Abstract

Past climatic change can be reconstructed from sedimentary archives by a number of proxies. However, few methods exist to directly estimate hydrological changes and even fewer result in quantitative data, impeding our understanding of the timing, magnitude and mechanisms of hydrological changes.

Here we present a novel approach based on δ^2H values of sedimentary lipid biomarkers in combination with plant physiological modeling, to extract quantitative information on past changes in relative humidity. Our initial application to an annually laminated lacustrine sediment sequence from western Europe deposited during the Younger Dryas cold period revealed relative humidity changes of up to 15% over sub-centennial timescales, leading to major ecosystem changes, in agreement with palynological data from the region. We show that by combining organic geochemical methods and mechanistic plant physiological models on well characterized lacustrine archives it is possible to extract quantitative ecohydrological parameters from sedimentary lipid biomarker δ^2H data.

1. Introduction

Predicting future changes in the water cycle using state-of-the art climate models is still associated with large uncertainties (IPCC, 2015). This is because we lack a mechanistic understanding of some of the key processes that influence the water cycle, in particular at regional spatial scales. A better mechanistic understanding of drivers and feedbacks within the hydrological cycle can be achieved from

reconstructing past hydrological changes from sedimentary archives. Stable isotope ratios of meteoric water, expressed as $\delta^{18}O$ and δ^2H (δD) values are an excellent tool in this respect, because their variability is associated with changes in temperature and source water (Bowen, 2008; Gat, 1996). The isotope ratios of precipitation can be recorded in ice core (Alley, 2000), terrestrial and marine paleoclimate archives through a variety of proxies, such as carbonates (Kanner et al., 2013; von Grafenstein et al., 1999), silicates (Tyler et al., 2008) and lipid biomarkers (Sachse et al., 2012).

Despite their potential, the interpretation of the stable isotope ratios from inorganic and organic proxies often allows only a *qualitative* assessment of past hydrological changes while *quantitative* reconstructions of hydrological changes from isotope proxy data, such as precipitation amount or relative humidity, have been difficult to achieve. This is problematic as quantifiable data are necessary for identifying the mechanistic drivers of past hydroclimate changes as well as their continental scale feedbacks and thresholds for example for vegetation changes. Moreover, quantitative data are needed to test the performance of state-of-the art climate models in simulating past and future changes in the hydrological cycle.

The interpretation of isotope proxies is typically not quantitative because multiple drivers can influence meteoric $\delta^{18}O$ and δ^2H values, hampering the assignment of single quantitative relationships between a hydrologic variable and δ^2H values recorded in a geological archive (Alley and Cuffey, 2001). The increased understanding of the interplay between environmental and plant physiological factors affecting lipid biomarker stable isotope ratios over the last decade (Feakins, 2013; Kahmen et al., 2013a; Kahmen et al., 2013b; Sachse et al., 2009; Smith and Freeman, 2006) has resulted in significant potential for quantitative paleohydrolologcial approaches, exemplified by a reconstruction of seasonality in precipitation and bog surface wetness in a Norwegian peatland (Nichols et al., 2009). Here we take this a step further, combining lipid biomarker hydrogen isotope measurements and plant physiological modeling to constrain the influence of multiple drivers on δ^2H values recorded in organic material and thus allow the extraction of quantitative information about changes in relative humidity from sedimentary archives.

Over the past decade, δ^2H values of lipid biomarkers from photosynthetic organisms have been increasingly used as proxies for reconstructing past changes in the continental hydrological cycle (Feakins, 2013; Rach et al., 2014; Sachse et al., 2012; Schefuss et al., 2011; Seki et al., 2011). In particular *n*-alkanes are ubiquitous in marine and lacustrine sediments and can be preserved over geological timescales (Peters et al., 2007). *n*-Alkanes can be traced back to aquatic or terrestrial sources, where short-chain homologues (nC_{17}-nC_{21}) are primarily synthesized by algae and aquatic plants (Aichner et al., 2010; Ficken et al., 2000), mid-chain n-alkanes (e.g. nC_{23}-nC_{25}) by submerged aquatic macrophytes or mosses (Aichner et al., 2010; Ficken et al., 2000; Gao et al., 2011), and long-chain n-alkanes ($>nC_{25}$) predominantly by higher terrestrial plants as a protective leaf wax layer on the leaf surface (Bush and McInerney, 2013; Eglinton and Hamilton, 1967).

Algae and submerged aquatic plants directly use lake (or ocean) water as their hydrogen source for lipid synthesis. δ^2H values from *n*-alkanes from aquatic organisms (δ^2H_{aq}) are thus related to the δ^2H value of the water these organisms live in (Aichner et al., 2010; Sachse et al., 2004) offset by a biosynthetic fractionation (ε_{bio}) between water and *n*-alkanes (Sachse et al., 2012) (Eq. (1)). Laboratory

2

culture studies (Zhang and Sachs, 2007) as well as field studies (Aichner et al., 2010; Sachse et al., 2004) have resulted in strong linear and nearly 1:1 relationships between source water and δ^2H_{aq} (Sachse et al., 2012), but have shown that species specific differences in ε_{bio} do exist (Zhang and Sachs, 2007).

$$(1) \quad \delta^2H_{aq} = \delta^2H_{precip} + \varepsilon_{bio(aq)}$$

Terrestrial plant leaf wax n-alkane δ^2H values (δ^2H_{terr}) have also been found to be linearly correlated to the organisms source water δ^2H values, yet not in a 1:1 relationship (Sachse et al., 2012), indicating additional influences on δ^2H_{terr} values. Recent greenhouse experiments and field studies have revealed that in particular the evaporative ^2H enrichment of leaf water shapes δ^2H_{terr} values (Kahmen et al., 2013a; Kahmen et al., 2013b). Soil water evaporation in the upper soil layers has been shown to be less significant for δ^2H_{terr}, as plants usually access the deeper, isotopically unenriched, soil layers (Dawson, 1993). As such, δ^2H_{terr} is affected mainly by the δ^2H value of plant source water (i.e. precipitation), the biosynthetic fractionation and leaf water deuterium enrichment (Δ^2H_e) (Eq. (2)).

$$(2) \quad \delta^2H_{terr} = \delta^2H_{precip} + \Delta^2H_e + \varepsilon_{bio(terr)}$$

Systematic differences in δ^2H_{terr} values have been observed for different plant types (especially between grasses and trees) (Diefendorf et al., 2011; Kahmen et al., 2013b), possibly indicating differences in either ε_{bio} (Sachse et al., 2012) or the fraction of leaf water used for lipid biosynthesis (Kahmen et al., 2013b) or yet unidentified factors. As such, vegetation changes in sedimentary records have been suggested to affect δ^2H_{terr} values and "vegetation corrections" have been proposed (Feakins, 2013).

Since evaporative ^2H enrichment of leaf water only affects terrestrial plants but not aquatic organisms, changes in sedimentary δ^2H_{terr} (Sachse et al., 2006) can be seen as a record of variations in terrestrial evaporative ^2H enrichment over time. Thus, by combining Eq. (1) and (2) under the assumption that ε_{bio} of both aquatic and terrestrial organisms was constant on the temporal and spatial scales of sedimentary integration, the difference between δ^2H_{aq} and δ^2H_{terr} values should mainly reflect the evaporative ^2H enrichment of leaf water (Eq. (3)). Whenever referring to an 'isotopic difference' between two pools (such as Δ^2H_e) we employ the mathematical correct 'epsilon' formula to calculate differences between two δ-values (Sessions and Hayes, 2005). For simplicity we use the following expression:

$$(3) \quad \Delta^2H_e = \delta^2H_{terr} - \delta^2H_{aq}$$

Variants of this concept (Sachse et al., 2004) have been used to qualitatively interpret changes in evapotranspiration through the isotopic difference between δ^2H_{terr} and δ^2H_{aq} (i.e. expressed as $\alpha_{TA/wat}$, δ^2H C_{23}–C_{31} and $\varepsilon_{terr-aq}$ (Jacob et al., 2007; Rach et al., 2014; Seki et al., 2011)). With recent progress in understanding of the determinants of δ^2H_{terr} values and the existing mechanistic understanding of the processes governing leaf water evaporative ^2H enrichment (Craig, 1965; Kahmen et al., 2011b; Sachse

115 et al., 2012), we propose a new framework – which we term the dual-biomarker (DUB) approach - to
116 extract quantitative hydrological information, namely changes in relative humidity (Δrh) from
117 sedimentary records. To illustrate the power of this approach with paleohydrological data, we combine
118 compound-specific hydrogen isotope measurements with plant physiological modeling on a previously
119 published Late Glacial record of δ^2H_{aq} and δ^2H_{terr} from sediments of Lake Meerfelder Maar (MFM),
120 Germany (Rach et al., 2014).

121

122 **2. Approach and Model**

123

124 The key assumptions of the DUB approach are that the difference between terrestrial and aquatic plant
125 derived n-alkane δ^2H values ($\varepsilon_{terr-aq}$) equals evaporative Deuterium enrichment of leaf water (Kahmen
126 et al., 2013b; Rach et al., 2014) over the timescale of sediment integration (i.e. decades in our case) and
127 that $\delta^2H_{lake\ water}$ equals $\delta^2H_{mean\ annual\ precipitation}$, a condition fulfilled for small catchment lakes in temperate
128 environments without any major inflow. Also the temporal delay in transfer of terrestrial n-alkanes
129 from source organisms into lake sediment should be below the temporal resolution of the samples,
130 which is fulfilled for sites with a very small catchment area and steep terrain, such as maar lakes.
131 Furthermore we assume that the biosynthetic fractionation (ε_{bio}) is constant for terrestrial and aquatic
132 source organisms on temporal and spatial scales of sedimentary integration (Sachse et al., 2012). We
133 also assume, that palynological data represent lake catchment vegetation so that those can be used to
134 assess source organisms of aquatic and terrestrial n-alkanes (Rach et al., 2014; Schwark et al., 2002).
135 To assess the influence of vegetation changes on our reconstructions, we employ two different
136 vegetation corrections based on palynological data, for which we assume that the amount of n-alkanes
137 produced by these different plants is equal to the pollen produced by them.
138 These assumptions and additional data are needed to parameterize the model, therefore we emphasize
139 that a robust application of the DUB model requires a good understanding of the paleolake system and
140 it's environment. As such, the DUB model should only be employed at a site which fulfills the
141 conditions presented above and where a number of additional, well constrained proxy data exist. As of
142 now, this limits the application of the DUB model to precipitation fed, small catchment (ideally maar
143 or crater) lakes in temperate regions.
144 δ^2H_{aq} in such systems can be regarded as a direct recorder of growing season average precipitation δ^2H
145 values and δ^2H_{terr} values largely reflect leaf water δ^2H values as has recently been demonstrated for
146 greenhouse and field grown plants (Kahmen et al., 2013a; Kahmen et al., 2013b). Leaf water in turn is
147 a function of the plant's source water and leaf water evaporative ^2H enrichment. We argue that soil
148 water evaporation is negligible as recently suggested by several observational studies and a global
149 assessment (Jackson et al., 1996; Jasechko et al., 2013; Kahmen et al., 2013a) and that precipitation is
150 the ultimate water source of aquatic organisms and terrestrial plants. In terrestrial plants however, the
151 source water becomes more enriched in deuterium due to plant transpiration before it is used for lipid
152 biosynthesis. As such, the isotopic difference between δ^2H_{terr} and δ^2H_{aq} ($\varepsilon_{terr-aq}$) can be attributed to
153 mean leaf water evaporative ^2H enrichment (Δ^2H_e) (Sachse et al., 2004). Based on recent field and
154 greenhouse studies we further assume, that $\varepsilon_{terr-aq}$ captures a growing season signal, probably biased

4

155 towards the earlier summer months in temperate climate zones as the majority of leaf waxes is
156 produced during leaf development with suggested integrational periods between weeks (Kahmen et al.,
157 2013b; Tipple et al., 2013) and several months (Sachse et al., 2015).
158
159 The major variables controlling leaf water isotope enrichment are well understood and mechanistic
160 models have been developed based on the Craig-Gordon evaporation model (Craig, 1965) that allow to
161 accurately predict or reconstruct leaf water Δ^2H_e values based on environmental and physiological
162 input variables (Barbour, 2007; Farquhar et al., 2007; Ferrio et al., 2009; Kahmen et al., 2011b) (Eq.
163 (4))

$$(4) \quad \Delta^2H_e = \varepsilon_+ + \varepsilon_k + (\Delta^2H_{wv} - \varepsilon_k)\frac{e_a}{e_i}$$

164
165 Δ^2H_e is determined by the equilibrium isotope fractionation between liquid and vapor (ε_+), the kinetic
166 isotope fractionation during water vapor diffusion from the leaf intercellular air space to the
167 atmosphere (ε_k), the ^2H depletion of water vapor relative to source water (Δ^2H_{wv}), and the ratio of
168 atmospheric vapor pressure and intracellular vapor pressure (e_a/e_i) and air temperature (T_{air}). In
169 addition, leaf temperature (T_{leaf}), stomatal conductance (g_s) and boundary layer resistance (r_b) are
170 essential secondary input variables for the prediction of e_i and ε_k, respectively. Reformulating Eq. (4)
171 allows expressing e_a as a function of Craig-Cordon variables (Eq. (5)). Since the atmospheric vapor
172 pressure (e_a) can also be calculated based on rh and saturation vapor pressure (e_{sat}) (Eq. (6)) we can
173 merge Eq. (5) and (6) to calculate relative humidity (rh) and to estimate quantitative changes in rh
174 (Δrh) (Eq. (7)).
175

$$(5) \quad e_a = \frac{e_i(\Delta^2H_e - \varepsilon_+ - \varepsilon_k)}{\Delta^2H_{wv} - \varepsilon_k}$$

176

$$(6) \quad rh = \frac{e_a \cdot 100\%}{e_{sat}}$$

177

$$(7) \quad \Delta rh = \frac{e_i(\Delta^2H_e - \varepsilon_+ - \varepsilon_k) \cdot 100\%}{e_{sat}(\Delta^2H_{wv} - \varepsilon_k)}$$

178
179 Equation (7) illustrates that Δrh can be inferred from a record of past changes in Δ^2H_e (i.e. a record of
180 $\varepsilon_{terr-aq}$) if the additional variables e_{sat}, e_i, Δ^2H_{wv}, ε_+ and ε_k can be constrained. In the following we discuss
181 the model parameterizations necessary to apply the DUB approach to estimate quantitative changes in
182 rh from sedimentary records.
183
184 Saturation vapor pressure e_{sat} (Eq. (8)) as well as the equilibrium fractionation factor ε_+ (Eq. (9)) are a
185 function of temperature (all given numbers and physically variable dependencies within the equations
186 are transferred from the Péclet-modified Craig-Gordon model by Kahmen et al 2011b and the original
187 leaf water enrichment model (Craig, 1965; Dongmann et al., 1974; Farquhar and Cernusak, 2005;

188   Farquhar and Lloyd, 1993)). The atmospheric pressure term (e_{atm}), which is also needed for calculation

189   of e_{sat}, describes (mean annual) atmospheric pressure as a function of the elevation above sea level (0

190   meters = 1013 hPa).

191

$$(8) \quad e_{sat} = \frac{1.0007 + 3.46 \cdot e_{atm}[hPa]}{1000000} \cdot 6.1121 \cdot exp\left(\frac{17.502 \cdot T_{air}[°C]}{240.97 + T_{air}[°C]}\right)$$

192

$$(9) \quad \varepsilon_+ = \left[exp\left(\frac{24.844 \cdot 1000}{(273.16 + T_{air}[°C])^2} - \frac{76.248}{273.16 + T_{air}[°C]} + 0.052612\right) - 1\right] \cdot 1000$$

193

194   For accurate estimates of e_{sat} as well as ε_+ information on air temperature (T_{air}) during the growing

195   season is thus required. Estimates of past T_{air} variability can be derived from paleotemperature proxy

196   data to estimate e_{sat} and ε_+ (e.g. chironomids (Heiri et al., 2014; Heiri et al., 2007), MBT/CBT (Blaga et

197   al., 2013)). In particular chironomid records, thought to represent spring and summer temperatures,

198   provide an ideal proxy of past mean growing season temperatures in this respect (Heiri et al., 2007).

199   Note that e_{sat} also depends on the atmospheric pressure (Eq. (8)), which can be estimated from

200   elevation above sea level and is treated as a constant in the model. Leaf-internal vapor pressure e_i on

201   the other hand is a function of leaf temperature (T_{leaf}). We assume for our calculations that T_{air} is a

202   good estimate of a growing season average T_{leaf} and e_i can thus be calculated as:

203

$$(10) \quad e_i = 6.13753 \cdot exp\left(T_{air}[°C] \cdot \frac{18.564 - \frac{T_{air}[°C]}{254.4}}{T_{air}[°C] + 255.57}\right)$$

204

205   We are aware that T_{leaf} can exceed air temperature in situations of extreme drought, when transpiration

206   and evaporative cooling is reduced, or in bright and sunny conditions (Leuzinger and Korner, 2007;

207   Scherrer et al., 2011). However, on cloudy days as well as on days with wind, T_{leaf} typically equals T_{air}

208   (Jones, 2013). Given the spatial and temporal integration of leaves in sedimentary records (covering

209   decadal to millennial timescales) it is thus unlikely that single drought events, where T_{leaf} would exceed

210   T_{air} dominate the overall relationship between T_{leaf} and T_{air} . Recent studies also show that for

211   temperatures between 15-20°C the T_{leaf} equals T_{air} on seasonal timescales (Kahmen et al., 2011b).

212   Another parameter affecting leaf water isotope enrichment is the ^{2}H-depletion of water vapor relative

213   to source water (Δ^2H_{wv}). In temperate climates liquid water and atmospheric water vapor are often in

214   isotopic equilibrium, especially when longer (annual to decadal) timescales are investigated (Jacob and

215   Sonntag, 1991). We therefore assume that Δ^2H_{wv} equals the equilibrium isotope fractionation between

216   vapor and liquid ε_+.

$$(11) \quad \Delta^2H_{wv} = -\varepsilon_+$$

217

218

219

6

220   In the model, Δ^2H_{wv} can thus be replaced by $-\varepsilon_+$ (Eq. (11)).

221   The kinetic isotope fractionation (ε_k) depends on the plant physiological variables stomatal

222   conductance (g_s) and boundary layer resistance (r_b) (Eq. (12)) (Kahmen et al., 2011b).

223

$$(12) \quad \varepsilon_k = \frac{16.4 \cdot \frac{1}{g_s[mol/m^2/s]} + 10.9 \cdot r_b[mol/m^2/s]}{\frac{1}{g_s[mol/m^2/s]} + r_b[mol/m^2/s]}$$

224

225   No direct proxies exist to reconstruct these plant physiological variables from sedimentary records, but

226   paleovegetation data can be used to parameterize the model with biome-averaged values for g_s and r_b

227   that are inferred from modern plants (Klein, 2014). We note that these plant physiological variables

228   exert only minor control on the model outcome, expected to lie within the analytical error of δ^2H lipid

229   measurements (Kahmen et al., 2011b), see also discussion below.

230   The latest iterations of leaf water models also include a Péclet effect, which describes the ratio of

231   convectional versus diffusional flow of water in the leaf (Eq. (4))(Kahmen et al., 2011b). However, we

232   did not include the Péclet effect in our calculations because we assume that variations in the Péclet

233   effect are minimal over time (Kahmen et al., 2009; Song et al., 2013) in particular for angiosperm

234   species.

235   When combining Eq. (9), (10), (11) and (12) with Eq. (7), we obtain a model for Δrh (Fig 1) that

236   requires only four major input variables: $\varepsilon_{terr-aq}$, air temperature (T_{air}) as well as literature-derived values

237   for stomatal (g_s) and boundary layer conductance (r_b) and one constant parameter ('site altitude above

238   sea level' for atmospheric pressure (e_{atm})) to calculate Δrh:

239

$$(13) \quad \Delta rh = e_i'(T_{air}) \cdot \left(\frac{\Delta^2H_e}{-e_{sat}'(e_{atm}, T_{air})(\varepsilon_+'(T_{air}) + \varepsilon_k'(g_s, r_b))} + \frac{1}{e_{sat}'(e_{atm}, T_{air})} \right) \cdot 100\%$$

240

241   Since we use $\varepsilon_{terr-aq}$ ($=\Delta^2H_e$) as an input variable, which is representative of leaf water isotope

242   enrichment above source water and not absolute δ^2H leaf water values, Eq. (13) predicts changes in rh

243   (Δrh) but not rh directly. In theory, Eq. (13) would also allow the calculation of rh values directly, if

244   absolute δ^2H_{precip} and $\delta^2H_{leafwater}$ was available. The current lack of experimentally determined

245   biosynthetic fractionation factors for the respective aquatic and terrestrial plants prevents this approach,

246   but future experimental research may result in robust estimates of ε_{bio}, potentially enabling the

247   reconstruction of absolute rh values (Zhang et al., 2009).

248
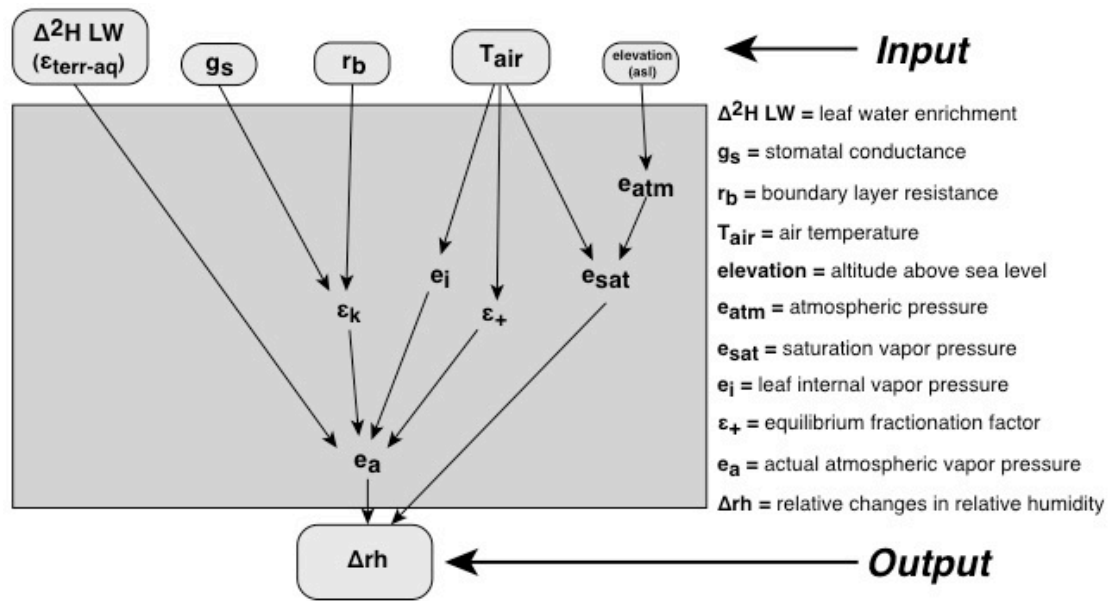

Fig. 1: Schematic overview showing the functional relationships between model variables of the DUB approach. Grey boxes on top mark the input parameters while the box size corresponds to the sensitivity of each variable on the result (small box ➔ low influence on Δrh; larger box ➔ higher influence on Δrh)

3. Uncertainties and sensitivity tests

3.1 Uncertainties

The DUB approach contains different variables (Fig. 1) with specific error ranges which can be quantified. These quantifiable errors (i.e. analytical uncertainties during isotope measurement or paleotemperature determination as well as ranges of values) can be used to set up an error propagation function and finally to provide an error range for the results (e.g. Eq. 16, Appendix). However, additional to these quantifiable uncertainties there are some still some catchment related non-quantifiable uncertainties (see Table 1 – Appendix and chapter 2) which can increase the error of the results and therefore need to be taken in consideration before applying to a certain catchment/ record. These unquantifiable uncertainties can however be minimized through the selection of a particular, well characterized lacustrine archive, fulfilling the conditions we outlined under chapter 2.
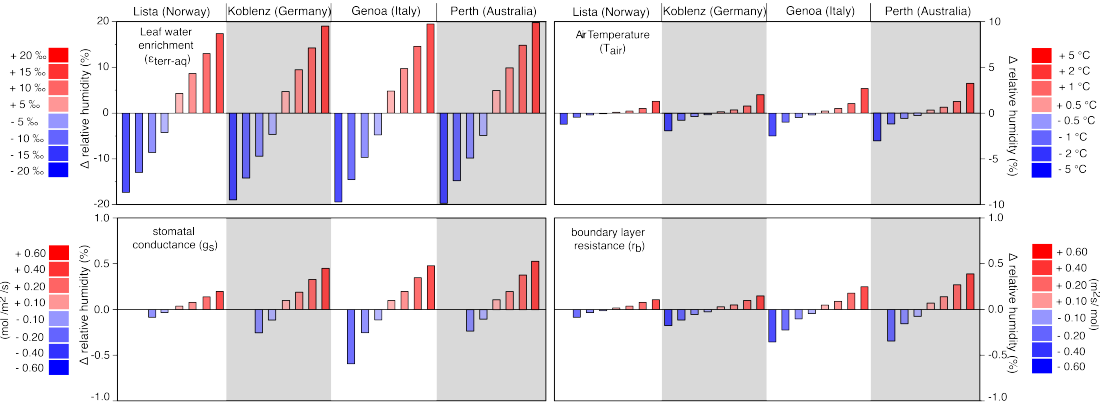

3.2 Sensitivity tests

To evaluate the robustness of our DUB approach for predicting Δrh in the context of uncertainties, we tested the sensitivity of the model to uncertainties in the four key input variables T_{air}, $\varepsilon_{terr-aq}$, g_s and r_b. In these sensitivity analyses we used a leaf water model, where all secondary variables (e_i, e_k, e_+, e_{sat}) are coupled to the primary input variables T_{air}, T_{leaf}, g_s and r_b (Kahmen et al., 2011b). We performed this test under a range of dramatically different climatic and ecological settings reflected by the climate conditions of Lista (Norway), Koblenz (Germany), Genoa (Italy) and Perth (Australia) that differ in

8

277　mean growing season temperatures and prevailing vegetation types. While the vegetation in Norway

278　and Australia is dominated by conifers and Mediterranean shrubland respectively, the prevailing

279　vegetation in Germany and Italy are broad leaf tree species. As baseline values for the sensitivity tests

280　we set T_{air} in the analyses to the growing season mean temperatures of each site, which was 9.4°C,

281　15°C, 17.2°C and 20.4°C for Lista, Koblenz, Genoa and Perth respectively (IAEA/WMO, 2006). Leaf

282　water evaporative enrichment $\varepsilon_{terr-aq,}$ (Δ^2H_e) was set to 25‰ (Lista), 35‰ (Koblenz), 45‰ (Genoa) and

283　55‰ (Perth), which reflects average growing season leaf water enrichment values for the tested

284　environments (Kahmen et al., 2013a). Base line data for plant physiological variables were biome

285　typical estimates that we obtained from the literature (Jones, 2013; Klein, 2014): stomatal conductance

286　(g_s) for Lista and Koblenz was set to 0.25 mol/m^2/s, while for Genoa and Perth the preset values were

287　0.45 and 0.35 mol/m^2/s, respectively (Klein, 2014). Boundary layer resistance (r_b) for Lista and Perth

288　was set to 0.5 m^{2}s/mol, while for Koblenz and Genoa this variable was set to 1.0 m^{2}s/mol (Jones,

289　2013).

290　The temperature sensitivity tests were performed by increasing and decreasing the respective T_{air}

291　values for a location by 0.5°C, 1°C, 2°C and 5°C (encompassing reconstructed temperature variations

292　during the last major abrupt climate shift in western Europe – the Younger Dryas period with about 4-

293　6°C (Goslar et al., 1995; Heiri et al., 2007)). $\varepsilon_{terr-aq}$ (Δ^2H_e) values were varied by ± 5‰, 10‰, 15‰ and

294　20‰ for each location which corresponds to evaporative leaf water enrichment in the test areas (spring

295　months) (Kahmen et al., 2013a). Plant physiological variables (g_s and r_b) were varied by ±0.1, ±0.2,

296　±0.4 and in maximum by ±0.6 mol/m^2/s and ±0.6 m^{2}s/mol, respectively. These tested variations in

297　plant physiological variables cover the expected variation in g_s and r_b for the local vegetation at the

298　sites described in the sensitivity analysis.

299　The sensitivity analyses showed similar results for all four tested environments (Fig. 2). This suggests a

300　similar behavior of the model under very different climate and ecological conditions. The DUB model

301　is most sensitive to changes in $\varepsilon_{terr-aq}$ (i.e. Δ^2H_e) and T_{air}, while the plant physiological variables (g_s, r_b)

302　showed only minor effects on Δrh (Fig 2). Specifically, a change of ±20‰ in $\varepsilon_{terr-aq}$ (i.e. Δ^2H_e) resulted

303　in a change ±20% in Δrh. A ±5°C change in T_{air} resulted in a 3% change in Δrh. Varying g_s and r_b

304　within the specified limits caused only changes in Δrh of 0.01 to 0.5% (Fig. 2), suggesting low model

305　sensitivity to plant physiological variables. A sensitivity test with variations in atmospheric pressure

306　(e_{atm}) of ±100hPa led to changes in Δrh of 0.05%. The difference in calculated Δrh for sites with low

307　(e.g. Lista) and high (e.g. Perth) growing season mean temperature were smaller than the regional

308　model sensitivity of the different input variables and are therefore negligible. Our sensitivity analyses

309　shows that the most critical variables for estimating changes in relative humidity with our model are

310　$\varepsilon_{terr-aq}$ and T_{air} (Fig 2).

311

Fig. 2: Sensitivity analyses for major model input variables ($\varepsilon_{terr-aq}$, T_{air}, g_s and r_b) on resulting Δrh values tested for four different climatic and ecological environments (Norway, Germany, Italy and Australia). Bars represent the effect on model output (Δrh) for each tested environment and its variation when the respective input variable will be varied by the marked value. Missing bars (i.e. for negative g_s and r_b) results from a bigger (negative) variation than the preset value (below 0).

4. Application: Reconstructing quantitative changes in Δrh during the Younger Dryas (YD) in Western Europe

In general, there are two approaches to validate a climate proxy. The most straight forward way is to test the proxy under modern hydroclimate conditions through variations in space or time and compare results with actual instrumental data, either along a modern climatological gradient or over the time period where instrumental data are available. The second possibility is the analysis of a longer time series during a period with otherwise known major changes in the parameter to be tested for.

For testing the DUB model, the first approach is not feasible. While highly resolved (ideally annual laminated) lacustrine sediments from temperate Europe covering the instrumental period (roughly the last 150 years) exist, no major changes in relative humidity occurred during this time. Using only (non-laminated) core top sediments (i.e. only one data point integrating the last decade) would not allow for testing the performance of the DUB approach, which aims to reconstruct relative changes in relative humidity, not absolute data. Testing the DUB approach along a modern climatic gradient is also difficult, because we cannot assume that the source of aquatic biomarkers (in our case nC$_{23}$) is always the same aquatic macrophyte in different lakes and ecosystems (Sachse et al., 2004), i.e. it is unlikely to encounter enough lake systems where the sources of aquatic biomarkers are comparable and which cover a large enough aridity gradient.

Therefore we decided to employ the second approach, i.e. test the proxy during a period of known and significant changes in relative humidity, such as the YD cold period (Rach et al., 2014). The YD as the last major abrupt climatic shift in younger earths history (between 12680 years BP and 11600 years BP) was characterized by a significant temperature decrease of 4-6°C (Goslar et al., 1995; Heiri et al., 2007), a relocation of atmospheric circulation patterns (Brauer et al., 2008) as well as major hydrological changes (i.e. significantly drier conditions) and ecological variations (propagation of grass and reduction of tree vegetation) in western Europe (Brauer et al., 1999a; Litt and Stebich, 1999; Rach et al., 2014). The relocation of atmospheric circulations patterns during Northern Hemispheric cooling

10

led to drier conditions in western Europe. This forced changes in the regional vegetation composition (Brauer et al., 1999a; Brauer et al., 2008; Rach et al., 2014). For this period a high resolution record of changes in $\delta^2 H_{aq}$ and $\delta^2 H_{terr}$ from a lacustrine archive which fulfills the requirements outlined above (i.e. precipitation fed, a very small catchment, available palynological and other climate proxy data (Brauer et al., 1999a; Litt and Stebich, 1999)), Lake Meerfelder Maar (MFM) in western Germany, exists. The presence of annual varves and a high temporal sampling resolution (decades) allow the evaluation of the timing of climatic and ecosystem changes - an ideal setting to illustrate the power of the DUB approach. A detailed description of the record and the available proxy data are given in Rach et al. (2014). Briefly, the annually laminated sediments of MFM covering the YD period contain abundant aquatic (nC_{23}) and higher terrestrial (nC_{29}) lipid biomarkers (*n*-alkanes) (Fig 3A). Based on the pollen record, the nC_{23} alkane can be related to the aquatic submerged plant *Potamogeton sp.* and the nC_{29} alkane to leaves originating from the terrestrial angiosperm trees *Betula* sp. and *Salix* sp. with input from grasses (Brauer et al., 1999a; Diefendorf et al., 2011). For the DUB approach we use the isotopic difference between $\delta^2 H$ values of the nC_{29} and of nC_{23} alkanes ($\varepsilon_{terr-aq}$) (Fig. 3B) as a measure for leaf water $^2 H$ enrichment ($\Delta^2 H_e$).

4.1 Model parameterization for the MFM application

4.1.1 Temperature

Since no paleotemperature proxy data are directly available for MFM, we use a high-resolution chironomid based temperature reconstruction from a nearby location, lake Hijkermeer in the Netherlands (Fig 3C), ca. 300 km N of MFM (see the Appendix). The Hijkermeer record is interpreted as a record of mean July temperatures for Western Europe with an mean error of about 1.59°C (Heiri et al., 2007). Since leaf wax synthesis occurs most likely during the early part of the growing season (spring and summer) (Kahmen et al., 2011a; Sachse et al., 2015; Tipple et al., 2013), the Hijkermeer record might slightly overestimate spring temperatures. However, when reconstructing Δrh during the Younger Dryas, it is important that paleotemperature data capture the changes in temperature before and during that period, rather than absolute temperatures.

4.1.2 Plant physiological parameters

We estimated plant physiological variables (g_s and r_b) based on literature data from the prevalent catchment vegetation inferred from available MFM pollen records (Brauer et al., 1999a; Litt and Stebich, 1999). These suggest that *Betula sp.* and *Salix sp.* were the dominant nC_{29} producing taxa but that grasses became more abundant during the YD (Brauer et al., 1999a; Litt and Stebich, 1999). Reported g_s values for these species growing under humid to arid conditions today range from 0.1 to 0.5 mol/m^2/s and boundary layer resistance (r_b) values from 0.95 to 1.05 mol/m^2/s (Klein, 2014; Schulze, 1982, 1986; Turner, 1984). As input variables for our modified model we therefore used mean values, i.e. 0.3 mol/m^2/s for g_s and 1.0 mol/m^2/s for r_b. We used the variance of ± 0.2 mol/m^2/s for g_s

384 and ± 0.1 mol/m²/s for r_b to calculate the error range of Δrh. We note the low sensitivity of the DUB

385 model outcome to variability in these variables (see Fig. 2, Appendix), as such that Δrh changes of less

386 that 0.1% result from varying g_s by 0.4 mol/m²/s or r_b by 0.1 mol/m²/s (Fig. 2).

387 **4.2 Estimation of uncertainty**

388

389 The estimation of uncertainty for Δrh is based on a linear error propagation (Eq. (16) - in the

390 Appendix) using specific error ranges for the individual input variables. For each input variable we

391 used their individual reported or estimated error (i.e. for chironomid interfered temperature

392 reconstruction: ± 1.5°C), for $\varepsilon_{terr-aq}$ the analytical uncertainty (standard deviation) of the respective

393 biomarker δ^2H measurements and for g_s and r_b the observed range of plant physiological parameters

394 between different species (g_s: 0.1-0.5 mol/m²/s, r_b: 0.95-1.05 m²s/mol). The resulting average error for

395 Δrh estimation during the investigated interval is 3.4% (see above and in the Appendix).

396

397

398 **4.3 Model results for the YD period at MFM**

399

400 Applying the DUB approach to the Late Glacial MFM record we can for the first time estimate the

401 magnitude by which rh changed during a distinct period of abrupt climatic change in the past. Our

402 quantification revealed substantial changes in relative humidity (Δrh) on the order of 30% (Fig 3D)

403 during the Late Glacial period, some of which occurred on multi-decadal timescales. To better illustrate

404 these changes we normalized our results to the mean of the period between 12.847 – 12680 BP (mean

405 Allerød) (Fig 3D), which is thought to have been warmer and moister than the Younger Dryas (Hoek,

406 2009).

407 In particular, at the onset of the YD at 12.680 years BP, Δrh decreased by 13% +/- 3.4% over 112 years

408 compared to mean Allerød level (Fig. 3D). During the YD (from 12.680-11.600 years BP) Δrh values

409 were on average 5% +/- 3.4% lower compared to the mean Allerød level. Furthermore in our high-

410 resolution dataset we observe a division of the YD into two distinct phases: the first part of the YD

411 (12.610-12.360 years BP) was characterized by low but relatively constant Δrh (variability between -

412 8% and -13% and a mean of -10%, compared to Allerød), whereas the variability in Δrh increases after

413 12360 years BP and ranges between -19% and +2% and a mean of -8% compared to Allerød mean

414 values (Fig. 3D). Towards the termination of the YD we reconstructed a strong increase in Δrh (up to

415 +20% above the Allerød level) over only 80 years. This increase started about 100 years before the YD

416 – Holocene transition at 11.600 BP (Fig. 3D), indicating that hydrological changes lead major

417 ecosystem changes, which formed the basis for the definition of the YD-Holocene boundary (Brauer et

418 al., 1999a; Brauer et al., 1999b). The onset of the Holocene was characterized by substantial variability

419 in Δrh, with a strong increase followed by a decrease to mean Allerød levels 150 years after the

420 transition. The reconstructed magnitude of changes, i.e. a ca. 9% reduction in rh during the YD

421 constitutes a shift from an oceanic to a dry summer climate, comparable to the difference in mean

422 annual rh between Central and Southern Europe today (Center for Sustainability and the Global

423 Environment (SAGE), 2002; New et al., 1999). The overall temporal pattern of reconstructed Δrh

changes is in good agreement with proxy data from western Europe (Bakke et al., 2009; Brauer et al., 1999a; Brauer et al., 2008; Goslar et al., 1993), which indicate a shift to drier conditions due to a southward displacement of the westerly wind system chanelling dry, polar air into Western Europe (Brauer et al., 2008; Rach et al., 2014).

Our approach reveals for the first time that substantial changes in rh of up to 20% can take place over very short time scales, i.e. several decades, leading to substantial changes in terrestrial ecosystems. While other proxy data reveal qualitative trends in aridification, our approach can be used to identify hydrological thresholds. Applied to high-resolution records, such as annually laminated lake sediments, the DUB approach can even be used to derive rates of hydrological changes and compare those with associated ecological changes (i.e. pollen records).
Fig. 3: (A) $\delta^2 H$ values of aquatic plants ($\delta^2 H_{aq}$, blue line) and higher terrestrial plants ($\delta^2 H_{terr}$, green line (Rach et al., 2014). **(B)** Terrestrial evapotranspiration ($\varepsilon_{terr-aq}$, orange line) during the Younger Dryas at MFM (Rach et al., 2014). **(C)** Original chironomid based temperature reconstruction from Hijkermeer

13

440 approach (purple dots). **(D)** Variability of Δrh during the YD cold period at MFM. The data are
441 normalized to mean Allerød level (12.847 – 12.680 years BP). The bold line marks the moving
442 average.

443

444 **4.4 The effect of vegetation change on $\varepsilon_{terr-aq}$ and the estimation of Δrh**

445

446 Numerous studies have established that vegetation changes can also affect the sedimentary leaf wax
447 δ^2H record, since significant differences in the net or apparent fractionation (ε_{app}) between source water
448 and lipid δ^2H values exist among different plant types, in particular between monocot and dicot (all
449 grasses) plants (Kahmen et al., 2013b; Tipple et al., 2013). Since the YD period at MFM was
450 characterized by an increased amount of grasses, we tested, how vegetation changes may affect Δrh
451 reconstructions through the DUB approach. For this we have developed two approaches to "correct"
452 δ^2H$_{terr}$ values, based on either a constant offset between monocot and dicot ε_{app} (Sachse et al., 2012) or
453 a lower sensitivity of grass derived leaf wax δ^2H values to leaf water isotope enrichment (Kahmen et
454 al., 2013b). Both approaches assume that palynological reconstructions are representative of leaf wax
455 producing plants and that both monocots and dicots produce similar quantities of n-alkanes.
456 We used available palynological data to quantify the relative distribution of major tree vegetation
457 (*Betula*, *Salix*) and grasses over the investigated period (Fig. 4B), expressed as the fraction of tress and
458 grasses, f_{trees} and f_{grass}, assuming that leaf waxes and pollen share a similar transport pathway in this
459 small, constrained crater catchment.

460

461 **4.4.1 Correction - case 1 – constant difference in ε_{app} between monocots and dicots**

462

463 The first vegetation correction for reconstructed leaf water enrichment ($\varepsilon_{terr-aq}$*) is based on the
464 assumption of a constant offset in biosynthetic isotope fractionation (ε_{bio}) between trees and grasses.
465 Observational evidence shows that leaf wax lipid δ^2H values (δ^2H$_{terr}$) from C3 monocots are on average
466 34‰ more negative that from C3 dicots (non-grasses) when growing at the same site (Sachse et al.,
467 2012). This value is based on an observed mean difference between apparent isotope fractionation (i.e.
468 the isotopic difference between source water and leaf wax n-alkanes, ε_{app}) values of C3 dicots (-111‰)
469 and C3 monocots (-141‰) within a global dataset (Sachse et al., 2012).
470 The difference between monocot and dicot n-alkane δ^2H could potentially affect our modeled Δrh
471 values, especially since an 23% increase in grass abundance in the MFM catchment during the YD has
472 been suggested by pollen studies (Brauer et al., 1999a; Litt and Stebich, 1999).The causes for these
473 differences in ε_{app} have been hypothesized to be due to species-specific differences in biosynthetic
474 fractionation (Sachse et al., 2012) or temporal differences in leaf wax synthesis during the growing
475 season (Tipple et al., 2013). Both scenarios would result in a more or less constant isotopic offset
476 between monocots and dicots growing under the same climatic conditions.
477 Assuming a mean isotopic difference of -34‰ between trees and grasses (Sachse et al., 2012), we
478 calculated a vegetation weighted correction value (-34*f_{grass}) for each data point. This value is then

14

subtracted from $\varepsilon_{\text{terr-aq}}$, and results in the vegetation corrected $\varepsilon_{\text{terr-aq}}$* value (Eq. (14)). Similar approaches for a pollen based vegetation reconstruction have been recently proposed and applied (Feakins, 2013; Wang et al., 2013).

$$(14) \quad \varepsilon_{terr-aq}* = \varepsilon_{terr-aq} - (-34 \cdot f_{grass})$$

4.4.2 Correction - case 2: different sensitivity to leaf water isotope enrichment in dicot vs. monocot leaf wax δ²H values

The second vegetation correction ($\varepsilon_{\text{terr-aq}}$**) is based on the assumption that the isotopic difference between monocot and dicot leaf wax *n*-alkanes is not constant, but dependent on environmental conditions (Kahmen et al., 2013b). Previous greenhouse studies imply that the difference in ε_{app} between dicots and monocots is variable depending with a change in humidity conditions (Kahmen et al., 2013b). In a high humidity climate chamber treatment (80% rh) monocots and dicots showed similar values for ε_{app} (-220‰ and -214‰ respectively) whereas in a low humidity treatment ε_{app} for monocots was substantially lower compared to dicots (-205‰ and -125‰ respectively) (Kahmen et al., 2013b), a finding that is in disagreement with the two hypotheses proposed above. Rather, the latter study hypothesized that grasses use a mixture of enriched leaf water and unenriched xylem water for lipid synthesis (Kahmen et al., 2013b). This hypothesis would imply that leaf wax *n*-alkane δ²H values of monocots do not record the full magnitude of the evaporative leaf water enrichment signal, but only a fraction (Sachse et al., 2009). A recent greenhouse study on grass derived *n*-alkane δ²H values of a broad spectrum of C3 and C4 grasses support this idea (Gamarra et al., 2016). Gamarra et al. suggest that the differences between *n*-alkane δ²H values from grasses and *n*-alkane δ²H values from dicotyledonous plants are caused by an incomplete transfer of leafwater Δ²H to the *n*-alkanes. As such, a sedimentary record of *n*-alkanes derived partly from grasses would also underestimate mean ecosystem leaf water enrichment. Under dry conditions this fraction was estimated to be ca. 18% for C3 grasses, based on one grass species (Wheat) studied (Kahmen et al., 2013b). The data from Gamarra et al. show that for C3 grasses only 38 – 61% of the leaf water evaporative ²H-enrichment signal (depending on the species) was transferred to leaf wax *n*-alkane δ²H values. To work with a conservative value and not to overestimate a potential leaf water enrichment signal in grass dervied *n*-alkane δ²H values we decided to use the data from Kahmen et al. (2013) for the wheat C3 grass. As such our correction approach would rather underestimate changes in relative humidity and represents as such the lower limit of reconstructed changes.

Under the assumption of different sensitivities to leaf water isotope enrichment of *n*-alkane δ²H values in monocot and dicot plants (Kahmen et al., 2013b) we developed a correction for $\varepsilon_{\text{terr-aq}}$ based on the experimentally determined mixing ratio between leaf water and unenriched xylem water in wheat, a C3 grass (Kahmen et al., 2013b), essentially by weighing the fraction of grass cover with a factor of 0.18: (Fig. 4B) (Eq. (15)).

$$(15) \quad \varepsilon_{terr-aq}** = \left(f_{trees} \cdot 1 + f_{grass} \cdot 0.18 \right) \cdot \varepsilon_{terr-aq}$$

517

4.5 Comparison of results from uncorrected ($\varepsilon_{terr-aq}$) and corrected ($\varepsilon_{terr-aq}$*, $\varepsilon_{terr-aq}$**) values

519

Results from the raw (Δrh) and both vegetation corrected scenarios (Δrh* and Δrh**) are within the calculated error range of 3.4% of Δrh (Fig. 4A) during the Allerød and the Early Holocene, but diverge by up to 10% during the YD, when C3 grass vegetation was estimated to have increased from 28% to 52% in the catchment of MFM (Fig. 4B). Vegetation corrected results (case 1 Fig. 4A) showed on average a 7% stronger decrease for Δrh* and only a 2% stronger decrease for Δrh** compared to uncorrected results. As such Δrh** values (case 2) are within the error range of uncorrected Δrh during the entire record.

Interestingly, both correction approaches, but in particular case 2, place the relatively large variability in uncorrected Δrh at the onset and the termination of the YD, where abrupt vegetation changes occurred. For example, uncorrected Δrh changes were predicted to be up to 35% during the termination of the YD, corresponding to the modern gradient between western Europe and the semi-desert areas in northern Africa (Center for Sustainability and the Global Environment (SAGE), 2002). Vegetation corrected Δrh** values were on the order of 20%, seemingly more reasonably representing local Late Glacial changes (Fig. 4A).

Our analysis shows that vegetation changes have the potential to affect the DUB approach estimates, but a lack of mechanistic understanding of the causes of the differences in δ^2H_{terr} between tree and grass vegetation (Sachse et al., 2012) makes an assessment of the validity of either (or any) correction approach difficult. Tentatively, the lower variability in Δrh** within the YD as well as the less pronounced shift in particular at the onset and termination of the YD (Fig. 4A) provides a more realistic scenario. But as of now, we regard the differences in predictions as the error of quantitative predictions from the DUB approach. This uncertainty is larger during periods characterized by vegetation changes and in our case maximum differences in prediction of Δrh between the Allerød and the YD are on the order of 11% (mean Allerød vs mean YD difference between Δrh and Δrh*).

543

16
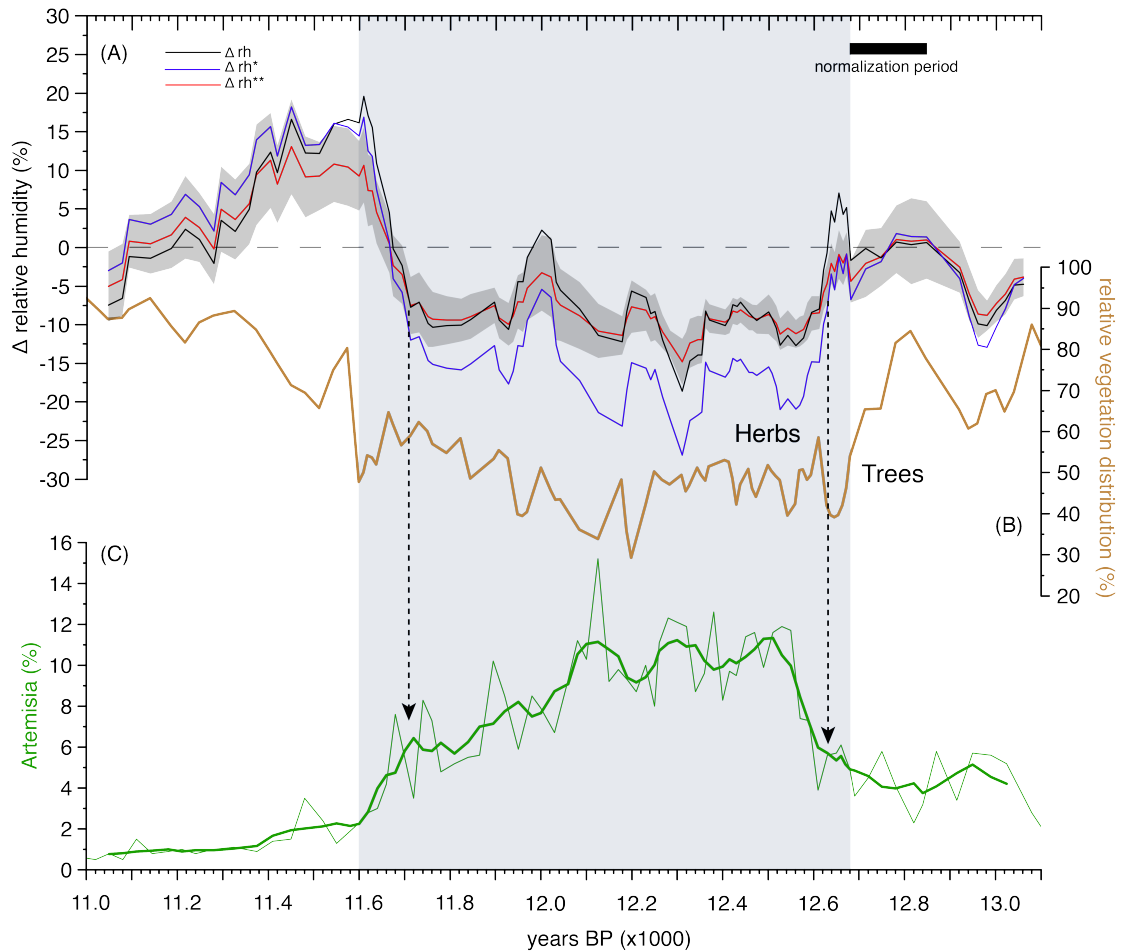

Fig. 4: (A) Reconstructed Δrh variability during the YD period (light grey shaded), without vegetation correction (**black line, Δrh**) with vegetation correction assuming a constant offset between C3 dicots and C3 monocots (**blue line, Δrh*),** with vegetation correction assuming different leaf water sensitivities among grasses and trees (**red line, Δrh****). The shaded area marks the error range for Δrh**. **(B)** relative distribution of trees and grasses in the catchment of MFM during the YD from pollen studies (Brauer et al., 1999a; Litt and Stebich, 1999). **(C)** Occurrence of Artemisia pollen in the catchment of MFM during YD (Brauer et al., 1999a; Litt and Stebich, 1999). Arrows highlight the contemporaneous major changes in Δrh and *Artemisia*.

4.6 Comparison of reconstructed Δrh with other proxy data

We can further demonstrate the validity of our approach by direct comparison to other hydroclimate proxies from the MFM record. For example, a classical palynological marker for more arid conditions is *Artemisia* pollen (D'Andrea et al., 2003). In the MFM catchment a prominent increase in the occurrence of *Artemisia* has been used to infer drier conditions during the YD (Fig. 4C) (Brauer et al., 1999a; Bremer and Humphries, 1993; D'Andrea et al., 2003; Litt and Stebich, 1999). When comparing the abundance of *Artemisia* pollen % (note that the *Artemisia* abundance data are not part of the vegetation corrections discussed above) to the DUB Δrh record, we observed striking similarities over the whole of the study period (Fig. 4A,C). Inferred wetter conditions during the second phase of the

17

564   YD, or centennial scale excursions to higher Δrh (such as between 12280 and 12170 years BP) go in

565   line with lower *Artemisia* pollen abundance after 12.100 BP. In fact, both independent datasets show an

566   inverse, statistically significant relationship (p < 0.001) (Fig. 5A-C), with high *Artemisia* pollen

567   abundance during periods of low Δrh values (Fig. 4A,C). The correlation between Δrh and *Artemisia* is

568   higher for vegetation corrected Δrh* and Δrh** (Fig. 5B,C) than uncorrected Δrh and in particular for

569   Δrh** the variance of the dataset is greatly reduced (Fig. 5C), providing support for the hypothesis that

570   vegetation changes could have affected the record.

571
573   **Fig. 5**: Correlation plots of normalized reconstructed Δrh vs. *Artemisia* population. (**A**) uncorrected Δrh

574   values vs. *Artemisia*. (**B**) Vegetation corrected Δrh values (Δrh*) vs *Artemisia*. (**C**) Vegetation

575   corrected Δrh values (Δrh**) vs *Artemisia*.

576

18

5. Conclusions

We present a novel approach for quantifying paleohydrological changes (i.e. changes in relative humidity) combining sedimentary lipid biomarker δ^2H values from aquatic and terrestrial lipids with mechanistic leaf water isotope modeling. This dual-biomarker approach (DUB) relies on the observation that aquatic and terrestrial organisms within the catchment of small lakes from temperate climate zones use distinct water sources, namely lake (i.e. precipitation) and ^2H-enriched leaf water as a source for their organic hydrogen. By taking advantage of the mechanistic understanding of and available models on leaf water isotope enrichment in terrestrial plants, we show it is possible to extract quantitative information about changes in relative humidity from sedimentary records.

Parameterizing and applying the DUB model to a lacustrine lipid biomarker δ^2H record from western Europe, we find strong and abrupt changes in rh at the onset and the termination of the YD occurring within the lifetime of a human generation. Specifically, our approach showed that shifts in rh of up to 13% +/- 3.4% occurred within only 112 years. This dramatic change corresponds to shifts in average biome rh from oceanic to dry summer climates. Our quantification showed that dry conditions prevailed during the Younger Dryas period with rh being between 8 and 15% lower on average compared to the Allerød, depending on how the possible effect of vegetation changes is accounted for. The pattern but also the magnitude of our rh reconstruction agrees well with other proxy data, such as the increase in the abundance of specific taxa adapted to dry conditions (e.g. *Artemisia*) during that time period.

Our analyses shows that the DUB approach is capable of quantifying past hydrological changes in temperate environments, when additional proxy data, especially on vegetation distribution and paleotemperature exist. We suggest that this approach can be particularly valuable in the future for the validation of climate models and to better understand uncertainties in predictions of future hydrological change under global warming. However, we stress that the DUB approach relies on a number of assumptions and is currently limited by our incomplete understanding of processes affecting the transport and deposition of in particular terrestrial biomarkers from their source to the sedimentary sink. To minimize the arising uncertainties, this approach should only be applied to small catchment lake systems which are fed by precipitation in temperate climate zones, when biomarker sources can be constrained by paleovegetation data (such as palynological records). It is particularly crucial to constrain the aquatic biomarker source, but in principle any aquatic lipid biomarker (macrophyte, algal) could be employed. Our reconstruction provides reasonable values of rh changes during the YD cold period, which are in agreement with ecosystem changes in the region. As such, the present approach provides a first step towards quantitative paleohydrological reconstructions.

617 **Appendix**

618

619 **Error propagation**

620

621 The uncertainty estimation (Δf, Eq. (16)) for the reconstructed Δrh variability is based on a linear error

622 propagation, which is the most conservative method for error estimations. This Method does not

623 require the same kind of the considered errors and provides therefore the possibility to combine

624 different kinds of errors with their specific ranges (i.e. measuring error, counting error, etc.). The

625 individual error ranges of the independent variables in our approach arise from different sources such

626 as analytical errors (chironomid interfered temperature reconstruction: ± 1.5°C), observed variations of

627 plant physiological parameters between different species (stomatal conductance: 0.1-0.5 mol/m^2/s,

628 boundary layer resistance: 0.95-1.05 m^{2}s/mol) and standard deviation of δ^2H measurements of

629 terrestrial and aquatic *n*-alkanes.

630 The specific uncertainty for $\varepsilon_{terr-aq}$** was preliminary determined by a separate error propagation using

631 the (analytical) standard deviation of the triplicate measurements of the sedimentary *n*-alkane δ^2H

632 values as well as the plant derived *n*-alkane δ^2H measurements by Kahmen et al 2013. The results of

633 these separate error estimation were integrated into the general error estimation of Δrh**.

634 In contrast to the linear error propagation a less conservative method (Gaussian error propagation)

635 requires a similarity of the errors, i.e. all errors are measurement or counting errors, which is not the

636 case in this study. The mean error when using the Gaussian method is however only 3.2% and therefore

637 only 0.2% smaller than the calculated error using the linear propagation.

638

639

$$(16) \quad \Delta f = \left| \frac{\partial rh}{\partial \varepsilon_{terr-aq}} \right| \cdot \Delta \varepsilon_{terr-aq}** + \left| \frac{\partial rh}{\partial r_b} \right| \cdot \Delta r_b + \left| \frac{\partial rh}{\partial g_s} \right| \cdot \Delta g_s + \left| \frac{\partial rh}{\partial T_{air}} \right| \cdot \Delta T_{air}$$

640

641

642 **Temperature data**

643

644 The temperature data used for the DUB model parameterization of the MFM case were taken from ref.

645 35 and constitute reconstructed summer temperatures based on chironomid analyses from Hijkermeer

646 (NL) (Heiri et al. (2007)), which, to our knowledge, constitutes the closest lateglacial paleotemperature

647 record to the MFM site (distance 311km). However, the dataset of the Hijkermeer consists only of 37

648 data-points between 13.000 BP and 11.000 BP with a temporal resolution varying between 26 to 167

649 years /sample. Therefore, we determined a new equidistant time-series for the temperature data, fitting

650 data-volume and temporal resolution of our Δ^2H$_e$ record from MFM (106 data-points with an 8 to 33

651 year-resolution). For calculating the equidistant time series we were using method "interpl" with the

652 specification "linear" in MATLAB (version R2010b).

assumption	explanation
$\delta^2H_{\text{lake water}} = \delta^2H_{\text{mean annual precipitation}}$	Stable hydrogen isotope composition of lake water equals mean annual stable hydrogen isotope compositions of precipitation (source water), as observed for small catchment lakes in temperate environments (Moschen et al., 2005)
$\varepsilon_{\text{terr-aq}}$ = leaf water evaporative ^{2}H enrichment	Difference between terrestrial and aquatic plant derived n-alkane δ^2H values equals evaporative Deuterium enrichment of leaf water (Kahmen et al., 2013b; Rach et al., 2014)
ε_{bio} = constant	Biosynthetic fractionation is constant for aquatic as well as terrestrial source organisms on temporal and spatial scales of sedimentary integration (Sachse et al., 2012)
no significant delay (i.e. below sample resolution, i.e decades) of terrestrial n-alkanes transfer from source organisms into lake sediment	Due to the very small catchment of MFM with steep and wind sheltered crater walls we can assume an almost instantaneous transfer of n-alkanes and pollen from source organisms to lake sediment. Likely autumn leaf litter is the main n-alkane source to the sediment. This is supported by the similar sample to sample (i.e. decadal) variability in the lipid δ^2H values. If, for example, terrestrial leaf wax n-alkanes would have a substantially longer residence time in the soils before being transported into the lake, then the decadal variability should be much smaller, as the soil would already deliver a more integrated signal into the lake
e_{atm} = constant	The atmospheric pressure is inferred from the altitude above sea level (0 meters = 1013 hPa), which remained unchanged. Short term weather related fluctuations (on the order of 100hPa) do not affect the model outcome (see text).
$T_{\text{leaf}} = T_{\text{air}}$	Leaf temperature equals air temperature on the timescale of sediment integration (decades) (Kahmen et al., 2011b)
$\Delta^2H_{\text{wv}} = -\varepsilon_+$	atmospheric water vapor equals equilibrium isotope fractionation between vapor and liquid, as often observed for long-term (several years) time series in temperate climates (Jacob and Sonntag, 1991)
no significant influence by Péclet effect	Variations in the Péclet effect are minimal over time in particular for angiosperm species (Kahmen et al., 2009; Song et al., 2013)
amount of produced n-alkanes from monocots and dicots are almost equal	Both of our vegetation correction approaches assume that palynological reconstructions are representative of leaf wax producing plants and that both monocots and dicots produce similar quantities of n-alkanes.

Vegetation data

Information about Lateglacial vegetation-cover in the catchment area of MFM is based on palynological analyses (Brauer et al. (1999), Litt & Stebich (1999)). We used Pollen percent data also for determining the vegetation distribution between trees and grasses for each datapoint. For using these vegetation data in our model it was necessary to determine an equidistant time-series according to age model of our Δ^2H_e values. For calculating these time series we used also method "interpl" with the specification "linear" in MATLAB (version R2010b).

Author contributions

Oliver Rach conducted model modifications, calculations and wrote the paper. Ansgar Kahmen provided the basic leaf water enrichment model and was responsible for plant physiological part and contributed in writing the paper. Achim Brauer was responsible for lake coring, provided the chronology and stratigraphy for Younger Dryas hydrological reconstruction and wrote the paper. Dirk Sachse conceived the research, acquired financial support and wrote the paper.

Competing financial interests

The authors declare no competing financial interests.
