30 **Abstract.** The 4.2 ka event has been widely investigated since it was suggested to be a
31 possible cause for the collapse of ancient civilizations. With the growth of proxy records for
32 decades, however, both its nature and its spatial pattern have become controversial. Here we
33 examined multi-proxy data of the grain-size distribution, ostracode assemblage, pollen
34 assemblage and the pollen-reconstructed mean annual precipitation from a sediment core at
35 Hulun Lake in northeastern Inner Mongolia spanning the period between 5000 and 3000 cal.
36 yr BP to identify the nature and the associated mechanism of the 4.2 ka event occurring in the
37 monsoonal region of eastern Asia. Higher sand fraction contents, littoral ostracodes
38 abundances and Chenopodiaceae pollen percentages together with lower mean annual
39 precipitations reveal a significant dry event at the interval of 4230–3820 cal. yr BP that could
40 be a regional manifestation of the 4.2 ka event in the northern margin of the East Asian
41 summer monsoon (EASM). We suggest that the drought would be caused by a large decline
42 in the intensity of the EASM on millennial-to-centennial scales that could be physically
43 related to persistent cooling of surface waters in the western tropical Pacific and the North
44 Atlantic. The cooling of western tropical Pacific surface waters could reduce moisture
45 productions over the source area of the EASM, while the cooling of North Atlantic surface
46 waters could suppress northward migrations of the EASM rainbelt, both leading to a
47 weakened EASM and thus decreased rainfall in the northern margin of the EASM.

60 **1 Introduction**

61

62 The 4.2 ka event has attracted worldwide interest since two articles published in the
63 periodical *Science* (Weiss and Bradley, 2001; deMenocal, 2001) demonstrated that the
64 drought that occurred 4.2 ka ago could be a possible cause for the collapse of ancient
65 civilizations. Judging from the viewpoint of the history of paleoclimate research, however,
66 almost no special attention had been paid to the 4.2 ka event prior to the publication of the
67 two highlighted articles when the Holocene climatic instability had become an increasingly hot
68 topic in the field of paleoclimatology.

69 In early 1990s when an oxygen isotope record for the Greenland Ice-core Project (GRIP)
70 Summit ice core has just come out, the Holocene climate was viewed as extremely stable in
71 contrast with large, abrupt climate changes during both the last two glaciations and the last
72 interglacial (Dansgaard et al., 1993). In 1995, however, concentrations of sea salt and
73 terrestrial dusts from the same ice core demonstrated that the Holocene climate of Greenland
74 was punctuated by 4 times of millennial-scale shifts during the periods of 8800–7800, 6100–
75 5000, 3100–2400 and 600–0 yr ago (O'Brien et al., 1995). Subsequently in 1997, an
76 integrated Holocene climatic record of accumulation rate, $\delta^{18}\text{O}$ -based temperature, chloride
77 and calcium concentrations, fire frequency and methane concentration for the Greenland Ice
78 Sheet Project II (GISP2) ice core revealed a cold event that occurred between 8.4 and 8.0 ka
79 ago, typically peaking at 8.25 cal. ka BP (Alley et al., 1997). This was first to put forward a
80 prominent, widespread climatic event for the warm Holocene, i.e., the 8.2 ka event. In any
81 case, however, no clear signals of the 4.2 ka event had been identified in the ice-core records
82 from Greenland.

83 Encouraged by the findings of O'Brien et al. (1995), Bond et al., (1997) launched an
84 investigation of deep-sea sediments in the North Atlantic and detected a series of abrupt shifts
85 that punctuated the Holocene climate through studies on ice-rafted debris in the sediments.
86 These abrupt climate events seemingly occurred at a cyclicity of 1470 ± 500 yr during the
87 Holocene, which did not generate any particularity for the 4.2 ka event. Taking the
88 paleoclimatic record of Greenland ice cores together, the 4.2 ka event appears to be
89 unexceptional for the Holocene climate in high latitudes of the Northern Hemisphere.

90 As early as in 1990s, in fact, the 4.2 ka event was first explained as a possible
91 contributor to the collapse of ancient civilization (Weiss et al., 1993). Weiss et al. (1993)
92 identified a marked increase in aridity and wind circulation occurring in northern
93 Mesopotamia at 2200 BC based on studies of archaeological sites on alluvial plains of the
94 Tigris and Euphrates Rivers, suggesting that the abrupt climatic change induced a considerable
95 degradation of land-use conditions and thus caused the collapse of the rain-fed agriculture
96 civilization of western Asia. Years later, the above-mentioned two articles (Weiss and Bradley,
97 2001; deMenocal, 2001) demonstrated that the drought that occurred 4.2 ka ago could explain
98 the societal collapse of Old World civilizations based on existing archaeological and
99 paleoclimatic data. This point of view has promoted extensive investigations into the causal
100 relationship between cultural evolution and climate change on archaeological records and also
101 drawn much attention from paleoclimatologists to researches of the 4.2 ka event. With the
102 accumulation of proxy records, however, both the nature of the 4.2 ka event (Marchant and
103 Hooghiemstra, 2004, Magny et al., 2009) and the manner of societal responses to climate
104 change (Drysdale et al., 2006; Staubwasser and Weiss, 2006) have become increasingly
105 controversial.

106 Researches on the 4.2 ka event and its impact on cultural evolution in China have been
107 motivated by Hsü's view that famines and mass migrations occurring in ancient China could
108 have resulted from regional droughts related to global cooling (Hsü, 1998). Wu and Liu (2004)
109 synthesized data from paleoclimatic records in eastern China and suggested that the climatic
110 anomaly that occurred ~4.2 ka ago produced a drought in the north and flooding in the south,
111 which was responsible for the collapse of neolithic cultures in the central plain of China
112 during the late third millennium BC. Liu and Feng (2012) recently examined the newly
113 published data of paleoclimatic and archaeological records spanning the transition from the
114 middle to late Holocene and offered a different interpretation from that of Wu and Liu (2004).
115 In brief, an abrupt climatic shift occurred in northern China at ~4 cal. ka BP; while in
116 southern China the ~4 cal. ka event had several effects. With the associated climatic drying at
117 ~4 cal. ka BP, Chinese Neolithic cultures both in the north and in the south collapsed; while
118 the Longshan Culture in the central plain thrived.

119 Here we examined the paleoclimatic data from a sediment core at Hulun Lake in
120 northeastern Inner Mongolia and focused on the research of the 4.2 ka event occurring in the
121 lake region. Hulun Lake is located in the northern margin of the East Asian summer monsoon
122 that represents a climatically sensitive zone. The multi-proxy paleoclimatic records from the
123 lake would provide new insights into the 4.2 ka event. This study is aimed to identify the
124 nature and the associated mechanism of the 4.2 ka event occurring in the monsoonal region of
125 eastern Asia.

126

127 **2 Study site**

128

129 Hulun Lake (48°30.667' to 49°20.667'N, 117°0.167' to 117°41.667'E), the fifth largest
130 lake in China, is situated about 30 km south of Manchuria, Inner Mongolia, China (Fig. 1). It
131 lies in an inland graben basin that was formed in the late Pliocene (Xu et al., 1989). It has an
132 area of 2339 km² and a maximum water depth of 8 m when the lake level attains to the
133 highest status at an elevation of 545.3 m a.s.l. (measurements in August 1964; Xu et al., 1989).
134 Today, the lake is closed and the maximum water depth is 5 m (Fig. 1). Low mountains and
135 hills of Mesozoic volcanic rocks border the lake on the northwest and form a fault-scarp
136 shoreline. Broad lacustrine and alluvial plains extend from the southern and eastern shores of
137 the lake with scattered aeolian dunes. The lake has a catchment of 37,214 km² within the
138 borders of China. Two rivers, the Herlun from the southwest and the Urshen Rivers from the
139 southeast, supply water for the lake (Fig. 1). The Dalanolom River, an intermittent river to the
140 northeast of the lake, drains the lake when the elevation of the lake level exceeds 543.4 m a.s.l.
141 and enters the lake when the lake level is lower and the discharge of the Hailar River is larger
142 as well (Xu et al., 1989) (Fig. 1).

143 Hulun Lake is located in a semi-arid area of the middle temperate zone (Fig. 1). The
144 climate of the lake's region is influenced by the East Asian monsoon and the Westerlies
145 (Chinese Academy of Sciences, 1984; Zhang and Lin, 1985). During summer, warm, moist
146 southerly air-masses interact with cold air from the northwest and produce most of the annual
147 precipitation. During winter, cold, dry northwesterly airflows prevail and generate strong
148 winds and cold weathers. In the lake region, mean annual temperature is 0.3°C with a July

149 average of 20.3°C and a January average of -21.2°C. Annual precipitation is 247 to 319 mm,
150 and over 80% of the annual precipitation falls in June–September. Annual evaporation
151 reaches 1400 to 1900 mm, which is ~6 times the annual precipitation. The lake is covered
152 with ~1 m of ice from November to April.

153 The ostracodes living in the lake today include *Limnocythere inopinata* (Baird),
154 *Candoniella suzini* Schneider, *Pseudocandona albicans* (Brady), *Pseudocandona compressa*
155 (Koch), *Cyclocypris serena* (Koch), *Ilyocypris gibba* (Ramdohr) and *Ilyocypris salebrosa*
156 Stepanaiths (Xu et al., 1989; Wang and Ji, 1995). *Limnocythere inopinata* is the dominant
157 species. Aquatic plants are scarce in the lake and confined to the areas of the river mouth and
158 parts of the nearshore zone.

159 The modern natural vegetation of the lake basin belongs to the middle temperate steppe
160 (Compilatory Commission of Vegetation of China, 1980; Xu et al., 1989). The vegetation
161 cover ranges from relatively moist forb-grass meadow-steppe in the piedmont belt to
162 moderately dry grass steppe on the alluvial plain and dry bunchgrass–undershrub *Artemisia*
163 steppe on the lacustrine plain. Halophilic Chenopodiaceae plants are distributed in the
164 lowlands. The forests are developed on the west slopes of the Great Hinggan Range, where
165 the Urshen and Hailar River rise, accompanied by scrubs and herbs under the trees. Larch
166 forests cover the southern part of the Hentiy Mountains where the Herlun River rises. Patches
167 of pine forests and birch shrubberies occur in the alpine belt.

168

169 **3 Material and methods**

170

171 3.1 Lithology and chronology of the HL06 core

172

173 Drilling was conducted at a water depth of 5 m in the central part of Hulun Lake in
174 January 2006 when the lake was frozen (Fig. 1), using a TOHO drilling system. A sediment
175 core was extracted to a depth beneath the lake floor of 1.7 m and is designated HL06
176 (49°07.615' N, 117°30.356' E; Fig. 1). The core section was split, photographed and described
177 on site and then cut into 1-cm segments, resulting in 170 samples for laboratory analyses.

178 The sediments of the HL06 core can be divided into three parts: 1) upper blackish-grey
179 oozy mud at depths of 0–35 cm, 2) middle dark grey to blackish-grey, massive sandy mud
180 with scattered fragments of ostracodes and mollusk shells at depths of 35–100 cm, and 3)
181 lower greenish-grey homogeneous mud at depths of 100–170 cm (Xiao et al., 2009).

182 Thirteen bulk samples were collected from organic-rich horizons of the HL06 core and
183 dated with an Accelerator Mass Spectrometry (AMS) system (Compact-AMS, NEC
184 Pelletron) at Paleo Labo Co., Ltd. in Japan. As shown in Xiao et al. (2009), the uppermost 0–1
185 cm of the core sediments yields a ^{14}C age of 685 ± 21 yr that was considered to result from
186 carbon reservoir effects on radiocarbon dating of the bulk organic matter of Hulun Lake
187 sediments. To produce an age–depth model for the HL06 core, the carbon reservoir age of
188 685 ± 21 yr was first subtracted from all the original ^{14}C ages, and then calibrations are
189 performed on the carbon reservoir-free ^{14}C ages. The conventional ages were converted to
190 calibrated ages using the OxCal3.1 radiocarbon age calibration program (Bronk Ramsey,
191 2001) with the IntCal04 calibration data (Reimer et al., 2004). The age–depth model indicates
192 that the HL06 core covers the last ~11,000 yr (Xiao et al., 2009).

193

194 3.2 Proxy analyses of the HL06 core

195

196 The HL06 core has been analysed at 1-cm interval for multiple proxies including
197 grain-size distribution (Xiao et al., 2009), ostracode assemblage (Zhai et al., 2011), and pollen
198 assemblage (Wen et al., 2010a) in order to investigate the Holocene history of changes in the
199 hydrology of Hulun Lake and in vegetation and climate of the lake region. Grain-size
200 distribution was determined with a Malvern Mastersizer 2000 laser grain-size analyzer (Xiao
201 et al., 2009). Each sample of sediment was pretreated with hydrogen peroxide to remove
202 organic matter and then with boiled hydrochloric acid to remove carbonates. The sample
203 residue was dispersed with sodium metaphosphate on an ultrasonic vibrator before grain-size
204 analysis.

205 For the ostracode assemblage analysis, each sample of ~300 mg of air-dried sediment
206 was pretreated with hydrogen peroxide–sodium carbonate solution (pH 9–10) to disaggregate
207 the sediment (Zhai et al., 2011). Fossil ostracode valves were extracted by sieving in water

208 through a 250-mesh sieve (63- μm pore size). Ostracode was identified and counted from the
209 sieve residue spread onto a glass plate with an Olympus stereomicroscope at 40 \times
210 magnifications following the taxonomy of Meisch (2000) and Hou et al. (2002). Most
211 samples yielded 300 to 4000 ostracode valves.

212 For the pollen assemblage analysis, each sample of ~ 1 g of air-dried sediment was
213 pretreated with hydrochloric acid to remove carbonates and with sodium hydroxide to remove
214 organic matter; the residue was then kept in hydrofluoric acid to remove silicates (Wen et al.,
215 2010a). Fossil pollen grains were extracted by wet sieving of the resulting residue through a
216 sieve diameter of 10 μm with an ultrasonic cleaner. Pollen was identified and counted with an
217 Olympus light microscope at 400 \times magnifications. More than 600 pollen grains were counted
218 for each sample. The percentages of tree and herb pollen taxa were based on the sum of the
219 total terrestrial pollen in a sample, and those of each taxon of both aquatic pollen and fern
220 spores based on the sum of the terrestrial pollen plus the aquatic pollen or fern spores of the
221 taxon in a sample.

222 In addition, the history of changes in precipitation in the Hulun Lake region during the
223 Holocene was quantitatively reconstructed (Wen et al., 2010b) based on the pollen profile of
224 the HL06 core (Wen et al., 2010a), using a pollen–climate transfer function for temperate
225 eastern Asia (Wen et al., 2013).

226

227 3.3 Proxy data from the HL06 core used for the present study

228

229 The segment of the HL06 core spanning the period between 5000 and 3000 cal. yr BP is
230 used for the present study to focus on the research of the 4.2 ka event occurring in the Hulun
231 Lake region. Fig. 2 shows the lithology and ages of the core segment between 105 and 55 cm
232 at depth, which covers the segment between dated horizons of a calibrated age older than
233 5000 cal. yr BP and of a calibrated age younger than 3000 cal. yr BP. Ages of sampled
234 horizons of the core segment spanning the period of 5000–3000 cal. yr BP were derived by
235 linear interpolation between radiocarbon-dated horizons using the mean values of 2σ ranges
236 of calibrated ages.

237 Data of grain-size distribution (Xiao et al., 2009), ostracode assemblage (Zhai et al.,
238 2011), pollen assemblage (Wen et al., 2010a), and mean annual precipitation (Wen et al.,
239 2010b) from the HL06 core for the period of 5000–3000 cal. yr BP were re-examined in the
240 present study in order to explore the detailed process of climate changes on
241 millennial-to-centennial scales in the Hulun Lake region around 4.2 cal. ka BP.

242

243 **4 Results**

244

245 The sediments of the core segment spanning the period of 5000–3000 cal. yr BP consist
246 of dark grey to blackish-grey, massive sandy mud in which the scattered fragments of
247 ostracode and mollusk shells can be seen (Fig. 2). Five radiocarbon dates provide age controls
248 for the core segment spanning the period of 5000–3000 cal. yr BP (corresponding to the core
249 depths of 97–68 cm) (Fig. 2; Table 1). Data of sand fraction content, littoral ostracodes
250 abundance, Chenopodiaceae pollen percentage, and mean annual precipitation from the core
251 segment spanning the period of 5000–3000 cal. yr BP were plotted against age in Figure 3.

252

253 4.1 Sand fraction content

254

255 The content of the sand fraction in the core sediments has an average of 7.5% for the
256 period of 5000–3000 cal. yr BP (Fig. 3). At the interval of 4560–3820 cal. yr BP (core depth:
257 92.0–82.5 cm), the sand fraction content shows higher-than-average values with a maximum
258 of 21.1% and an average of 15.0% (Fig. 3).

259

260 4.2 Littoral ostracodes abundance

261

262 The abundance of the littoral ostracodes including *Pseudocandona albicans*,
263 *Pseudocandona* sp., *Candoniella subellipsoidea*, and *Cypridopsis* sp. from the core sediments
264 has an average of 22 valves g⁻¹ for the period of 5000–3000 cal. yr BP (Fig. 3). At the interval
265 of 4380–3380 cal. yr BP (core depth: 90.0–75.5 cm), the littoral ostracodes abundance shows

266 higher-than-average values with a maximum of 70 valves g^{-1} and an average of 40 valves g^{-1}
267 (Fig. 3).

268

269 4.3 Chenopodiaceae pollen percentage

270

271 The percentage of Chenopodiaceae pollen from the core sediments has an average of
272 42.9% for the period of 5000–3000 cal. yr BP (Fig. 3). At the interval of 4610–3460 cal. yr
273 BP (core depth: 92.5–77.0 cm), the Chenopodiaceae pollen percentage shows
274 higher-than-average values with a maximum of 60.2% and an average of 51.3% (Fig. 3).

275

276 4.4 Mean annual precipitation

277

278 The mean annual precipitation in the lake region reconstructed on the pollen profile of
279 the sediment core has an average of 297.3 mm for the period of 5000–3000 cal. yr BP (Fig. 3).
280 At the interval of 4580–3580 cal. yr BP (core depth: 92.0–79.5 cm), the mean annual
281 precipitation shows lower-than-average values with a minimum of 264.0 mm and an average
282 of 278.2 mm (Fig. 3).

283

284 **5 Discussion**

285

286 5.1 Climatic implication of proxy data from the HL06 core

287

288 Grain-size distributions of the core sediments show that the clay, silt and sand fractions
289 average 35.8%, 60.6% and 3.6% of the clastic materials during the Holocene, respectively
290 (Xiao et al., 2009). Sand grains from the nearshore zone of Hulun Lake could be transported
291 to and deposited in the central part of the lake when the lake assumed low stands. Therefore
292 increases in the relative percentage of the sand fraction in the core sediments were interpreted
293 to indicate drops in the water level of Hulun Lake (Xiao et al., 2009). We thus infer that
294 higher values of the sand fraction content at the interval of 4560–3820 cal. yr BP imply
295 relatively lower lake levels at that time (Fig. 3).

296 Ostracode assemblages of the core sediments suggest that fourteen species of ostracodes
297 belonging to nine genera occur in Hulun Lake during the Holocene and *Limnocythere*
298 *inopinata* is the dominant species (Zhai et al., 2011). *Pseudocandona albicans*,
299 *Pseudocandona* sp., *Candoniella subellipsoidea*, and *Cypridopsis* sp. from the core sediments
300 were interpreted as littoral ostracode taxa because these ostracodes usually live in small water
301 bodies and shallow waters and have a wide tolerance to water temperature or salinity (Zhai et
302 al., 2011). We thus infer that higher values of the littoral ostracodes abundance at the interval
303 of 4380–3380 cal. yr BP imply relatively lower lake levels at that time (Fig. 3).

304 Pollen assemblages of the core sediments suggest that dry grass steppe dominated by
305 *Artemisia* and Chenopodiaceae plants were developed in the Hulun Lake basin during most of
306 the Holocene (Wen et al., 2010a). In the modern steppe of northern China, Chenopodiaceae
307 predominates over *Artemisia* in the desert steppe as compared with in the typical steppe.
308 Therefore increases in the relative percentage of Chenopodiaceae pollen in the core sediments
309 were interpreted to indicate decreases in the effective moisture in the lake basin (Wen et al.,
310 2010a). We thus infer that higher values of the Chenopodiaceae pollen percentage at the
311 interval of 4610–3460 cal. yr BP imply relatively lower effective moistures in the lake basin
312 at that time (Fig. 3).

313 The pollen-reconstructed mean annual precipitation yields a value of around 285 mm in
314 the Hulun Lake region for the last decades (Wen et al., 2010b). This value of the mean annual
315 precipitation falls within the range of observed data of the annual precipitation (247–319 mm),
316 demonstrating the validity of the pollen–climate transfer function in quantitatively
317 reconstructing the regional precipitation. Therefore lower values of the mean annual
318 precipitation at the interval of 4580–3580 cal. yr BP denote relatively drier conditions in the
319 lake basin at that time (Fig. 3).

320

321 5.2 The nature and timing of the 4.2 ka event in the Hulun Lake region

322

323 As remarked above, the sand fraction content and the littoral ostracodes abundance of
324 the lake sediments can be used as indicators of changes in the lake level that is closely related
325 to changes in the water balance (precipitation plus runoff minus evaporation) of the lake; while

326 the Chenopodiaceae pollen percentage can be used as a direct indicator of changes in the
327 effective moisture in the lake basin. The mean annual precipitation can directly indicate
328 changes in the amount of precipitation in the lake basin. During the period of 5000–3000 cal.
329 yr BP, data of the sand fraction content, littoral ostracodes abundance, Chenopodiaceae pollen
330 percentage, and the mean annual precipitation can be well correlated with each other,
331 although the intervals of a relatively drier climate in the lake basin registered by different
332 proxies differ slightly in the time of start and end (Fig. 3).

333 In order to detect the pattern of temporal changes in the regional dry–wet condition
334 during the period of 5000–3000 cal. yr BP, principle component analysis (PCA) was
335 performed to analyze the time series of data of the sand fraction content, littoral ostracodes
336 abundance, Chenopodiaceae pollen percentage, and the mean annual precipitation. All the raw
337 data of the 4 proxies were standardized, and then PCA was conducted on the standardized
338 data with the proxies as variables. F1, F2 and the first three factors of PCA capture 74.5%,
339 15.4% and 97.9% of the total variance within the data set, respectively. As shown in Figure 3,
340 PCA F1 with an average of 0 for the period of 5000–3000 cal. yr BP displays
341 higher-than-average values at the interval of 4540–3480 cal. yr BP (core depth: 92.0–77.5 cm)
342 with a maximum of 1.71 and an average of 0.88.

343 PCA F1 reflects the common characteristics of the aforementioned four proxies for the
344 relatively drier climate in the lake region at the interval of 4540–3480 cal. yr BP.
345 Discrepancies in both the timing of the relatively drier interval from each proxy and the detail
346 of different proxies on centennial to multi-decadal scales within the interval can be explained
347 by differences in the response of different proxies to changes in the regional precipitation and
348 the lake’s hydrology. We thus suggest that the climatic drying occurring in the Hulun Lake
349 basin could be the regional manifestation of the 4.2 ka event.

350 In order to delimitate a dry event from the relatively drier climate at the interval of
351 4540–3480 cal. yr BP reflected by PCA F1, we define a central interval at which PCA F1
352 displays values that are larger than its average for the interval of 4540–3480 cal. yr BP (0.88).
353 This central interval started at 4230 cal. yr BP and ended at 3820 cal. yr BP with duration of
354 410 yr, which exactly delineates a peak interval for each of the four proxies (Fig. 3). We thus

355 suggest that the dry event corresponding to the 4.2 ka event occurred in the Hulun Lake
356 region at 4230–3820 cal. yr BP and lasted for 410 yr.

357

358 5.3 Possible cause of the 4.2 ka event in the Hulun Lake region

359

360 Hulun Lake is situated in the northern marginal zone of the East Asian summer
361 monsoon (EASM) (Fig. 1). Modern observations indicate that precipitation in the Hulun Lake
362 region reaches its peak value in July and ~70% of the annual precipitation falls in late June
363 through early August (Xu et al., 1989). Changes in the precipitation of the lake region in the
364 summer half-year totally follow the northward migrations of the EASM rainbelt (Fig. 4),
365 indicating that increases in the precipitation of the lake region would be closely related to
366 increases in the strength of the EASM. These data suggest that the dry event that occurred in
367 the Hulun Lake region at 4230–3820 cal. yr BP implies a large decline of the EASM.

368 The northward migrations of the EASM rainbelt in rainy seasons of East Asia are
369 characterized by two discontinuous jumps (i.e., jumping first to the Yangtse River–Huaihe
370 River basin, southwestern Japan and southern Korea in late June and then to northern China,
371 northeastern China and northern Korea in middle July after landing in southern China in late
372 May) (Fig. 4), which are influenced not only by the ocean–atmosphere interactions in the
373 tropical Pacific because the moisture/rainfall brought by the EASM onto the land derives
374 from the western tropical Pacific but also by the pattern of atmospheric circulation over
375 Northern Hemisphere high latitudes because the EASM frontal rainfall results from the
376 interaction between the warm-moist, southerly air-masses and the cold-dry, northwesterly
377 airflows (Chinese Academy of Sciences, 1984; Zhang and Lin, 1985). In Figure 5, therefore,
378 dry–wet oscillations in the Hulun Lake region reflected by PCA F1 for the period of 5000–
379 3000 cal. yr BP are compared with the sea-surface-temperature (SST) record from the western
380 tropical Pacific (Stott et al., 2004) and the hematite-stained-grains (HSG) record from the
381 North Atlantic (Bond et al., 2001).

382 As shown in Fig. 5, the large decline of the EASM occurring at 4230–3820 cal. yr BP
383 coincides, within age uncertainties, with decreases in the SST of the western tropical Pacific
384 (Stott et al., 2004) and with increases in the HSG concentration in the North Atlantic

385 sediments (Bond et al., 2001). This coincidence implies a physical link between the EASM
386 decline on millennial-to-centennial scales and the persistent cooling of surface waters of the
387 western tropical Pacific as well as the North Atlantic. In brief, continual decreases in sea
388 surface temperature of the western tropical Pacific presumably caused by more intense, more
389 frequent El Niño (Moy et al., 2002) could reduce the formation of water vapor over the source
390 area of the EASM, thereby decreasing the moisture available for transport via the EASM
391 circulation from the western tropical Pacific onto the Asian inland and leading to a weakened
392 EASM. While decreases in sea surface temperature of the North Atlantic could suppress the
393 northward migration of the EASM front, thereby hampering the northward jumps of the
394 EASM rainbelt and resulting in weakened rainfall in the northern marginal zone of the
395 EASM.

396

397 **6. Conclusions**

398

399 Multiple proxies of a sediment core at Hulun Lake in northeastern Inner Mongolia
400 reveal a prominent dry event occurring at the interval of 4230–3820 cal. yr BP that could be
401 the regional manifestation of the 4.2 ka event in the northern marginal zone of the EASM. The
402 drought would have resulted from a large decline of the EASM that could be physically linked
403 with the persistent cooling of surface waters of the western tropical Pacific and the North
404 Atlantic on millennial-to-centennial scales.

405 Although more and more proxy data have been obtained, an integrated view of the 4.2
406 ka event is still far beyond reach. Future studies should be focused on the investigation of
407 high-quality, high-resolution proxy records from more, climatically sensitive and
408 geographically representative regions in order to explore the spatiotemporal pattern of the 4.2
409 ka event and the associated dynamic mechanism.

511

512 **Figure 1.** Map of Hulun Lake (from <http://www.maps.google.com>) showing the location of
513 the HL06 core. The bathymetric survey of the lake was conducted in July 2005 with a FE-606
514 Furuno Echo Sounder (contours in meters). The inset gives a sketch map of China showing
515 the current northern limit of the East Asian summer monsoon (dashed line) defined as the
516 400-mm isohyet of mean annual precipitation (Chinese Academy of Sciences, 1984; Zhang
517 and Lin, 1985) and the location of Hulun Lake (solid circle). EASM shown in the inset
518 indicates the East Asian summer monsoon.

519

520 **Figure 2.** Lithological log and age–depth model of the segment of the HL06 core between
521 105 and 55 cm at core depth (covering the period between 5000 and 3000 cal. yr BP). Solid
522 circles represent the mean values of 2σ ranges of calibrated ages of carbon reservoir-corrected
523 radiocarbon dates. The carbon reservoir correction factor is 685 ± 21 yr, ^{14}C age of the
524 uppermost 1 cm of the core sediments. Modified after Xiao et al. (2009).

525

526 **Figure 3.** Time series of sand fraction (%) (Xiao et al., 2009), littoral ostracodes valve (valves
527 g^{-1}) (Zhai et al., 2011), Chenopodiaceae pollen (%) (Wen et al., 2010a), and mean annual
528 precipitation (mm) (Wen et al., 2010b) from the HL06 core spanning the period between 5000
529 and 3000 cal. yr BP as well as the PCA F1 obtained from the aforementioned four proxies.
530 The chronology was derived from the carbon reservoir-corrected age–depth model; ages of
531 sampled horizons were determined by linear interpolation between radiocarbon-dated
532 horizons using the mean values of 2σ ranges of calibrated ages (Xiao et al., 2009). Vertical

533 dashed lines show the averages of each proxy data as well as the average of PCA F1 values
534 during the period between 5000 and 3000 cal. yr BP. Light grey bars mark the intervals at
535 which the proxy or PCA F1 has higher-than-average (lower-than-average for mean annual
536 precipitation) values. The dark grey bar superimposed on light grey bars represents the
537 interval at which PCA F1 values are higher than the average of the higher-than-average values
538 for 5000–3000 cal. yr BP.

539

540 **Figure 4.** A sketch map of eastern China, Korea and western Japan showing precipitation
541 rates of the current East Asian summer monsoon. Data are averaged by observations of the
542 years 1979–2007 and expressed in mm d^{-1} at a grid resolution of $0.25^\circ \times 0.25^\circ$. (a) On the 4th,
543 5th and 6th pentads of July and 1st pentad of August. (b) On the 5th and 6th pentads of June
544 and the 1st and 2nd pentads of July. (c) On the 5th and 6th pentads of May and the 1st and
545 2nd pentads of June.

546

547 **Figure 5.** Correlation of dry–wet oscillation in the Hulun Lake region denoted by PCA F1
548 factor from the four proxies of the HL06 core with sea-surface temperature (SST, $^\circ\text{C}$)
549 reconstructed on the Mg/Ca ratio of *Globigerinoides ruber* from MD98-2176 core in the
550 western tropical Pacific (Stott et al., 2004) and hematite-stained grain concentration (HSG, %)
551 in VM29-191 core from the North Atlantic (Bond et al., 2001). The shaded bar marks an
552 interval of dry event occurring in the Hulun Lake region at 4230–3820 cal. yr BP.

553

554 **Table 1.** AMS radiocarbon dates of samples from the segment of the HL06 core between 105
555 and 55 cm at core depth (covering the period between 5000 and 3000 cal. yr BP). The
556 radiocarbon date of the uppermost 1 cm of the core sediments used for carbon reservoir
557 correction is shown. Modified after Xiao et al. (2009).
