intensify the BSI on synoptic time scales, but the integrated effect of
115 these storms tends to decrease the BSI on annual to decadal time scales. At the same
116 time, an eastward shift and overall strengthening of the Aleutian Low pressure center
117 during the period between 2000–2005 and 2005–2011 increased the sea level pressure
118 in the Aleutian Basin south of the Bering Strait by 5 hPa, in contrast to overall
119 decreased pressure of the Aleutian Low system, thus decreasing the water column
120 density through isopycnal uplift by weaker Ekman suction. This change thereby raised

121 the dynamic sea surface height by 4.2 m along the Bering Strait pressure gradient,
122 resulting in the BSI increase by 4.5 cm/s, or 0.2 Sv (calculated based on the
123 cross-section area of $4.25 \times 10^6 \text{ m}^2$). This increase constitutes about one quarter of the
124 average long-term BSI volume of $\sim 0.8 \text{ Sv}$ (Roach et al., 1995). Such a large
125 contribution clearly identifies changes in the Aleutian Low strength and position as a
126 key factor regulating the BSI on inter-annual time scales.

127 The BSI also transports nutrients from the Pacific to the Arctic. A rough estimation
128 suggests that the BSI waters significantly contribute to marine production in the Arctic
129 (Yamamoto-Kawai et al., 2006). High marine production in the Chukchi Sea of up to
130 $400 \text{ gC m}^{-2} \text{ y}^{-1}$ in part is thought to reflect the high nutrient fluxes by the BSI (Walsh
131 and Dieterle, 1994; Sakshaug, 2004). A recent enhancement of biological productivity
132 and the biological pump in the Beaufort and Chukchi Seas has been associated with the
133 retreat of sea ice (summarized by Harada et al., 2016). This phenomenon is attributed to
134 an increase of irradiance in the water column (Frey et al., 2011; Lee and Whitledge,
135 2005), wind-induced mixing that replenishes sea surface nutrients (Carmack et al.,
136 2006), and their combination (Nishino et al., 2009). However, the nutrient flux into the
137 Arctic Ocean was not evaluated in this context. The investigation of BSI intensity and
138 marine production during the Holocene will be useful to understand on-going changes
139 in marine production in the Arctic Ocean.

140

141 ***2.2. Mineral distribution in the Chukchi Sea sediments***

142 Spatial variation in mineral composition of surficial sediments along the western
143 Arctic margin has been investigated in a number of studies using different
144 methodological approaches but showing an overall consistent picture (e.g., Naidu et al.,

145 1982; Naidu and Mowatt, 1983; Wahsner et al., 1999; Kalinenko, 2001; Viscosi-Shirley
146 et al., 2003; Darby et al., 2011; Kobayashi et al., 2016). A recent study of mineral
147 distribution in sediments from the Chukchi Sea and adjacent areas of the Arctic Ocean
148 and the Bering Sea suggests that the quartz/feldspar (Q/F) ratio is higher on the North
149 American than on the Siberian side of the western Arctic (Fig. 2; Kobayashi et al.,
150 2016). These results are consistent with earlier studies including mineral determinations
151 of shelf sediments and adjacent coasts (Vogt, 1997; Stein, 2008). Darby et al. (2011)
152 show a trend of decreasing Q/F ratio in dirty sea ice from North American margin to the
153 Chukchi Sea and further to the East Siberian Sea. This zonal gradient of the Q/F ratio
154 suggests that quartz-rich but feldspar-poor sediments are derived from the North
155 American margin by the BG circulation, whereas feldspar-rich sediments are delivered
156 to the Chukchi Sea from the Siberian margin by currents along the East Siberian slope
157 (Kobayashi et al., 2016). Thus, this ratio can be used as a provenance index for the BG
158 circulation reflecting changes in its intensity in sediment-core records (Kobayashi et al.,
159 2016).

160 Kaolinite is generally a minor component of clays in the western Arctic but relatively
161 abundant in the Northwind Ridge and Mackenzie Delta areas where the BG circulation
162 exerts an influence (Naidu and Mowatt, 1983; Kobayashi et al., 2016). Kaolinite in the
163 Northwind Ridge originated from ancient rocks exposed on the North Slope and was
164 delivered by water or sea ice via the Beaufort Gyre circulation (Kobayashi et al., 2016).

165 Kobayashi et al. (2016) also indicate that both the (chlorite + kaolinite)/illite and
166 chlorite/illite ratios (CK/I and C/I ratios, respectively) are higher in the Bering Sea and
167 decrease northward throughout the Chukchi Sea, reflecting the diminishing strength of
168 the BSI (Fig. 2). These results are consistent with earlier studies showing that illite is a

169 common clay mineral in Arctic sediments (Kalinenko, 2001; Darby et al., 2011),
170 whereas, chlorite is more abundant in the Bering Sea and the Chukchi shelf areas
171 influenced by the BSI (Naidu and Mowatt, 1983; Kalinenko, 2001; Nwaodua et al.,
172 2014; Kobayashi et al., 2016). Chlorite occurs abundantly near the Bering Sea coasts of
173 Alaska, Canada, and the Aleutian Islands (Griffin and Goldberg, 1963). The
174 chlorite/illite ratio is higher in the bed load of rivers and deltaic sediments from
175 southwestern Alaska than from northern Alaska and East Siberia, reflecting differences
176 in the geology of the drainage basins (Naidu and Mowatt, 1983). Because chlorite
177 grains are more mobile than illite grains under conditions of intense hydrodynamic
178 activity, chlorite grains are transported a long distance from the northern Bering Sea to
179 the Chukchi Sea via the Bering Strait (Kalinenko, 2001). In the surface sediments of the
180 Chukchi Sea, the CK/I ratio shows a good correlation with the C/I ratio, indicating that
181 both ratios can be used as a provenance index for the BSI (Kobayashi et al., 2016).

182 Ortiz et al. (2009) constructed the first chlorite-based Holocene record of the BSI by
183 quantifying the total chlorite plus muscovite abundance based on diffuse spectral
184 reflectance of sediments from a northeastern Chukchi Sea core. The record shows a
185 prominent intensification of the BSI in the middle Holocene. However, a record from
186 just one site is clearly insufficient to characterize sedimentation and circulation history
187 in such a complex area. More records of mineral proxy distribution covering various
188 oceanographic and depositional environments are needed to further our understanding
189 of the evolution of the BSI.

190 The Holocene dynamics of the BG circulation is also poorly understood. A study of
191 sediment core from the northeastern Chukchi slope identified centennial- to
192 millennial-scale variability in the occurrence of Siberian iron oxide grains presumably

193 delivered via the BG (Darby et al., 2012). However, transport of these grains depends
194 not only on the BG, but also on circulation and ice conditions in the Eurasian basin,
195 which complicates the interpretation and necessitates further proxy studies of the BG
196 history.

197

198 **3. Samples and methods**

199 3.1. Coring and sampling

200 This study uses three sediment cores from the northern and northeastern margins of
201 the Chukchi Sea: ARA02B 01A-GC (gravity core; 563 cm long; 73°37.89'N,
202 166°30.98'W), HLY0501-05JPC/TC (jumbo piston core/trigger; 1648 cm long,
203 72°41.68'N, 157°31.20'W) and HLY0501-06JPC (1554 cm long; 72°30.71'N,
204 157°02.08'W) collected from 111 m, 462 m and 673 water depth, respectively (Fig. 1).
205 The sediments in 01A-GC and in the Holocene part of 05JPC/TC (0–1300 cm) and
206 06JPC (0–935 cm) consist predominantly of homogeneous clayey silt (fine-grained
207 unit). This unit of cores 05JPC and 06JPC is underlain by a more complex
208 lithostratigraphy with laminations and coarse ice rafted debris indicative of
209 glaciomarine environments affected by glacial/deglacial processes (“glaciomarine unit”;
210 McKay et al., 2008; Lisé-Pronovost et al., 2009; Polyak et al., 2009).

211 In total 110 samples were collected for mineralogical analysis from core 01A-GC at
212 intervals averaging 5 cm, equivalent to approximately 80–90 years (see chronology
213 description below), down to a depth of 545 cm (ca. 9.3 ka). In core 05JPC/TC, 44
214 samples were collected from fine-grained unit at intervals averaging 30 cm (equivalent
215 to approximately 210–220 years) down to a depth of 1286 cm (ca. 9.3 ka), and 7
216 samples were collected from the underlying glaciomarine sediments. In core 06JPC, 79

217 samples were collected from fine-grained unit at intervals of 10 cm (equivalent to
218 approximately 90 years) down to a depth of 937 cm (ca. 8.0 ka), and 46 samples were
219 collected from the underlying glaciomarine unit.

220 We also analyzed 16 surface sediment samples (0–1 cm) from the eastern Beaufort
221 Sea near the Mackenzie River delta and 3 surface sediment samples from the western
222 Beaufort Sea to fill the gaps in the dataset of Kobayashi et al. (2016) (Fig. 2). These
223 samples were obtained during the RV Araon cruises in 2013 and 2014 (ARA04C and
224 ARA05C, respectively; supplementary table 1).

225

226 3.2. Chronology

227 Age for core 01A-GC was constrained by seven accelerator mass spectrometry
228 (AMS) ^{14}C ages of mollusc shells (Supplementary Table 2; Stein et al., 2017). The core
229 top in ARA 01-GC may not represent the modern age due to some sediment loss in the
230 coring process. This is indicated by the absence of oxidized brown sediment at the core
231 top, as opposed to a multi-corer collected at the same site. Nevertheless, we believe that
232 the top of 01-GC is close to the sediment surface based on the biomarker distribution.
233 IP_{25} and brassicasterols show a downward decreasing trend in their concentrations in the
234 top 10 cm (Stein et al., 2017). We suppose that this indicates their degradation with
235 burial. A similar extent of brassicasterol concentration decrease occurs also in some of
236 the deeper intervals, but is unique for the upper ~200 cm, while the IP_{25} decrease at the
237 top is unique for the entire record. Therefore, the core top of 01A-GC was assumed to
238 represent sediment surface in the age-depth model. ^{14}C ages were converted to calendar
239 ages using the CALIB7.0 program and marine13 dataset (Reimer et al., 2013). Local
240 reservoir correction (ΔR) for 01A-GC sited in surface waters was assumed 500 years

241 (McNeely et al., 2006; Darby et al., 2012). The age model was constructed by linear
242 interpolation between the ^{14}C datings (3.1–8.6 ka). Ages below the dated range were
243 extrapolated to the bottom of core (9.3 ka).

244 In core 05JPC/TC, age was constrained by six AMS ^{14}C ages of mollusc shells from
245 core 05JPC (Supplementary Table 2; Barletta et al., 2008; Darby et al., 2009). Local
246 reservoir correction (ΔR) was assumed to be 0 years as the core site is washed by
247 Atlantic intermediate water (Darby et al., 2012). Concurrent age constraints for 05JPC
248 were provided by ^{210}Pb determinations in the upper part (05TC) and paleomagnetic
249 analysis (Barletta et al., 2008; McKay et al., 2008). The age model for core 05JPC/TC
250 was constructed by linear interpolation between the ^{14}C datings (2.4–7.7 ka) as well as
251 the assumed modern age of the 05TC top, with the assumption that the offset of JPC to
252 TC is 75 cm (Darby et al., 2009). Ages below the dated range were extrapolated to the
253 bottom of homogenous fine-grained unit at 1300 cm (9.4 ka).

254 In core 06JPC, age was tentatively constrained by ten paleointensity datums based on
255 regional paleomagnetic chronology and a ^{14}C age of benthic foraminifera (8.16 ka at
256 918 cm) (Supplementary Table 2; Lisé-Pronovost et al., 2009), with the assumption that
257 the offset of JPC to TC is 147 cm (Ortiz et al., 2009). The age model for core 06JPC
258 was constructed by linear interpolation between the paleointensity datums (2.0–7.9 ka).

259

260 3.3. XRD mineralogy Mineral composition was analyzed on MX-Labo X-ray
261 diffractometer (XRD) equipped with a $\text{CuK}\alpha$ tube and monochromator. The tube
262 voltage and current were 40 kV and 20 mA, respectively. Scanning speed was $4^\circ/2\theta/\text{min}$
263 and the data sampling step was $0.02^\circ/2\theta$. Each powdered sample was mounted on a glass
264 holder with a random orientation and X-rayed from 2 to $40^\circ/2\theta$. An additional precise

265 scan with a scanning speed of $0.2^{\circ}2\theta/\text{min}$ and sampling step of $0.01^{\circ}2\theta$ from 24 to
266 $27^{\circ}2\theta$ was conducted to distinguish chlorite from kaolinite by evaluation of the peaks
267 around $25.1^{\circ}2\theta$ (Elvelhøi and Rønningsland, 1978). In this study, the
268 background-corrected diagnostic peak intensity was used for evaluating the abundance
269 of each mineral. The relative XRD intensities of quartz at $26.6^{\circ}2\theta$ ($d = 3.4 \text{ \AA}$), feldspar
270 including both plagioclase and K-feldspar at $27.7^{\circ}2\theta$ ($d = 3.2 \text{ \AA}$), illite including mica at
271 $8.8^{\circ}2\theta$ ($d = 10.1 \text{ \AA}$), chlorite including kaolinite (called “chlorite+kaolinite” hereafter)
272 at $12.4^{\circ}2\theta$ ($d = 7.1 \text{ \AA}$), kaolinite at $24.8^{\circ}2\theta$ ($d = 3.59 \text{ \AA}$), chlorite at $25.1^{\circ}2\theta$ ($d = 3.54$
273 \AA), and dolomite at $30.9^{\circ}2\theta$ ($d = 2.9 \text{ \AA}$) were determined using MacDiff software
274 (Petschick, 2000) based on the peak identification protocols of Biscaye (1965).

275 The mineral ratios used in this study are defined based on XRD peak intensities (PI)
276 as:

$$277 \quad Q/F = \text{quartz/feldspar} = [\text{PI at } 26.6^{\circ}2\theta]/[\text{PI at } 27.7^{\circ}2\theta]$$

$$278 \quad CK/I = (\text{chlorite+kaolinite})/\text{illite} = [\text{PI at } 12.4^{\circ}2\theta]/[\text{PI at } 8.8^{\circ}2\theta]$$

$$279 \quad C/I = \text{chlorite/illite} = [\text{PI at } 25.1^{\circ}2\theta]/[\text{PI at } 8.8^{\circ}2\theta]$$

$$280 \quad K/I = \text{kaolinite/illite} = [\text{PI at } 24.8^{\circ}2\theta]/[\text{PI at } 8.8^{\circ}2\theta]$$

281 The standard error of duplicate analyses in all samples averaged 1.1, 0.08 and 0.05
282 for Q/F, CK/I and C/I ratios, respectively.

283 Clay minerals (less than $2\text{-}\mu\text{m}$ diameter) in core 01A-GC were separated by the
284 settling method based on the Stokes' law (Müller, 1967). To produce an oriented powder
285 X-ray diffractometry (XRD) sample, the collected clay suspensions were
286 vacuum-filtered onto $0.45\text{-}\mu\text{m}$ nitrocellulose filters and dried. Ethylene glycol ($50 \mu\text{l}$)
287 was then soaked onto the oriented clay on the filters. Glycolated sample filters were
288 stored in an oven at 70°C for four hours and then immediately subjected to XRD

289 analyses. Each sample filter was placed directly on a glass slide and X-rayed with a tube
290 voltage of 40 kV and current of 20 mA. Scanning speed was $0.5^\circ/2\theta/\text{min}$ and the
291 data-sampling step was $0.02^\circ/2\theta$ from 2 to $15^\circ/2\theta$. An additional precise scan with a
292 scanning speed of $0.2^\circ/2\theta/\text{min}$ and sampling step of $0.01^\circ/2\theta$ from 24 to $27^\circ/2\theta$ was
293 conducted to distinguish chlorite from kaolinite by evaluation of the peaks around
294 $25.1^\circ/2\theta$ (Elvelhøi and Rønningsland, 1978). The standard errors of duplicate analyses in
295 all samples averaged 0.05 and 0.06 for CK/I and C/I ratios, respectively.

296 The diffraction intensity of chlorite+kaolinite at 7.1 \AA was significantly positively
297 correlated with that of chlorite at 3.54 \AA ($r = 0.89$), but not with that of kaolinite at 3.59
298 \AA ($r = 0.39$) in western Arctic surface sediments (Kobayashi et al., 2016), indicating that
299 the diffraction intensity of chlorite+kaolinite is governed by the amount of chlorite rather
300 than that of kaolinite.

301 Spectral analyses of the downcore Q/F and C/I variability were performed using the
302 maximum entropy method provided in the Analyseries software package (Paillard et al.,
303 1996).

304

305 **4. Results**

306 ***4.1. Surface sediments of the Beaufort Sea***

307 Because the dataset of Kobayashi et al. (2016) has only one sample in the eastern
308 Beaufort Sea, we added the data of 16 samples from the eastern Beaufort Sea near the
309 Mackenzie delta and 3 samples from the western Beaufort Sea to fill the gaps in their
310 dataset. More clearly than Kobayashi et al. (2016), the new combined dataset shows that
311 the surface sediments in the eastern Beaufort Sea have the higher Q/F and lower CK/I
312 and C/I ratios than those in the Chukchi Sea (Fig. 2A–C; Supplementary table 1).

313 The Q/F ratio showed a westward decreasing trend from the eastern Beaufort Sea to
314 the East Siberian Sea and its offshore area (Fig. 2D). This supports a notion that
315 quartz-rich but feldspar-poor sediments are derived from the North American margin by
316 the BG circulation, whereas feldspar-rich sediments are delivered to the Chukchi Sea
317 from the Siberian margin by currents along the East Siberian slope (Vogt, 1997; Stein,
318 2008; Darby et al., 2011; Kobayashi et al., 2016).

319 The CK/I and C/I ratios showed a northward decreasing trend in the Chukchi Sea and
320 the Chukchi Borderland (Fig. 2E). These results are consistent with earlier studies
321 showing that illite is a common clay mineral in Arctic sediments (Kalinenko, 2001;
322 Darby et al., 2011), whereas, chlorite is more abundant in the Bering Sea and the
323 Chukchi shelf areas influenced by the BSI (Naidu and Mowatt, 1983; Kalinenko, 2001;
324 Nwaodua et al., 2014; Kobayashi et al., 2016).

325 These trends support the conclusion of Kobayashi et al. (2016) mentioning that the
326 Q/F ratio can be used as a provenance index for the BG circulation reflecting a
327 westward decrease in its intensity, and the CK/I and C/I ratios can be used as a
328 provenance index for the BSI reflecting a northward decrease in its intensity. The
329 provenance and transportation of these detrital minerals are discussed in detail in Naidu
330 and Mowatt (1983), Kalinenko (2001), Nwaodua et al. (2014) and Kobayashi et al.
331 (2016).

332

333 ***4.2. Cores 01A-GC, 05JPC/TC and 06JPC***

334 Quartz, feldspar, including plagioclase and K-feldspar, illite, chlorite, kaolinite and
335 dolomite were detected in the study samples. Plagioclase comprises a variety of
336 anorthite to albite. Microscopic observations of smear slides for the study samples

337 revealed that quartz and feldspar are the two major minerals in the composition of
338 detrital grains.

339 The variation patterns of the Q/F, C/I, CK/I and K/I ratios are different between
340 fine-grained and glaciomarine units in cores 05JPC/TC and 06JPC (Fig. 3;
341 Supplementary tables 3–5). The ratios of fine-grained unit are relatively stable
342 compared with those in glaciomarine units. The higher Q/F ratio in glaciomarine units is
343 consistent with the finding of previous studies that quartz grains are abundant in the
344 western Arctic sediments delivered from the Laurentide ice sheet during glacial and
345 deglacial periods (Bischof et al., 1996; Bischof and Darby, 1997; Phillips and Grantz,
346 2001; Kobayashi et al., 2016). Some peaks correspond to dolomite-rich layers (“D” in
347 Fig. 3). Variation in the K/I ratio was associated with that in the Q/F ratio (Fig. 3),
348 which is in harmony with an idea that kaolinite was delivered via the Beaufort Gyre
349 circulation (Kobayashi et al., 2016). The C/I and CK/I ratios are lower in glaciomarine
350 unit than in fine-grained unit in 06JPC (Fig. 3C), which is consistent with the closure of
351 Bering Strait in the last glacial (Elias et al., 1992), but this difference is not significant
352 in 05JPC (Fig. 3B). High amplitude fluctuations were observed in the C/I and CK/I
353 ratios in the fine-grained sediments in 01A-GC and 06JPC (Fig. 3A and C). Similar
354 fluctuations partly appeared in 05JPC/TC despite its lower sampling resolution (Fig.
355 3B).

356 The Q/F ratio in cores 01A-GC, 05JPC/TC and 06JPC shows a gradual long-term
357 decrease throughout the Holocene (Fig. 4A). In cores 01A-GC and 06JPC studied in
358 more detail, the Q/F ratio also indicates millennial- to century-scale variability (Fig. 4A).
359 Variations of the 5-point running average highlight millennial-scale patterns (Fig. 4A).

360 The variations are generally asynchronous between both cores on this timescale, which
361 strongly depends on their age-depth models.

362 In core 01A-GC, the CK/I and C/I ratios show a general increase after ca. 9.5 ka with
363 the highest values occurring between 6 and 4 ka, and high ratios around 2.5 ka and 1 ka
364 (Fig. 4B). In core 06JPC, the ratios show a general increase after 9.2 ka with higher
365 values occurring between 6 and 3 ka (Fig. 4B). In core 05JPC/TC, slightly higher ratios
366 occur between 6 and 3 ka after a gradual increase from 9.3 ka (Fig. 4B).

367

368 **5. Discussion**

369 ***5.1. Holocene trend in the Beaufort Gyre circulation***

370 The zonal gradient of the Q/F ratio in western Arctic sediments shown in Fig. 2
371 suggests that quartz-rich but feldspar-poor sediments are derived from the North
372 American margin by the BG circulation, whereas feldspar-rich sediments are delivered
373 to the Chukchi Sea from the Siberian margin by currents along the East Siberian slope,
374 and the ratio can be used as an index for the BG circulation reflecting changes in its
375 intensity in sediment-core records (Kobayashi et al., 2016). A consistent upward
376 decrease in the Q/F ratio in three different cores under study (Fig. 4A) suggests that the
377 BG weakened during the Holocene. This pattern is consistent with an orbitally-forced
378 decrease in summer insolation at northern high latitudes from the early Holocene to
379 present. High summer insolation likely melted sea ice in the Canada Basin, in particular
380 in the coastal areas (Fig. 5). The evidence of lower ice concentrations at the Canada
381 Basin margins in the early Holocene was shown in the fossil records of bowhead whale
382 bones from the Beaufort Sea coast (Dyke and Savelle, 2001) and driftwood from
383 northern Greenland (Funder et al., 2011). This condition could decrease the stability of

384 the ice cover at the margins of the Canada Basin, which accelerated the rotation of the
385 BG circulation (Fig. 5), by comparison with observations from recent decades (Shimada
386 et al., 2006). A decrease in summer insolation during the Holocene should have
387 increased the stability of sea-ice cover along the coasts, resulting in the weakening of
388 the BG.

389 Recent observations show that the BG circulation is linked to the AO (Proshutinsky
390 and Johnson, 1997; Rigor et al., 2002). In the negative phase of the AO, the Beaufort
391 High strengthens and intensifies the BG. If the gradual weakening of the BG during the
392 Holocene were attributed to atmospheric circulation only, a concurrent shift in the mean
393 state of the AO from the negative to positive phase would be expected. This view,
394 however, contradicts the existing reconstructions of the AO history showing multiple
395 shifts between the positive and negative phases during the Holocene (e.g., Rimbu et al.,
396 2003; Olsen et al., 2012). We, thus, infer that the decreasing Holocene trend of the BG
397 circulation is attributed not to changes in the AO pattern, but rather to the increasing
398 stability of the sea-ice cover in the Canada Basin.

399 Based on a Holocene sediment record off northeastern Chukchi margin, Darby et al.
400 (2012) suggested strong positive AO-like conditions between 3 and 1.2 ka based on
401 abundant ice-rafted iron oxide grains from the West Siberian shelf. In contrast, a mostly
402 negative AO in the late Holocene can be inferred from mineralogical proxy data
403 indicating a general decline of the BSI after 4 ka (Ortiz et al., 2009), which could be
404 attributed to a stronger Aleutian Low (Danielson et al., 2014) that typically corresponds
405 to the negative AO (Overland et al., 1999). Olsen et al. (2012) also concluded that the
406 AO tended to be mostly negative from 4.2 to 2.0 ka based on a redox proxy record from
407 a Greenland lake. In order to comprehend these patterns, we need to consider not only

408 the atmospheric circulation, but also sea-ice conditions. Based on the Q/F record in this
409 study, summer Arctic sea-ice cover shrank in the early to middle Holocene, so that fast
410 ice containing West Siberian grains could less effectively reach the Canada Basin
411 because sea ice would have melted on the way to the BG (Fig. 5). Later in the Holocene
412 the ice cover expanded, and West Siberian fast ice could survive and be incorporated
413 into the BG (Fig. 5). We infer, therefore, that sediment transportation in the BG is
414 principally governed by the distribution of summer sea ice and the resultant stability of
415 the ice cover in the Canada Basin.

416

417 ***5.2. Millennial variability in the BG circulation***

418 In addition to the decreasing long-term trend, the Q/F ratio in 01A-GC and 06JPC
419 clearly displays millennial- to century-scale variability (Fig. 4A). Variation in the Q/F
420 ratio of both 01A-GC and 06JPC indicates a significant periodicity of ~2100 and ~1000
421 years with weak periodicities of ~500 and ~360 years, consistent with prominent
422 periodicities in the variation of total solar irradiance (Fig. 6) (Steinhilber et al., 2009). A
423 comparison with the record of total solar irradiance (Steinhilber et al., 2009) shows a
424 general correspondence, where stronger BG circulation (higher Q/F ratio) corresponds
425 to higher solar irradiance (Fig. 7). A ~200-year phase lag between the solar irradiance
426 and the Q/F ratio in 01A-GC and 06JPC may be attributed to the underestimation of
427 local carbon reservoir effect. This pattern suggests that millennial-scale variability in the
428 BG was principally forced by changes in solar irradiance as the most likely forcing.
429 Proxy records consistent with solar forcing were reported from a number of
430 paleoclimatic archives, such as Chinese stalagmites (Hu et al., 2008), Yukon lake
431 sediments (Anderson et al., 2005) and ice cores (Fisher et al., 2008), as well as marine

432 sediments in the northwestern Pacific (Sagawa et al., 2014) and the Chukchi Sea (Stein
433 et al., 2017). Because solar forcing is energetically much smaller than changes in the
434 summer insolation caused by orbital forcing, we suppose that solar activity did not
435 directly affect the stability of ice cover in the Canada Basin. Alternatively, we suggest
436 that the solar activity signal was amplified by positive feedback mechanisms, possibly
437 through changes in the stability of sea-ice cover and/or the atmospheric circulation in
438 the northern high latitudes.

439 In addition to cycles consistent with the solar forcing, Darby et al. (2012) reported a
440 1,550 year cycle in the Siberian grain variation in the Chukchi Sea record. This cycle
441 was, however, not detected in our data indicative of the BG variation (Fig. 6). This
442 difference suggests that the occurrence of Siberian grains in the Chukchi Sea sediments
443 primarily reflects the formation and transportation of fast ice in the eastern Arctic Ocean
444 rather than changes in the BG circulation.

445

446 ***5.3. Holocene changes in the Bering Strait Inflow***

447 Northward decreasing trends in the CK/I and C/I ratios in surface sediments in the
448 Chukchi Sea suggests that chlorite-rich sediments are derived from the northern Bering
449 Sea via Bering Strait, and the ratios can be used as an index for the BSI reflecting
450 changes in its intensity in sediment-core records (Kobayashi et al., 2016). Although the
451 variations of the CK/I and C/I ratios are not identical among three study cores (Fig. 4B),
452 there is a common long-term trend showing a gradual increase from 9 to 4.5 ka and a
453 decrease afterwards (Fig. 4B). Large fluctuations are significant in 01A-GC from 6 to 4
454 ka, and this fluctuation is also seen in 6JPC to some extent (Fig. 4B).

455 The higher CK/I and C/I ratios in core 01A-GC in the middle Holocene correspond to
456 higher linear sedimentation rates estimated by interpolation between ¹⁴C dating points,
457 but this correspondence is not seen in cores 05JPC/TC and 06JPC (Fig. 4C). We assume
458 that these higher sedimentation rates at 01A-GC indicate intensified BSI, because fine
459 sediment in the study area is mostly transported by currents from the Bering Sea and
460 shallow southern Chukchi shelf (Kalinenko, 2001; Darby et al., 2009; Kobayashi et al.,
461 2016). The difference of chlorite and sedimentation rate records between 01A-GC and
462 05JPC/06JPC may be related to either 1) variable sediment focusing at different water
463 depths, or 2) redistribution of the BSI water between different branches after passing the
464 Bering Strait. 1) A sediment-trap study demonstrated that shelf-break eddies in winter
465 are important to carry fine-grained lithogenic material from the Chukchi Shelf to the
466 slope areas (Watanabe et al., 2014). This redeposition process may have weakened the
467 BSI signal in slope sediments of 05JPC/06JPC compared with outer shelf sediments of
468 01A-GC. 2) Both the Alaskan Coastal Current (ACC) and the central current can
469 transport sediment particles to the 05JPC/TC and 06JPC area (red and yellow arrows,
470 respectively, in Fig. 1; Winsor and Chapman, 2004; Weingartner et al., 2005). In
471 comparison, the western branch is more likely to carry sediment particles to the site of
472 01A-GC (blue arrow in Fig. 1). Redistribution of the BSI water may have caused
473 different response of BSI signals. Although it is not clear which process made the
474 difference of BSI signals between 01A-GC and 05JPC/06JPC cores, it is highly possible
475 that the sedimentation rate and mineral composition of 01A-GC are more sensitive to
476 changes in BSI intensity than those of two other sites.

477 Diffuse spectral reflectance in core HLY0501-06JPC indicated that chlorite +
478 muscovite content is especially high in the middle Holocene between ca. 4 and 6 ka

479 (Supplementary Fig. S1; Ortiz et al., 2009). However, this pattern was not confirmed by
480 our XRD analysis, where XRD intensities of chlorite and muscovite (detected as illite in
481 this study) as well as the C/I and CK/I ratios did not show an identifiable enrichment
482 between 4 and 6 ka (Supplementary Fig. S1). We need more research to understand the
483 discrepancy of the results.

484

485 **5.4. Millennial variability in the BSI**

486 Variation in the C/I ratio of 01A-GC indicates a significant periodicity of 1900, 1000,
487 510, 400 and 320 years (Fig. 6A). The 1900, 1000 and 510 years are consistent with
488 prominent periodicities in the variation of total solar irradiance (Fig. 6C) (Steinhilber et
489 al., 2009). On the other hand, variation in the C/I ratio of 06JPC indicates a periodicity
490 of 2200, 830 and 440 years (Fig. 6B). The periodicity is different from that in 01A-GC
491 (Fig. 6A). This suggests that there are different agents of BSI signals in cores 01A-GC
492 and 06JPC. In core 01A-GC, 1000-year filtered variation in the C/I ratio is nearly
493 antiphase with those of the Q/F ratio and total solar irradiance (Steinhilber et al., 2009)
494 between 0 and 5 ka (Fig. 7). This suggests that millennial-scale variability in the
495 western branch of the BSI was forced by changes in solar irradiance after 5 ka. Recent
496 observations demonstrated that the BSI flows northwestward, especially when easterly
497 winds prevent the ACC (Winsor and Chapman, 2004). Because the easterly winds drive
498 the BG circulation, this mechanism cannot explain the increase of BSI intensity when
499 the BG weakened. Alternatively, it is also possible that the solar forcing could
500 independently regulate the western branch of the BSI via unknown atmospheric-oceanic
501 dynamics.

502

503 **5.5. Ocean circulation, sea ice and biological production**

504 The BSI, an important carrier of heat to the Arctic, affects sea-ice extent in the
505 Chukchi Sea (e.g., Shimada et al., 2006). Sea-ice concentrations in the Chukchi Sea
506 during the Holocene were reconstructed by dinoflagellate cysts (de Vernal et al., 2005;
507 2008; 2013; Farmer et al., 2011) and biomarker IP₂₅ (Polyak et al., 2016; Stein et al.,
508 2017).

509 In central northern Chukchi Sea, IP₂₅ records showed that sea-ice concentration
510 indicated by PIP₂₅ index in core 01A-GC was lower in 9–7.5 ka and 5.5–4 ka (Fig. 8A;
511 Stein et al., 2017), suggesting less sea-ice conditions in the periods. The low sea-ice
512 concentration during 9–7.5 ka is consistent with the results of previous studies based on
513 dinoflagellate cyst and IP₂₅ records showing the sea-ice retreat widely in the Arctic
514 Ocean, which was attributed to higher summer insolation during the early Holocene
515 (Dyke and Savelle, 2001; Vare et al., 2009; de Vernal et al., 2013; Stein et al., 2017). On
516 the other hand, the sea-ice retreat during 5.5–4 ka cannot be explained by higher
517 summer insolation. This period corresponds to that of higher C/I and CK/I ratios
518 indicative of the stronger BSI at 01A-GC (Fig. 8A). This suggests that the strengthened
519 BSI during this period contributed to sea-ice retreat in the central Chukchi Sea.

520 In the northeastern Chukchi Sea, dinoflagellate cyst and biomarker IP₂₅ records from
521 several cores in the northeastern Chukchi Sea, including 05JPC, demonstrate that
522 sea-ice concentration in this area was overall higher in the early Holocene than in the
523 middle and late Holocene (Fig. 8; de Vernal et al., 2005; 2008; 2013; Farmer et al.,
524 2011; Polyak et al., 2016). This pattern is in contrast to reconstructions from other
525 Arctic regions that show lower sea-ice concentrations in the early Holocene (de Vernal
526 et al., 2013). This discrepancy suggests that the intensified BG circulation exported

527 more ice from the Beaufort Sea to the northeastern Chukchi Sea margin. Furthermore,
528 the heat transport from the North Pacific to the Arctic Ocean by the BSI was likely
529 weaker in the early Holocene than at later times as indicated by the C/I and CK/I ratios
530 of cores 06JPC and 01A-GC (Fig. 8). We infer that this combination of stronger BG
531 circulation and weaker BSI in the early Holocene resulted in increased sea-ice
532 concentration in the northeastern Chukchi Sea despite high insolation levels (Fig. 5). In
533 comparison, intense BSI, a crucial agent of heat transport from the North Pacific to the
534 Arctic Ocean, along with weaker BG in the middle Holocene likely reduced sea-ice
535 cover in the Chukchi Sea. During the late Holocene, characterized by the weakest BG
536 and moderate BSI, sea-ice concentrations were intermediate and strongly variable (Fig.
537 8; de Vernal et al., 2008, 2013; Polyak et al., 2016).

538 The nutrient supply by the BSI potentially affects marine production in the Chukchi
539 Sea. We tested this possibility to compare our BSI record with marine production
540 records from cores 01A-GC (Park et al., 2016; Stein et al., 2017). Isoprenoid GDGTs
541 and brassicasterol showed concentration maxima during the periods between 8 and 7.5
542 ka and 6 and 4.5 ka (Fig. 8A). Isoprenoid GDGTs are produced by marine Archaea
543 (Nishihara et al., 1987) that use ammonia, urea and organic matter in the water column
544 (Qin et al., 2014). Brassicasterol is known as a sterol which is abundant in diatoms
545 (Volkman et al., 1986). Their abundance can, thus, be used as proxies to indicate marine
546 production in the water column. The periods with abundant isoprenoid GDGTs and
547 brassicasterol corresponded to the periods of low PIP₂₅ indicative of less sea ice (Fig.
548 8A). This correspondence suggests that the biological productivity increased with the
549 retreat of sea ice in the Chukchi Sea during the middle Holocene. The BSI indices, the
550 C/I and CK/I ratios, showed a maximum between 6 and 4 ka, which corresponded to the

551 periods of high marine production, but the corresponding maximum between 8 and 6.5
552 ka is not significant. Also, correspondence between the BSI indices and biomarker
553 concentrations are not clear after 4 ka. This suggests that marine production was not a
554 simple response to nutrient supply but was affected by other processes such as the
555 increase of irradiance in the water column (Frey et al., 2011; Lee and Whitley, 2005)
556 and wind-induced mixing that replenishes sea surface nutrients (Carmack et al., 2006).

557

558 *5.6. Causes of BSI variations*

559 Chukchi Sea sedimentary core records indicate a considerable variability in the BSI
560 intensity, with a common long-term trend of a gradual increase from 9 to 4.5 ka and a
561 decrease afterwards (Fig. 4B). Below we discuss the possible controls on this
562 variability.

563 The timing of the initial postglacial flooding of the ~50-m-deep Bering Strait was
564 estimated as between ca. 12 and 11 ka (Elias et al., 1992; Keigwin et al., 2006;
565 Jakobsson et al., 2017). Gradual intensification of the BSI inferred from the increase in
566 chlorite content from ca. 9 to 6 ka may have been largely controlled by the widening
567 and deepening of the Bering Strait with rising sea level, although other factors as
568 discussed below yet need to be tested. After the sea level rose to nearly present position
569 by ca. 6 ka, its influence on changes in the BSI volume was negligible.

570 The possible driving forces of the BSI at full interglacial sea level may include
571 several controls. One is related to the sea surface height difference between the Pacific
572 and Atlantic Oceans regulated by the atmospheric moisture transport from the Atlantic
573 to the Pacific Ocean across Central America (Stigebrandt, 1984). Increase in this
574 moisture transport during warm climatic intervals (Leduc et al., 2007; Richter and Xie,

575 2010; Singh et al., 2016) may have intensified the BSI. Salinity proxy data for the last
576 90 ka from the Equatorial East Pacific confirm increased precipitation during warm
577 events, but also show the trans-Central America moisture transport may operate
578 efficiently only during intervals with a northerly position of the Intertropical
579 Convergence Zone due to orographic constraints (Leduc et al., 2007). The existing
580 Holocene salinity records from the North Pacific (e.g., Sarnthein et al., 2004) do not yet
581 provide sufficient material to test the impact of these changes on the BSI.

582 Interplay of the global wind field and the AMOC has been proposed as another
583 potential control on the BSI (De Boer and Nof, 2004; Ortiz et al., 2012). Results of an
584 analytical ocean modeling experiment (Sandal and Nof, 2008) based on the island rule
585 (Godfrey, 1989) suggest that weaker Subantarctic Westerlies in the middle Holocene
586 could decrease the near surface, cross-equatorial flow from the Southern Ocean to the
587 North Atlantic, thus enhancing the BSI and Arctic outflow into the Atlantic. This
588 hypothesis waits to be tested more thoroughly, including robust proxy records of the
589 Subantarctic Westerlies over the Southern Ocean.

590 Finally, BSI can be controlled by the regional wind patterns in the Bering Sea
591 (Danielson et al., 2014), as explained above in Section 2.1. Oceanographic observations
592 of 2000–2011 clearly show a decadal response of the BSI to a change in the sea level
593 pressure in the Aleutian Basin affecting the dynamic sea surface height along the Bering
594 Strait pressure gradient. In order to conclude if this relationship holds on longer time
595 scales, longer-term records are needed from areas affected by the BSI and the Bering
596 Sea pressure system.

597 A number of proxy records from the Bering Sea and adjacent regions, both marine
598 and terrestrial, have been used to characterize paleoclimatic conditions related to

599 changes in the Bering Sea pressure system (e.g., Barron et al., 2003; Anderson et al.,
600 2005; Katsuki et al., 2009; Barron and Anderson, 2011; Osterberg et al., 2014). Various
601 proxies used in these records consistently show that the Aleutian Low was overall
602 weaker in the middle Holocene than in the late Holocene, opposite to the BSI strength
603 inferred from our Chukchi Sea data (Fig. 4B). For example, multi-proxy data from the
604 interior Alaska and adjacent territories (Kaufman et al., 2016, and references therein)
605 indicate overall drier and warmer conditions in the middle Holocene, consistent with
606 weaker Aleutian Low and stronger BSI. Diatom records from southern Bering Sea
607 indicate more abundant sea ice in the middle Holocene, also suggestive of a weaker
608 Aleutian Low (Katsuki et al., 2009). Alkenone and diatom records from the California
609 margin show that the sea surface temperature was lower in the middle Holocene,
610 suggesting stronger northerly winds indicative of weaker Aleutian Low (Barron et al.,
611 2003). Intensification of the Aleutian Low in the late Holocene, which follows from
612 these results, would have decreased sea level pressure in the Aleutian Basin, and thus
613 the strength of the BSI, consistent with overall lower BSI after ca. 4 ka inferred from
614 the Chukchi Sea sediment-core data (Fig. 4). Considerable climate variability of the
615 Bering Sea region captured in the upper Holocene records, some of which have very
616 high temporal resolution, is also closely linked to the pressure system changes
617 (Anderson et al., 2005; Porter, 2013; Osterberg et al., 2014; Steinman et al., 2014). In
618 particular, weakening of the Aleutian Low is reflected in Alaskan ice (Porter, 2013;
619 Osterberg et al., 2014) and lake cores (Anderson et al., 2005; Steinman et al., 2014) at
620 intervals centered around ca. 2 and 1–0.5 ka BP, which may correspond to BSI increases
621 in the Chukchi core 01A-GC at ca. 2.5 and 1 ka BP (Fig. 4), considering the
622 uncertainties of the sparse age constraints in the upper Holocene and/or underestimation

623 of reservoir ages. Overall, the Aleutian Low control on the BSI on century to millennial
624 time scales is corroborated by ample proxy data in comparison with the other potential
625 controls, although more evidence is still required for a comprehensive interpretation.

626

627 **6. Summary and Conclusions**

628 Distribution of minerals in surficial bottom sediments from the Chukchi Sea shows
629 two distinct trends: an East-West gradient in quartz/feldspar ratios along the shelf
630 margin, and a northwards decrease in the chlorite contents. These trends are consistent
631 with the propagation of the Beaufort Gyre circulation in the western Arctic Ocean and
632 the Bering Strait inflow to the Chukchi Sea, respectively. Application of these
633 lithological proxies to sedimentary records from the north-central and northeastern parts
634 of the Chukchi Sea allows for an identification of the Holocene paleoceanographic
635 patterns with century to millennial resolution. Results of the identified Holocene
636 changes in the BG circulation and the BSI are summarized in Table 1.

637 The inferred BG weakening during the Holocene, likely driven by the
638 orbitally-controlled summer insolation decrease, indicates basin-wide changes in the
639 Arctic current system and suggests that the stability of sea ice is a key factor regulating
640 the Arctic Ocean circulation on the long-term (e.g., millennial) time scales. This
641 conclusion helps to better understand a dramatic change in the BG circulation during the
642 last decade, probably caused by sea-ice retreat along the margin of the Canada Basin
643 and a more efficient transfer of the wind momentum to the ice and underlying waters
644 (Shimada et al., 2006). These results suggest that the rotation of the BG is likely to be
645 further accelerated by the projected future retreat of summer Arctic sea ice.

646 The identified millennial to multi-centennial variability in the BG circulation
647 (quartz/feldspar ratio) is consistent with Holocene fluctuations in solar irradiance,
648 suggesting that solar activity affected the BG strength on these timescales.

649 Changes in the BSI inferred from the proxy records show a considerable variability
650 between the investigated sediment cores, likely related to interactions of different
651 current branches and depositional processes. Overall, we conclude that after the
652 establishment of the full interglacial sea level in the early Holocene, the BSI variability
653 was largely controlled by the Bering Sea pressure system (strength and position of the
654 Aleutian Low). Details of this mechanism, as well as contributions from other potential
655 BSI controls, such as climatically-driven Atlantic-Pacific moisture transfer and the
656 impact of global wind stress, need to be further investigated. A consistent intensification
657 of the BSI identified in the middle Holocene was associated with a decrease in sea-ice
658 extent and an increase in marine production, indicating a major influence of the BSI on
659 sea ice and biological activity in the Chukchi Sea. In addition, multi-century to
660 millennial fluctuations, presumably controlled by solar activity, are discernible in core
661 01A-GC that has been characterized with the highest age resolution.

662

663 **Acknowledgements**

664 We thank all of the captain, crew and scientists of RV *Araon* for their help during the
665 cruise of sampling. We also thank Yu-Hyeon Park, Anne de Vernal, Seth L. Danielson,
666 Julie Brigham-Grette and Kaustubh Thirumalai for valuable discussion, So-Young Kim,
667 Hyo-Sun Ji, Young-Ju Son, Duk-Ki Han and Hyoung-Jun Kim for assistance in coring
668 and subsampling and Keiko Ohnishi for analytical assistance. Comments by Martin
669 Jakobsson, Tomas M. Cronin, and an anonymous reviewer improved greatly this

670 manuscript. The study was supported by a grant-in-aid for Scientific Research (B) the
671 Japan Society for the Promotion of Science, No. 25287136 (to M.Y.) and Basic
672 Research Project (PE16062) of Korean Polar Research Institute and the NRF of Korea
673 Grant funded by the Korean Government (NRF-2015M1A5A1037243) (to S.I.N.).

Table 1. Summary of Holocene variability in the BG and BSI in northern Chukchi Sea

Current system	Holocene trends	Multi-centennial to Millennial cyclicality
Beaufort Gyre (BG) circulation	Gradual weakening in response to decreasing summer insolation	0.36, 0.5, 1, and 2-ky cycles paced by changes in solar activity
Bering Strait inflow (BSI)	Geographically variable. Mid-Holocene strengthening evident at the 01A-GC site, presumably due to weaker Aleutian Low	Geographically variable. ~0.36, 0.5, 1, and 2-kyr cycles paced by changes in solar activity are identifiable in 01A-GC

966

967 **Figure captions**

968

969 Fig. 1. Index map showing location of cores ARA02B 01A-GC (this study),
970 HLY0501-05JPC/TC (this study and Farmer et al., 2011), HLY0501-06JPC (this study
971 and Ortiz et al., 2009), and HLY0205-GGC19 (Farmer et al., 2011), as well as surface
972 sediment samples (Kobayashi et al., 2016, with additions). BSI = Bering Strait inflow,
973 BC = Barrow Canyon, HN = Hanna Shoal, and HR = Herald Shoal. BG = Beaufort
974 Gyre, ACC = Alaskan Coastal Current, SBC = Subsurface Boundary Current, ESCC =
975 East Siberian Coastal Current, TPD = Transpolar Drift. Red, yellow and blue arrows
976 indicate BSI branches. AO+ and AO- indicate circulation in the positive and negative
977 phases of the Arctic Oscillation, respectively.

978

979 Fig. 2. Spatial distributions of the diffraction intensity ratios of (A) feldspar to quartz
980 (Q/F), and of (B) chlorite+kaolinite and (C) chlorite to illite (CK/I and C/I, respectively)
981 of bulk sediments, and (D) the longitudinal distribution of the Q/F ratio in the western
982 Arctic (>65°N) and (E) the latitudinal distribution of the CK/I and C/I ratios in the
983 Bering Sea and the western Arctic (>150°W). The C/I ratio could not be determined in
984 some coarse-grained sediment samples. Data from Kobayashi et al. (2016) with
985 additions for the Beaufort Sea (See supplementary Table 1 in more detail). The
986 regression lines in panel E show the geographic trends in mineral proxy distribution for
987 the Chukchi Sea. The Bering Sea sediments do not show a systematic pattern, probably
988 reflecting multiple sources of chlorite, such as the Yukon River, Aleutian Island, etc.
989 The enlarged maps of the Mackenzie River delta and Yukon River estuary are shown in
990 supplementary Figs. 1 and 2.

991

992 Fig. 3. Depth profile in (A) quartz/feldspar (Q/F) ratio, (chlorite + kaolinite)/illite
993 (CK/I), chlorite/illite (C/I) and kaolinite/illite (K/I) ratios with 1σ -intervals (analytical
994 error) and the diffraction intensity of dolomite (D) in cores (A) ARA02B 01A-GC, (B)
995 HLY0501-05JPC/TC and (C) HLY0501-06JPC (Supplementary Tables 2–4). Crosses
996 indicate radiocarbon dates in 01-GC and 5JPC and paleointensity datums in 06JPC.
997 Open circles in Panel B indicate 05TC samples. Note that the depth scale for 01A-GC is
998 doubled for presentation purposes.

999

1000 Fig. 4. Holocene changes in (A) quartz/feldspar (Q/F) ratio and the June insolation at
1001 75°N , (B) (chlorite + kaolinite)/illite (CK/I) and chlorite/illite (C/I) ratios, and (C) linear
1002 sedimentation rates (LSR) between age tie points in cores ARA02B 01A-GC,
1003 HLY0501-05JPC/TC and HLY0501-06JPC. Note that the age model for 06JPC is very
1004 tentative, so that a peak in LSR at ca. 2 ka could be an artifact of spurious age controls.

1005

1006 Fig. 5. Conceptual map showing the distribution of summer sea ice and the rotation of
1007 the Beaufort Gyre (BG) in the early, middle and late Holocene, inferred from the
1008 quartz/feldspar (Q/F) proxy record. Also shown is the Bering Strait inflow (BSI)
1009 intensity inferred from the (chlorite + kaolinite)/illite (CK/I) and chlorite/illite (C/I)
1010 ratios. Red arrow indicates the drift path of Kara Sea grains (KSG; Darby et al., 2012).

1011

1012 Fig. 6. Max Entropy power spectra of variation in the quartz/feldspar (Q/F) and
1013 chlorite/illite (C/I) ratios in core ARA02B 01A-GC ($N=85$, $m=21$) and

1014 HYL0501-06JPC (N=79, m=22) during 1.4–7.9 ka and the total solar irradiance (N=932,
1015 m=140)(Steinilber et al., 2009) during the last 9.3 ka.

1016

1017 Fig. 7. Detrended variations in the solar irradiance (TSI; Steinilber et al., 2009), the
1018 quartz/feldspar (Q/F) ratio in logarithmic scale in cores ARA02B 01A-GC and
1019 HYL0501-06JPC and the chlorite/illite (C/I) ratio in core ARA02B 01A-GC during the
1020 Holocene, with 400-year moving averages and 1,000-year filtered variations indicated
1021 by dark colored and black lines, respectively. The detrended values were obtained by
1022 cubic polynomial regression.

1023

1024 Fig. 8. Changes in (A) (chlorite + kaolinite)/illite (CK/I) and chlorite/illite (C/I) ratios,
1025 PIP₂₅ (P_DIP₂₅ and P_BIP₂₅ based on IP₂₅ and dinosterol or brassicasterol concentrations)
1026 indices (Stein et al., 2017), and isoprenoid GDGT (Park et al., 2016) and brassicasterol
1027 concentrations (Stein et al., 2017) in core ARA02B 01A-GC, (B) CK/I and C/I ratios in
1028 core HLY0510-5JPC/TC, IP₂₅ concentrations in core HLY0510-5JPC (Polyak et al.,
1029 2016), mean annual sea ice cover concentration (scale from 0 to 10) estimated from
1030 dinoflagellate cyst assemblages in cores 05JPC and GGC19 (de Vernal et al., 2013).
