

We thank very much editor L. Menviel for her additional comments that helped improve our manuscript. Below is the answer to L. Menviel latest comments.

1) Regarding EPC changes and their link to the upwelling. Thanks for providing maps of vertical transports and winds. Indeed the annual wind changes might be small, but it seems that the changes in vertical transport could impact EPC in the EEP and EEA... It is difficult for me to judge with what is available, but could you please check again.

Response: In order to make it clearer we have updated the previous Fig. R1c and have added the changes in carbon export as contour lines (Fig. R3). In the Pacific Ocean the regions affected by a decrease in carbon export production (blue lines) depict an increase in vertical mass flux (red shade), which is the opposite process expected. Therefore, we suggest that this decrease in carbon export production could potentially come from a signal in the Southern Ocean where these water masses originate. Similarly, in the Atlantic basin, the regions depicting an increase in carbon export production (black lines) show a relative decrease in vertical mass flux. Only in the 8°S-16°S area, the increase in vertical mass flux may also have a positive influence on the carbon export production.

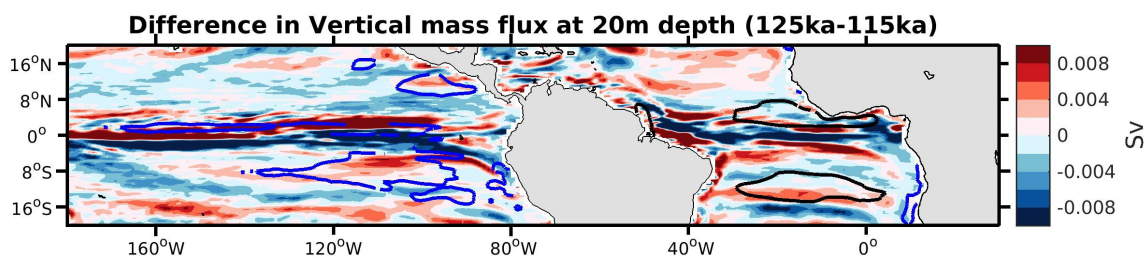

Figure R3: Difference in Vertical volume flux (positive depicts upward) between 125ka and 115ka. The blue (black) lines depict a decrease (increase) by $-4 \text{ g C m}^{-2} \text{ yr}^{-1}$.

Please check your statement about changes in wind speed in Section 3.3. p8, as this does not seem fully consistent with the figures you provided.

Response: We have revised the statement in Section 3.3 accordingly to Fig. R3.

Revision: "Although there are changes in surface wind speeds and vertical mass fluxes (not shown here) in the Equatorial regions, they do not consistently explain the simulated changes in export production (i.e., stronger wind and upwelling in eastern Equatorial Pacific at 125ka compared to 115ka, where a decrease in export production is simulated; in parts of the Equatorial Atlantic some increase in export production may be related to the simulated stronger upwelling at 125ka)."

2) In section 3.1., in the sentence you modified (L.4-5, p6): please add "an" before "increase": "...and an increase in mixed layer depth..."

Response: Done.

3) P8, L. 9: Since 125ka was before 115ka I would suggest to rephrase as:

“SSW boundary seems to be slightly poleward at 125ka (~60S) compared to 115ka (~58S).”

Response: We have modified the sentence accordingly.

Revision: "In addition, the SSW boundary (Fig. 3b,d, light purple dashed-lines) seems to be slightly poleward at 125ka (~60°S) compared to 115ka (58°S)."

4) P13, Please modify the last sentence of the amended section as follows: “...the LIG in order to simulate a decrease in atmospheric CO2 content”

Response: Done.

Ocean carbon inventory under warmer climate – the case of the Last Interglacial

Abstract. During the Last Interglacial period (LIG), the transition from 125ka to 115ka provides a case study for assessing the response of the carbon system to different levels of high-latitude warmth. Elucidating the mechanisms responsible for interglacial changes in the ocean carbon inventory provides constraints on natural carbon sources and sinks and their climate sensitivity which are essential for assessing potential future changes. However, the mechanisms leading to modifications of the ocean's carbon budget during this period remain poorly documented and not well understood. Using a state-of-the-art Earth System model, we analyze the changes in oceanic carbon dynamics by comparing two quasi equilibrium states: the early, warm Eemian (125ka) versus the cooler, late Eemian (115ka). We find considerably reduced ocean dissolved inorganic carbon (DIC; -314.1 Pg C) storage under the warm climate state at 125ka as compared to 115ka, mainly attributed to changes in the biological pump and ocean DIC disequilibrium components. The biological pump is mainly driven by changes in interior ocean ventilation timescales, but the processes controlling the changes in ocean DIC disequilibrium remain difficult to assess and seem more regionally affected. While the Atlantic bottom water disequilibrium is affected by the sea-ice induced SSW/NSW organization, the upper layer changes remain unexplained. Due to its large size, the Pacific accounts for the largest DIC-loss, approximately 57% of the global decrease. This is largely associated with better ventilation of the interior Pacific water mass. However, the largest simulated DIC differences per unit-volume are found in the southern sourced waters of the Atlantic. Our study shows that the deep water geometry and ventilation in the South Atlantic is altered between the two climate states where warmer climatic conditions cause southern sourced waters to retreat southward and northern sourced waters to extend further south. This process is mainly responsible for the simulated DIC reduction by restricting the extent of DIC rich southern sourced water, thereby reducing the storage of biological remineralized carbon at depth.

1 Introduction

The Last interglacial (LIG, or Eemian) is composed of a warm onset around 125ka before present (BP) characterized by warmer temperature in the high latitudes relative to the present and a progressive cooling toward 115ka when the last glaciation was initiated (Otto-Bliesner et al., 2006; Masson-Delmotte et al., 2010). Evidence from land, ice, and ocean records identify the former as the period with the most intense global warming during the last 200,000 years (Turney and Jones, 2010; Dorthe Dahl-Jensen et al., 2013; Capron et al., 2014) mainly due to changes in the orbital configurations. If anthropogenic greenhouse

gas emissions continue unabated, a climatically anomalously warm state is expected to occur in the near future with a warming that may be equivalent to the high-latitude reconstructed temperature for the LIG (Otto-Bliesner et al., 2013) by the end of this century. The changes in the warm Eemian period may therefore be considered an analog for a future warmer climate.

Few model based studies examine the carbon cycle dynamics for the LIG period with a particular focus on the ability of models to simulate the transient changes in atmospheric CO₂ concentration, which remains relatively stable around 270-280 ppm without displaying any trends (Lourantou et al., 2010; Schneider et al., 2013). Most of these studies provide a better understanding of the land carbon budget particularly highlighting the importance of temperature changes on the land vegetation and slow processes of CO₂ change such as peatland carbon dynamics and CaCO₃ shallow water accumulation (Schurgers et al., 2006; Kleinen et al., 2016; Brovkin et al., 2016). Although they are numerous studies that have analyzed the role of the ocean carbon cycle in regulating the atmospheric CO₂, especially for the interglacial-glacial transition period (Ridgwell, 2001; Sigman and Boyle, 2000; Menviel et al., 2012), to the authors' knowledge, there is no study that investigate in details changes in marine carbon and nutrient cycling during the Eemian period of the LIG (125ka – 115ka).

With respect to changes in large-scale ocean circulation, reconstructions indicate that deep Atlantic circulation patterns and water mass geometries likely change over this interval. While mid-depth ventilation of northern sourced waters is maintained in the ~~north~~-North Atlantic by the sustained NADW formation throughout the LIG (McManus et al., 2002; Mokeddem et al., 2014), southern sourced waters expanded at depth toward 115ka (Govin et al., 2009). In addition to large-scale circulation changes, temperature-induced changes in carbon solubility pumps and biological production are expected to alter the ocean carbon budget, in particular in the interior ocean. Other changes such as sea-ice extent and ocean ventilation could also affect ocean carbon sequestration rate during the LIG. Elucidating the mechanisms responsible for changes in the ocean carbon distribution and inventory is of interest as it provides past constraints and context for evaluating the response of natural carbon sources and sinks to future climate change. This study aims to fill this knowledge gap by analyzing and comparing, in terms of ocean carbon dynamic, two opposite states of the LIG: the early and warm Eemian onset (125ka) versus the cooler and late Eemian (115ka). Using a state-of-the-art Earth System model, our study addresses the regional differences in the ocean carbon storage and the underlying mechanisms.

The paper is organized as follows: in Section 2, we describe the model, the experiment design, as well as the terms and metrics used to quantify the differences in carbon dynamics during the two periods. Section 3 presents the results of the model simulations, while discussions and comparison with previous studies are presented in Section 4. Finally, the study is summarized in Section 5.

2 Method

2.1 Model description

The present study uses output of an updated version of the Norwegian Earth System model (NorESM1-ME), which has been recently developed to efficiently perform multi-millennial and ensemble simulations (Bentsen et al., 2013; Luo et al., 2018). This model includes an isopycnal-coordinate ocean general circulation model based on the Miami Isopycnal Coordinate Ocean

Model (MICOM, Bleck et al., 1992) and a biogeochemical ocean module adapted from the Hamburg Oceanic Carbon Cycle (HAMOCC5) model (Maier-Reimer, 1993; Maier-Reimer et al., 2005; Tjiputra et al., 2013). The inorganic seawater carbon chemistry in HAMOCC5 includes prognostic partial pressure of CO₂ (pCO₂) according to the Ocean Carbon-Cycle Model Intercomparison Project (OCMIP) protocols. The pCO₂ is computed as a function of temperature, salinity, dissolved inorganic carbon (DIC), total alkalinity (TALK) and pressure. This adapted version of HAMOCC5 does not include prognostic weathering fluxes, but employs a 12-layers sediment model following Heinze et al. (1999), which is particularly relevant for long-term transient simulations. The horizontal resolution of the land and atmospheric components is approximately 2°, while the ocean and ice components have higher resolutions of approximately 1°. In the vertical, the ocean model adopts 53 isopycnal layers.

The land component in NorESM (CLM4, Community Land Model version 4) is based on version 4 of the CLM family (Lawrence et al., 2012a). The land surface is sub-gridded into three sub-gridded entities: land units, columns and plant functional types (PFTs). These sub-gridded cells are used to represent large-scale patterns of the landscape, variability in the soil and snow state variables, and the exchanges between land surface and atmosphere, respectively. Each of the sub-grid entities has its own prognostic variables, is independent and experiences the same atmospheric forcing. Each cell is averaged and weighted with its fractional area.

The marine ecosystem is based on a Nutrient-Phytoplankton-Zooplankton-Detritus (NPZD) model that includes dissolved organic carbon (DOC). The inorganic nutrients consist of three macronutrients (phosphate, nitrate and silicate) and one micronutrient (dissolved iron). A constant Redfield ratio is adopted in the model as $P : C : N : \Delta O_2 = 1 : 122 : 16 : -172$. The phytoplankton growth rate is expressed as function of temperature, light (Smith, 1936; Eppley, 1972), phosphate, nitrate and dissolved iron availability, and its loss is regulated by an exudation and mortality rate, in addition to zooplankton grazing. The penetration of light decreases with depth following an exponential function, which responds to a gradual extinction factor formulated as a function of water depth and chlorophyll concentration (Maier-Reimer et al., 2005). The model prescribes a global constant vertical sinking speed of particles produced in the euphotic zone (above 100 m depth). The particulate organic carbon (POC), which comprises dead phytoplankton and zooplankton, sinks through the water column with a speed of 5 m day⁻¹ and is remineralized at a constant rate of 0.02 day⁻¹ when oxygen is available. Other particles such as opal shells and particulate inorganic carbon (PIC) sink at a speed of 60 and 30 m day⁻¹, respectively. Particulates that reach the sea floor without being remineralized interact chemically with the sediment pore water via bioturbation and vertical mixing and advection within the sediment layers. In the model, the air-sea gas exchange of CO₂ and O₂ only occurs between the ocean surface and the atmosphere in ice-free regions and is computed according to the following three components (Wanninkhof, 1992): the gas solubility in seawater, which is computed as a function of surface salinity and temperature according to Weiss (1970, 1974); the gas transfer velocity, which is proportional to the square of the surface wind speed and is computed as a function of the Schmidt number; and finally the air-sea gradient of gas partial pressures. To better elucidate various biogeochemical processes on the carbon cycle, the model is updated to also include preformed O₂, TALK and PO₄ tracers in the biogeochemical module. At surface, these preformed tracers are set to their non-preformed value and are advected passively by the ocean circulation in the interior without any other sources and sinks. Finally, in order to provide information of the water mass ages since its last contact with the atmosphere, an idealized age tracer is implemented and simulated in the NorESM model. Hence, the age tracer

is set to zero for all water masses at the ocean surface and subsequently transported and mixed passively with circulation in the ocean interior and integrated with the model time step. This tracer is also used to estimate the the ventilation rate of different interior water masses.

2.2 Experiment setup

Two equilibrium experiments are performed over the Eemian, one near the onset (warmer than today; 125ka) and one at the end (colder; 115ka) of the Last Interglacial. Both experimental configurations follow the standard protocols of the third phase of the Paleoclimate Modelling Intercomparison Project (PMIP3; *URL = <https://pmip3.lsce.ipsl.fr/>*), with a fixed vegetation coverage from the pre-industrial boundary conditions. The only differences with the pre-industrial configurations are the orbital parameters and the greenhouse gases concentrations (CO_2 , CH_4 , N_2O). For the experiment at 125ka (115ka), the atmospheric CO_2 , CH_4 and N_2O levels are prescribed to be 276 ppmv (273 ppmv), 640 ppb (472 ppb) and 263 ppb (251 ppb), respectively. The two experiments are branched off from 1000 years of spin up with a pre-industrial set up and forced with their respective interglacial boundary conditions for 4000 simulation years.

In the last 50 years of Eemian forcing simulations the ocean is close to equilibrium. Only small drifts remain, mainly in the Pacific basin where the equilibrium is still not fully established. Therefore, the global ocean DIC and TALK slightly decrease at 125ka (115ka) experiment by approximately $-0.15 \text{ PgC yr}^{-1}$ ($-0.06 \text{ PgC yr}^{-1}$) and $-0.01 \text{ Pmol yr}^{-1}$ ($-0.01 \text{ Pmol yr}^{-1}$), respectively. However, these drifts are small compared to the absolute ocean budget in DIC (37391 and 37705 PgC) and TALK (3291 and 3303 Pmol) for the experiment 125ka and 115ka, respectively. The differences in pCO_2 and TALK budget are small between the two experiments. Such changes would affect the DIC budget by about 32 PgC. The CO_2 flux is relatively constant and depicts the ocean as a weak source to the atmosphere with an outgassing of 0.12 ± 0.06 at 115ka and $0.15 \pm 0.06 \text{ Pg C.yr}^{-1}$ at 125ka. In addition, the difference in sedimentation rates between the two experiments ($\approx 6.10^{-4} \text{ PgC}$) appears to be negligible compared to the difference in DIC budget.

2.3 DIC decomposition

In order to analyze the oceanic carbon cycle, dissolved inorganic carbon (DIC) is decomposed into its preformed and biological components (Eq. (1)), following Bernadello et al. (2014):

$$DIC^{tot} = DIC^{pre} + DIC^{bio} \quad (1)$$

The preformed component of DIC (DIC^{pre}) comprises saturated and disequilibrium parts (Eq. (2)).

$$DIC^{pre} = DIC^{sat} + DIC^{dis}, \quad (2)$$

where the DIC at saturation (DIC^{sat}) describes the DIC concentration when the water parcel is in full equilibrium with the atmospheric CO_2 when it is last in contact at surface. In our model it seems to mainly refer to changes in preformed ALK. However, we compute this variable offline with the inorganic carbon chemistry program CO2SYS developed in Matlab (van Heuven et al., 2011) computation including other parameters such as the model output of preformed alkalinity ($TALK^{pre}$),

performed phosphate (PO_4^{pre}), surface silicate, salinity and temperature. In addition, the atmospheric CO_2 concentration from each experiment is used. To complete the CO2SYS input, we applied the dissociation constants K1 and K2 introduced by Mehrbach et al. (1973) and refitted by Dickson and Millero (1987). The disequilibrium part of DIC (DIC^{dis}) measures the disequilibrium state of the surface water with respect to the atmosphere. This parameter is computed from the DIC^{tot} (output) to which the biological and saturated DIC components (DIC^{bio} and DIC^{sat}) are subtracted. Therefore, all components are included in its calculation. A negative DIC^{dis} occurs when the water parcel sinks into the ocean interior before a full equilibration with the atmosphere is obtained, which lead to an undersaturation of the water parcel. This undersaturation can also be reinforced by biological CO_2 consumption at the surface, which tends to increase the time scale needed for the water parcel to equilibrate. On the contrary, a positive DIC^{dis} translates into a supersaturation. This latter occurs when deep waters, which contains high concentration of DIC because of remineralization processes, upwell or mix vertically with the surface waters (Follows and Williams, 2004). Both, DIC^{dis} and DIC^{sat} are transported by ocean circulation into the interior ocean.

The biological component of DIC comprises (1) the interior remineralization of organic matter (expressed in carbon), which is produced in the euphotic layer via photosynthesis (also referred to as soft-tissue pump) and (2) the remineralization of planktonic calcium carbonate shells (expressed in carbon; calcium carbonate pump). These two remineralization components are added to form the biological component of DIC, as shown in Eq. (3).

$$DIC^{bio} = DIC^{soft} + DIC^{carb}. \quad (3)$$

The remineralization of soft tissues (hereafter DIC^{soft}) contributes via phosphate (PO_4)-remineralization through a carbon phosphorus stoichiometric ratio $r_{C:P} = 122$. This component is calculated from the difference between the total and the performed PO_4 according to

$$DIC^{soft} = r_{C:P}(PO_4^{tot} - PO_4^{pre}). \quad (4)$$

The carbonate pump contributes through the dissolution of $CaCO_3$ hard shells, calculated as difference between the total and the performed alkalinity and PO_4 following

$$DIC^{carb} = 0.5[TALK^{tot} - TALK^{pre} + r_{N:P}(PO_4^{tot} - PO_4^{pre})], \quad (5)$$

where $r_{N:P} = 16$ is the Redfield ratio adopted by the model and the phosphate term accounts for the alkalinity changes owing to the soft-tissue pump.

In our analysis, we show differences between the warmer 125ka and the colder 115ka experiments. We therefore use the delta notations ΔDIC^{tot} , ΔDIC^{sat} , ΔDIC^{soft} , ΔDIC^{carb} and ΔDIC^{dis} to refer changes between the warmer and the colder periods.

2.4 Water mass analysis

In order to identify water mass sources, we apply the 'PO' tracer as defined by Broecker (1974). It is computed using phosphate and oxygen fields following

$$PO = O_2 + r_{O:P} \times PO_4 \quad (6)$$

where $r_{O:P} = 172$ is the phosphorus to oxygen stoichiometric ratio used in the model. This tracer is presumed to be nearly constant for a specific water mass. It is based on the principle that phosphate is released, while oxygen is used during remineralization, and vice versa during biological production. The distinction of water masses using PO is useful for contrasting water masses with very different surface PO values. Here, we mainly use PO to identify northern- and southern-sourced water masses (NSW and SSW) in the deep ocean below 1000 m depth characterized by low and high PO values, respectively.

3 Results

Section 3.1 describes the sea surface temperature and sea ice changes while changes in water mass properties are discussed in Sect. 3.2. The near surface changes that particularly influence the biological pump is addressed in Sect. 3.3 and global to regional oceanic DIC storage changes are presented in Sect 3.4. The analysis is performed over the average of the last 50 years of the simulations. In addition, the global ocean is divided into three main basins: Atlantic, Indian and Pacific.

3.1 Sea Surface Temperature and Sea-ice

Our model simulates a global and annual increase of sea surface temperature (SST; $+0.27^\circ\text{C}$) at 125ka relative to 115ka experiment. This warming is mainly simulated in the high latitudes (Fig. 1a-d) where higher SSTs are simulated throughout the year in the Southern Ocean, south of Greenland, the Norwegian sea and the northern part of the Pacific Ocean. This persistent warming at 125ka induces the sea ice to melt (Fig. 1, green and purple lines). Consequently, in the areas where sea-ice extent is reduced, there is more air-sea gas exchange and [an](#) increase in mixed layer depth (MLD; Fig. 1, black lines in the Southern Ocean). In the Labrador Sea the mixed layer depth at 125ka is deeper of more than 100m than at 115ka. This is due to higher salinity simulated in this region at 125ka. At lower latitudes, the SSTs vary more spatially and seasonally. For example, in some parts of the Atlantic Ocean (North Atlantic drift, Equatorial and some sections of the Subantarctic near 45°S band) cooler SSTs are simulated over several seasons ($\Delta\text{SST} < 0$, Fig. 1a-b). While the North Atlantic drift depicts cooler SSTs during boreal winter and spring (Fig. 1a-b), colder SSTs last until the boreal summer in the Equatorial region of the Atlantic Ocean (Fig. 1a-c). The 45°S latitude band remains cooler over the four seasons. Here, the MLD seems to be more controlled by changes in salinity instead of temperature distribution.

We note that relative to the preindustrial, based on proxy (Hoffman et al., 2017), our model simulates consistent spatial feature of annual SST anomalies at 125ka. It simulates (i) strongest warming in the high latitude, specifically in parts of the Southern Ocean, (ii) weak cooling in the low latitude, (iii) cooler SST in most of Indian Ocean, and (iv) warmer north-east

Pacific, among others. Nevertheless, the amplitude of SST warming and cooling at specific sites tend to be weaker in our model. This feature appears to be common in other global models and could be attributed to their low spatial resolutions (Hoffman et al., 2017).

3.2 Water mass properties

In order to analyze the water mass properties, it is useful to examine the changes in the overturning circulation. Figure 2 shows the global overturning stream function in the Southern Ocean for both experiments. The Antarctic circumpolar current is simulated stronger and deeper at 125ka compared to 115ka (Fig. 2). This strengthening is mainly occurring in the Pacific section of the Southern Ocean (near $50^{\circ}S$), suggesting an increase of the ventilation rate of the intermediate waters formed in this region. The Atlantic section of the Southern Ocean remains weakly modified. Indeed, using the same model simulations as the present study, Luo et al. (2018, supplementary information Fig. S8) show that the surface wind speed in the east and west southern Atlantic are relatively similar at 125ka and 115ka. In addition, they also show that the simulated AMOC at 125ka is as vigorous as at 115ka but deepened by about 300m depth. This suggests that the mid-depth and bottom water in the North Atlantic Ocean should be better ventilated at 125ka than at 115ka.

These changes in the overturning circulation affect the water mass age tracer. Analyzing this parameter allows us to examine the interior ocean ventilation rate. A reduction in water mass age translates to a stronger ventilation rate and vice versa for an increase in age. The differences in water mass age between 125ka and 115ka are presented in Fig. 3 depicting the zonally averaged sections for each ocean basin. The water mass ages in the Atlantic and the Indian Oceans show similar patterns with mean older water masses in the upper layers at 125ka (roughly +100 years), and younger water masses below 1000 m depth (by as much as 500 years younger). This is consistent with a deeper and slightly deeper AMOC at 125ka as shown in Luo et al. (2018). The Southern Ocean (south of $50^{\circ}S$) contains younger water masses throughout the entire water column in both basins at 125ka, translating a stronger ventilation rate. This is likely due to changes in the SSW to NSW distribution. Figure 4 shows that there is a clear distinction between interior water mass structure in the Atlantic basin between 115ka (Fig. 4a) and 125ka (Fig. 4c). It shows that below 2000m depth the SSW retreats further southward at 125ka relative to 115ka in the Atlantic basin. This confinement in SSW is induced by the change in the Antarctic sea-ice cover (Fig 1). Such processes have been introduced by Ferrari et al. (2014). However, the model also simulates a modification in SSW density (-0.2 kg m^{-3} at 125ka compared to 115ka, Fig 4a,c). This reduction in water density is mainly driven by the input of low salinity fresh water from the melting of the Antarctic sea-ice and may have an additional impact on determining the Atlantic distributions of NSW and SSW. As a result of sea-ice retreat, the winter mixed layer depth in this area increases, inducing younger water mass age in the Southern Ocean. At the near surface ($\approx 800\text{m}$ depth) the SSW seems to enter further north in the Atlantic basin at 125ka (Fig. 4c) relative to 115ka (Fig. 4a).

While such large redistributions of northern and southern origin deep waters only occur in the Atlantic, these changes also influence water properties in the Indian Ocean due to the 'downstream' advection of younger deep water into the interior during the warmest period (125ka - Fig. 3b). In addition to simple advection of younger water northward in the Indian basin, the residence time of Indian Ocean's deep water must also decrease since the ventilation ages decrease northward at depth.

By contrast, in the Pacific Ocean, the zonally averaged bottom water mass ages are simulated to be older at 125ka (Fig. 3c). However, this basin can be divided between the western and eastern side. While the western side is also influenced by the younger water masses created in the Atlantic Ocean, the eastern side waters of the basin are simulated to be older at 125ka by as much as 300 years. These older water masses are created in the Pacific SO and may be affected by a flattening of the isopycnals south of $60^{\circ}S$ at 125ka (Fig. 4d, gray lines). This flattening of the isopycnals is influenced by both sea-ice melting and higher SSTs, and suggests stronger stratification and weaker subduction rate. In addition, the SSW boundary ~~seems to be shifted southward from $58^{\circ}S$ at 115ka to $60^{\circ}S$ at 125ka~~ (Fig. 3b,d, light purple dashed-lines) seems to be slightly poleward at 125ka ($\sim 60^{\circ}S$) compared to 115ka ($\sim 58^{\circ}S$). This may suggest that more surface water originating from the subtropical gyre (more depleted in phosphate) enters the Pacific section of the Southern Ocean. Finally, the Pacific intermediate waters are simulated as younger at 125ka when compared to 115ka (Fig. 3c), which is consistent with the strengthening of upper cell of the overturning circulation previously mentioned for this region.

The southern sourced waters are particularly affected in terms of geometry distribution. We therefore divide the changes from these SSW into the three basins. Table 1 summarizes the changes occurring below 1000 m depth in the SSW in terms of volume, DIC and water mass age for each basin and reveals the Atlantic as the most affected area under warmer climate conditions. The relative difference in all those three characteristics (ΔV_{SSW} , ΔAge_{SSW} and ΔDIC_{SSW}) between 125ka and 115ka are the greatest in the Atlantic (-37% , -262 years and -0.92 g C m $^{-3}$). This demonstrates that the ventilation mechanism in the Atlantic sector of the SO is likely to be more sensitive (than in other basins) to climate change.

In response to the different forcings between 125ka and 115ka, significant changes are simulated in deep water ventilation rates and water mass distribution in the three basins. While the responses in the Atlantic and Indian Oceans have some similarity (better deep water ventilation), the Atlantic basin seems to be the most sensitive and simulates also water mass geometry changes. However, the ventilation rate in the Pacific Ocean depicts an opposite sign of change than the Atlantic and Indian Oceans. In the next section we discuss how these modification impact the near surface productivity in our model.

3.3 Near surface productivity

Figure 5 shows the differences in carbon export production (EPC) and phosphate (PO₄) at the surface of the ocean between 125ka and 115ka. When comparing 125ka to 115ka experiments, our model simulates two major features characterized by (i) an increase in EPC in the equatorial region of the Atlantic Ocean (Fig. 5a, turquoise rectangle) and (ii) a reduction in EPC of similar magnitude in the equatorial region of the Pacific Ocean (Fig. 5a, purple rectangle). Although there are changes in surface wind speeds and vertical mass fluxes (not shown here) in the Equatorial regions, they do not consistently explain the simulated changes in export production (i.e., stronger wind ~~speed in the Equatorial Pacific Ocean and weaker wind speed in~~ and upwelling in eastern Equatorial Pacific at 125ka compared to 115ka, where a decrease in export production is simulated; in parts of the Equatorial Atlantic ~~region some increase in export production may be related to the simulated stronger upwelling~~ at 125ka). However, nutrient changes in the Atlantic and Pacific sections of the Southern Ocean are consistent with the changes in export production and therefore we suggest the following mechanism. In the Atlantic Ocean, the Subantarctic water ($45^{\circ}S$ latitude band) corresponds to the southern sourced intermediate water formation in the model. This water mass sinks and reemerges

along the Equator (Fig. 5, turquoise rectangles). This pattern expected from models and modern observations shows that the intermediate and mode waters formed in the high southern latitudes feed the subtropical thermocline and act as a predominant source of nutrients important for sustaining low-latitude biological productivity (Gu and Philander, 1997; Sarmiento et al., 2004b). We acknowledge that there is uncertainty in the complex pathways of the subantarctic water masses toward the Equator simulated in the model. Nevertheless, due to higher preformed and remineralized phosphate in the subantarctic water sinking region, more PO_4 is advected through this 'ocean tunnel' to the equator and therefore leads to an increase in EPC (Fig. 5a, turquoise rectangle). A similar 'ocean tunnel' (Fig. 5, purple rectangle) connects the high and low latitude in the Pacific Ocean but results in the opposite sign of change. Here, as pointed out in Sect. 3.2, more subtropical waters seems to enter the Pacific Southern Ocean at 125ka than at 115ka. These waters are depleted in phosphate compared to southern sourced waters. As a result, less phosphate is subducted toward the equatorial Pacific Ocean (Fig. 5b, purple rectangle) leading to a reduction in the EPC near the equatorial upwelling (Fig. 5a, purple rectangle).

There are no significant changes in the biological activity in the Indian Ocean or the remaining of the Southern Ocean. Only a weaker carbon export at 125ka relative to 115ka is simulated around 40°S and the Arabian sea.

Thus, the simulations reveal that changes in Southern Hemisphere thermocline ventilation regions modulate basin scale productivity and export production even within an interglacial period with modest changes in external forcing. This result is broadly consistent with previous studies suggesting that the upper limb of the biogeochemical divide is critical for setting biological export production and is sensitive to climate changes (Sarmiento et al., 2004a; Marinov et al., 2006; Moore et al., 2018). Despite zonally homogeneous forcing we find a basinally heterogeneous response in both Subantarctic ventilation and in low latitude productivity which is similar to, albeit more extreme than, the basin specific response simulated for future warming and stratification (Moore et al., 2018).

These changes in surface physical and biological activities could also have implications on the exchanges of carbon between near-surface and interior water masses, and therefore the interior carbon budget. In the next section, ventilation changes at 125ka are compared to 115ka by analyzing the simulated water mass properties.

3.4 Global and regional carbon budgets

Figure 6 shows the difference in the carbon inventory vertical profiles between 125ka and 115ka as simulated by our model. The changes in DIC^{tot} , DIC^{sat} , DIC^{soft} , DIC^{carb} and DIC^{dis} are averaged over a 500 m depth interval. The global amount of DIC^{tot} is -314.1 PgC in the ocean under the warmer condition (Fig. 6a, gray ΔDIC^{tot}). Since the atmospheric CO_2 is kept constant in each experiment, this carbon loss at 125ka compared to 115ka is implicitly assumed to be balanced out by the changes in the land carbon reservoir. Here, the Atlantic Ocean accounts for 15% (-49.1 PgC) of that global decrease, while the Indian and the Pacific basins contribute to 28% (-87.2 PgC) and 57% (-179.0 PgC), respectively. Only in the near-surface layers the model simulates a positive ΔDIC^{tot} , which translates to higher surface DIC concentration at 125ka relative to 115ka. Most of the ocean interior has lower DIC concentration at 125ka with the strongest difference in ΔDIC^{tot} simulated between 2000 – 3000 m depths for each basin (Fig. 6b-d). The soft-tissue pump and the disequilibrium effect are the main contributors for the reduced carbon inventory depicted at 125ka at global scale (Fig. 6a, green and purple bars) -

each accounting for a third of the total -314.1 PgC decrease. Similarly, ΔDIC^{tot} in the Atlantic basin is also predominantly controlled by the biological pump, i.e. the soft-tissue plus carbonate pump throughout the entire water column with a decrease at depth and an increase in the near-surface (Fig. 6b). Except for the upper ocean, the contribution from saturation component related to temperature and salinity change is generally negligible.

The ΔDIC^{tot} of the Indian basin also depicts a strong reduction at 125ka relative to 115ka. Here the soft-tissue and saturation components simulate the strongest decrease (Fig. 6c, green and blue bars). In addition, near-surface changes in ΔDIC^{tot} are controlled by the changes in ΔDIC^{sat} . Similarly, the near-surface layer of the Pacific Ocean is also controlled by the changes in saturation component (Fig. 6d), simulating a positive difference of about $+18$ PgC. Changes in the deeper layers are mainly attributed to the disequilibrium effect and the soft-tissue pump accounting for a decrease of -83.6 PgC and -44.0 PgC at 125ka relative to 115ka, respectively. However, the saturation component also has a considerable influence on the carbon storage with persistent negative ΔDIC^{sat} throughout the water column.

In order to address the regional changes, we analyze the differences in each DIC components further by calculating the zonally averaged values in each basin. Figures 7, 8 and 9 depict these differences for the Atlantic, Indian and Pacific basins, respectively. As shown in Fig. 6a, the carbon inventory of the Atlantic is reduced mainly below 1500 m depth. Here the Southern Hemisphere is the most affected region, which depicts the strongest differences in ΔDIC^{tot} (Fig. 7a, blue shades). This pattern corresponds well to the changes in soft-tissue pump (Fig. 7b). Near the surface, higher carbon export (Fig. 5a) increases the remineralization of organic matter leading to higher DIC concentration at 125ka. At depth, the slightly deeper AMOC at 125ka (compared to 115ka), leads to better ventilated mid-depth to bottom waters in the Northern Hemisphere leading to less remineralized organic matter by reducing the water mass age. This is reflected by the negative ΔDIC^{soft} and ΔDIC^{carb} , translating to a less effective soft-tissue and carbonate pump at 125ka. Positive changes in ΔDIC^{tot} in near surface waters and bottom water at $20^\circ N$ also arise from the soft-tissue and carbonate signal due to the increase of the alkalinity (not shown here) and slightly older water masses along the African coast. The bottom waters in the Southern Hemisphere are mainly controlled by a stronger disequilibrium effect, i.e. negative change in comparison to 115ka. This change in disequilibrium is due to the sea-ice induced retreat of the SSW and the inflow of more NSW between $50^\circ S$ and the Equator at 125ka. The NSW water mass, formed in the North Atlantic, is generally more subject to biological production during its near surface northward transport before sinking into the interior than the SSW (Duteil et al., 2012). The biological production consumes DIC during photosynthesis and pushes the water mass further out of the equilibrium with the atmospheric CO_2 , inducing ΔDIC^{dis} to be more negative. The negative values of ΔDIC^{dis} are conserved when the water parcel flows southward into the deep ocean. For this reason, the regions that are no longer influenced by SSW at 125ka depict a negative ΔDIC^{dis} (Fig. 7d). However, the upper layers of the Atlantic Ocean are mostly simulated with higher DIC^{dis} (positive ΔDIC^{dis} ; or less disequilibrium at 125ka). This could be induced by more SSW (less disequilibrated than NSW) entering further north the Atlantic basin at the near surface as suggests Fig. 4c. Finally, the loss of carbon in the Southern Ocean is shown to be mainly attributed to a decrease of the saturation component at 125ka. This decrease is mainly attributed to lower TALK^{pre} (not shown here) possibly provoked by the melting of the sea-ice.

The DIC storage in the Indian Ocean generally shows a decrease at 125ka with the strongest changes occurring at depth north of $30^{\circ}S$ (Fig. 8a, dark blue shade). Positive ΔDIC^{tot} are nevertheless simulated in the region that may correspond to the AAIW (Fig. 8a, red shade). Similar to the Atlantic basin, the pattern of the soft-tissue pump changes corresponds to the ΔDIC^{tot} pattern throughout most of the Indian Ocean. This decrease in biological remineralization is in agreement with the water mass age changes seen in Sect. 3.2 (Fig. 3b): younger water masses account for less biologically-induced DIC content. However, the bottom and the surface waters show opposite signs in the ΔDIC^{tot} , which suggests that other processes are acting in these regions. The differences in the carbonate pump remain small and roughly follow the pattern of the soft-tissue pump (Fig. 8c). Changes in the bottom water ΔDIC^{tot} can be attributed primarily to the difference in the disequilibrium effect which is probably affected by larger influence of NSW at 125ka relative to 115ka as described for the Atlantic basin, and to a slight reduction in the saturation component. In addition, the disequilibrium component might also be influenced by stronger carbon export in the Southern Ocean (as the positive ΔDIC^{soft} and Fig. 5a suggest). The strong positive ΔDIC^{dis} simulated at near-surface along the Indian coast is well in agreement with lower SSTs (Fig. 1a-c) allowing more DIC to be absorbed at 125ka and a strong reduction in carbon export production (Fig. 5a). Finally the negative ΔDIC^{sat} depicted in the top layers in the north of the Indian Ocean is mainly attributed to a change in water mass origin from 115ka to 125ka. During 115ka the SSW upwells from the deep ocean into the Arabian sea. By contrast, at 125ka, the waters coming from the Indonesian region mix with SSW. These Indonesian throughflow water masses initially coming from the Pacific Ocean are affected by strong precipitation in the Indonesian basin, which reduces the ALK at the surface and therefore DIC^{sat} .

The Pacific basin shows the strongest DIC^{tot} decrease in the Northern Hemisphere, mainly due to the reduction in soft-tissue pump (Fig. 9b). This decrease in biogenic carbon is induced by better ventilated water mass around $30^{\circ}N$ (Fig. 3c), which may come from the increase of the overturning circulation in the upper cell of the Pacific Ocean. On the opposite, the DIC inventory of the high latitude Southern Hemisphere bottom and near-surface waters is larger at 125ka relative to 115ka. This is attributed to the changes in soft-tissue pump, which is more effective at 125ka due to longer residence time of the water masses (Fig. 3c). The carbonate pump has a relatively low impact on the total ΔDIC inventory in the Pacific basin but follows the same pattern than the changes in the organic carbon remineralization. The disequilibrium effect accounts for the strongest decrease of DIC throughout the basin as seen by the negative ΔDIC^{dis} in almost all regions (Fig. 9d). However, the bottom waters seems to be the most affected and become more undersaturated at 125ka relative to 115ka. This may be influenced by the slowing down of the subduction process in the Southern Ocean, induced by the flattening of the isopycnals. The possible higher carbon export production in the SO south of $60^{\circ}S$ (Fig. 5a) may also pushes the water mass further out of equilibrium. Finally, the saturation component is controlling the changes occurring in the near-surface waters (Fig. 9e). Lower saturations are attributed to higher export of calcium carbonate south of $60^{\circ}S$, which lower the alkalinity at the surface and thereby the buffering capacity. On the other hand, the calcium carbonate formation decreases north of $60^{\circ}S$, resulting in a higher alkalinity and buffering capacity.

4 Discussion

The ocean plays an important role in storing carbon and, thus, in the long term regulation of atmospheric CO₂ levels. The processes involved in regulating the ocean carbon inventory are likely to change under warmer future conditions. In this study, we simulate two equilibrium states of the penultimate interglacial period using a state-of-the-art Earth System Model and make a first attempt at quantifying the biogeochemical and physical processes responsible for carbon storage changes caused by different (interglacial) orbital configurations and background climates. Significant decreases in the ocean carbon storage capacity are found under a warmer climate. More than 48% of this decrease is induced by the reduction of the biological pump. This decrease is found to be mainly driven by the shorter residence time of interior deep water masses arising from changes in Southern Ocean sea-ice extent that influence the NSW/SSW water mass geometry, in addition to changes in overturning circulation in the Atlantic (deeper but almost equally vigorous) and Pacific basins (stronger upper cell).

Using the available proxy reconstructions during the LIG period allows us to assess the validity of important features in our model results. We assess the validity of the simulated 115ka to 125ka water mass geometry change using LIG proxy reconstructions of bottom water $\delta^{13}C$, a water mass tracer strongly but inversely related to carbon and PO₄ contents (Eide et al., 2017). Similar to our results, expanded SSW in the late compared to early LIG is inferred from such reconstructions to explain bottom water $\delta^{13}C$ decreases in different regions proximal to the Southern Ocean (Ninnemann and Charles, 2002; Govin et al., 2009). Bottom water $\delta^{13}C$ reconstructions indicate less influence of NSW in the deep South Atlantic at 115ka than at 125ka (Ninnemann et al., 1999; Govin et al., 2009). In addition, persistent (millennial-scale) mid-depth NSW ventilation extending from the LIG and into the subsequent glacial inception is also suggested based on proxy reconstructions (Mokeddem et al., 2014; McManus et al., 2002) and is consistent with model simulations (Born et al., 2011; Wang and Mysak, 2002). In our study, even though the AMOC is simulated slightly stronger and deeper at 125ka, vigorous AMOC persists until 115ka ventilating the North Atlantic mid-depth. We also note that our model may not properly represent North Atlantic overflows due to its sparse resolution. This can further add uncertainties to North Atlantic water ventilation.

Also consistent with our results, ice core proxies indicate that Southern Ocean sea ice extent is greater at 115ka than at 125ka (Wolff et al., 2006; Röthlisberger et al., 2008), while our model reproduces the volumetric SSW expansion in response to this increase in Southern Ocean sea ice extent as suggested for glacial climates (e.g. Ferrari et al. (2014)). Our model results suggest similar sea ice (Fig. 1) and SSW expansions (Fig. 4a), albeit muted compared to glacial changes, occurred in response to LIG orbital configuration changes and without continental ice sheet growth (not included in the model), indicating a relatively tight coupling between Antarctic climate, sea ice, and the deep Atlantic water mass geometry changes influencing ocean carbon storage.

The changes in ocean carbon storage simulated by our model are significant and demonstrates that warm (interglacial) ocean carbon content changes with climate forcing. While atmospheric CO₂ is fixed in our model preventing a direct assessment of ocean carbon changes on atmospheric CO₂, the decrease in deep carbon storage and shoaling of the DIC pool during the warm 125Ka interval is generally consistent with higher atmospheric CO₂ levels at this time. Our estimated changes in ocean carbon budget is in the range of previous modeling effort study that also suggests weaker ocean carbon storage during the beginning

of the LIG (125ka) relative to the glacial inception (115ka). Schurgers et al. (2006) obtains a difference in atmospheric and terrestrial carbon storage of about 40 PgC and 350 PgC, respectively, between the onset and end of the LIG. This potentially translates to a weaker ocean carbon storage of 310 PgC at the onset compared to the late LIG, which corresponds well in absolute magnitude with our findings of 314.1 PgC decrease at 125ka. However, their simulated atmospheric CO₂ steadily increases over this period, which potentially points toward more carbon needing to be stored in land or ocean toward the end of the LIG.

On the contrary, Brovkin et al. (2016) simulate more ocean DIC^{tot} at 125ka than 115ka using simpler EMIC models. This increase is mainly attributed to the shallow water carbonate precipitation implemented in their model. This process is not included in our model and could explain the differences in the results. However, their simulated change in atmospheric CO₂ after 121ka is in the opposite direction (increasing of roughly 20 ppm) ~~than that~~ of the atmospheric trend (a decrease of roughly 3 ppm) observed in the ice core data. This suggests that either (or both) the terrestrial or ~~both the terrestrial and~~ the oceanic carbon ~~reservoirs do~~ reservoir does not take enough carbon toward the end of the LIG in order to ~~bring down the~~ simulate a decrease in atmospheric CO₂ content.

Concerning the modification in the upper ocean productivity under warmer climatic conditions, our model study shows a heterogeneous response in phosphate availability and carbon export production especially between the Atlantic and Pacific basins. Moore et al. (2018) also highlight such biogeochemical divide response for future projections under warmer climatic conditions. This implies that future anthropogenic CO₂ forcings may have a similar impact on the biogeochemical divide with that of past forcings. Therefore, reconstructing and understanding the large scale productivity responses to past climate forcing are critical for assessing both global and regional sensitivity of the ocean carbon dynamic to climate change.

There are limitations to our study. Factors that could influence ocean carbon storage including sea level, riverine input of nutrients, and atmospheric dust loading are all set to preindustrial levels in our simulations, but may be different in the LIG. Global sea level, for example, may be as much as 6-9 m above present (Kopp et al., 2009). In addition, our model does not include weathering fluxes, which might influence the carbon budget on such longtime scale. Further, we compare two quasi-equilibrated states, which is unrealistic and ignores transient forcings and shorter-term variability. This may explain differences between our model results and some proxy reconstructions. For example, proxy reconstructions suggest that both NSW and SSW ventilation may have varied considerable near 125ka (Galaasen et al., 2014; Hayes et al., 2014). The changes suggested by these studies include reductions of NSW and expansions of SSW similar to our modeled 115-125ka equilibrium difference, but then occurring as short-lived (centennial-scale) transient events associated with freshwater input episodes during the final phase of northern deglaciation (Galaasen et al., 2014). Our quasi-equilibrated model simulations for 115ka and 125ka, also lack ice sheet and the corresponding freshwater input variability, and do not address such shorter-term changes that could affect the ocean carbon inventory (Stocker and Schmittner, 1997). However, short-lived changes would likely have less impact on the ocean carbon inventory than the longer-term (millennial-scale) changes we address, the latter allowing all carbon system components and ocean dynamics to adjust. Thus, we still expect our model simulations to provide insight into baseline changes and redistribution of ocean DIC forced by the different LIG orbital configurations, supported by the important role of deep

Atlantic water mass geometry changes coupled with its similarity to the long-term (millennial-scale) evolution inferred from proxy reconstructions (Fig. 3).

5 Conclusions

Ongoing anthropogenic warming raises questions about the oceanic carbon sink and its efficiency under a warmer climate condition. In this study, we use the fully-coupled NorESM model to simulate two quasi-equilibrium states of the Last Interglacial: one period is globally colder (115ka) and one is globally warmer (125ka) than today. We focus on the differences in ocean carbon cycle that occur at 125ka in comparison to 115ka, specifically the differences at global and basin scales. We provide a detailed description of the biogeochemical and physical processes that are responsible for the ocean carbon inventory changes under warmer climate conditions during the LIG at the temporal and spatial scales discussed here.

We find that the global ocean carbon budget decreases during the warm (125ka) period by 314.1 PgC and are related mainly to better ventilation in the interior ocean. The Pacific Ocean has the largest reduction and accounts for 57% of the global DIC loss. The response of the Pacific ventilation in a warmer climate shown in this study is consistent with previous studies (Menviel et al., 2014, 2015). The Indian and Atlantic basins account for 28% and 15%, respectively. These quantities mostly reflect basin volumes. The southern-sourced waters (SSW) are revealed to play an instrumental role for the DIC changes in the interior below 1000 m depth. In these waters, the Atlantic is highlighted to be the region where the strongest DIC loss occur per unit volume and is characterized by a stronger ventilation and a DIC^{tot} decrease of about 37% compared to its respective value at 115ka.

The reduced DIC budget at 125ka occurs mostly in the interior ocean, while there is a weak increase in the top 1000 to 1500 m depths. Two factors contribute mainly to the drop in the DIC budget in the interior ocean are (1) a weaker biological component from both the soft-tissue and the carbonate pumps that dominates at the depth between 1000 to 3000 m, and (2) a stronger disequilibrium effect (i.e. more negative) of DIC in the bottom waters. However, the processes affecting the disequilibrium component can arise from different factors such as changes in the physical pump, overturning circulation or biological pump. No general process could be attributed to its variation which seems to be regionally affected. While the SSW seem to become more undersaturated at 125ka, the NSW seem to be more saturated. Further experiments with for instance fixed biological productivity or overturning circulation could help to identify the sensitivity of this component to such factors, but remain too expensive to perform with our model.

The weakening of the biological component at depth is driven by younger water masses simulated in the interior ocean. This decrease in residence time of the water masses is provoked by the strong SST modifications that affect the ventilation at 125ka as compared to 115ka. Higher SST, especially in the high latitudes, induces strong summer sea-ice retreat in the Atlantic sector of the Southern Ocean and stratification in the Pacific Ocean. In the Atlantic basin, this results in a more southerly confined SSW and southward expansion of NSW in the deep ocean. These water masses are advected by the Antarctic circumpolar current into the Indian and the western Pacific basins. The eastern Pacific Ocean is influenced by water masses coming from

the Pacific sector of the Southern Ocean, with a warmer SST that hinders the ventilation and increases the residence time of the interior water masses on the eastern side of the basin.

Concerning the modification in the upper ocean productivity under warmer climatic conditions, our model study reveals clear yet heterogeneous changes in phosphate availability and carbon export production especially between the Atlantic and Pacific basins. Such inter-basinal response in the biogeochemical divide is also highlighted by Moore et al. (2018) for future projections under warmer climatic conditions. This implies that changes in the biogeochemical divide could somewhat be similarly impacted from past and future anthropogenic CO_2 forcings although the basin-specific responses suggest that it may not be *a priori* simple to predict the pattern or sign of the response of large-scale productivity to a given common forcing. Given the economic importance of basin-scale productivity and the sensitivity found in past and future simulations, reconstructing and understanding the pattern and validating the sign and (model) response of large-scale productivity to climate forcing is therefore critical for assessing not only the sign but also the sensitivity of global productivity to climate change.

The remaining uncertainties include, among others, the use of pre-industrial states for some boundary conditions and the absence of fresh water input, which could modify the spatial response particularly during the early interglacial period which might include the final episodes of continental deglaciation. This is due to the lack of knowledge on such forcing during past climate. Additional model-based studies using different Earth system models would be useful to confirm the robustness of our findings and further improve our understanding of the carbon dynamics and the feedback in the ocean under warmer climate. Finally, our model-based study suggests that past warm periods experienced considerable carbon cycle and ocean DIC changes, linked to the response of the interior-ocean ventilation and biological productivity to high-latitude warming and interglacial background climate differences. It also suggests that the Atlantic part of the Southern Ocean is most sensitive to past climate change and hence could be a potential indicator of similar large-scale circulation changes in the future. Close monitoring of this region could be critical to better understand climate feedback on the carbon cycle under future warmer climate.

Table 1. Difference in southern sourced water (Δ_{SSW}) in the global ocean and for each basin. Row 1 shows the volume (V_{SSW}) according to our $PO \geq 0.57 \text{ mol O m}^{-3}$ criteria. Row 2 and 3 summarizes the DIC and water mass age mean value for the two period of study. The changes relative to 115ka are given as a percentage in parenthesis.

	Global	Atlantic	Indian	Pacific
$\Delta V_{SSW} [10^6 \text{ km}^3]$	-3.43 (1%)	-18.91 (37%)	+9.76 (8%)	+5.72 (1%)
$\Delta DIC_{SSW} [\text{gCm}^{-3}]$	-0.34 (1.2%)	-0.92 (3.3%)	-0.61 (2.1%)	-0.36 (1.2%)
$\Delta Age_{SSW} [\text{years}]$	-108 (9.3%)	-262 (78.2%)	-152 (29.0%)	-39 (3.0%)

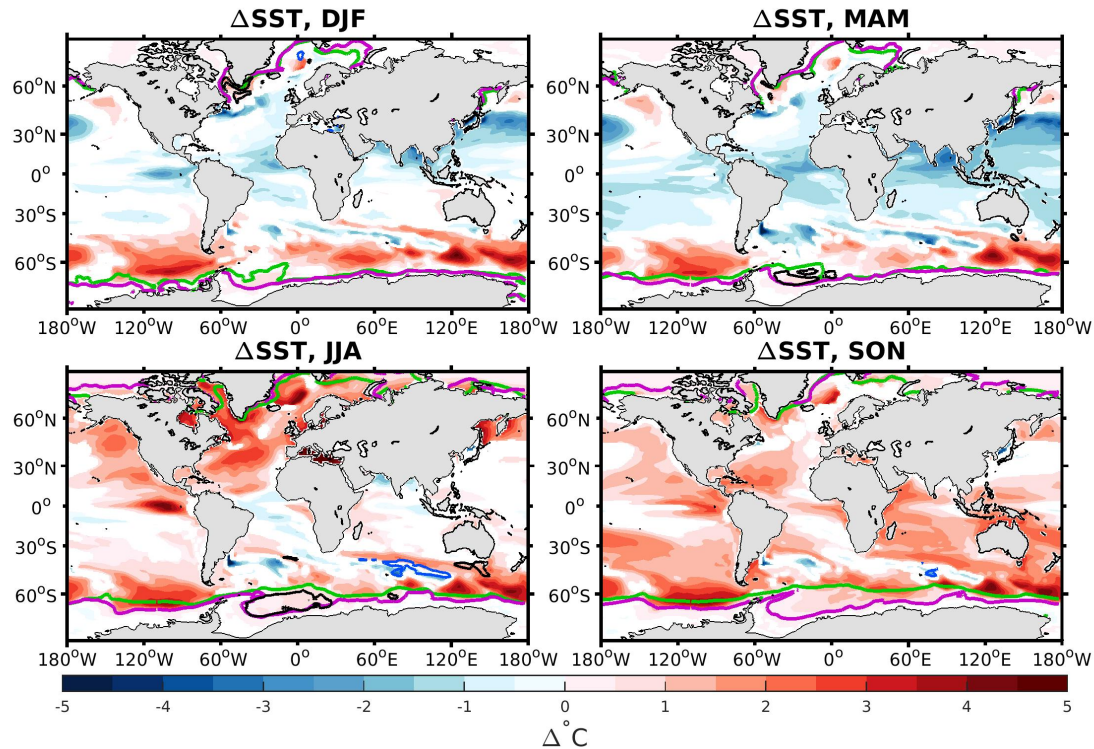

Figure 1. Difference in Sea Surface Temperature (ΔSST) between 125ka and 115ka. Only significant differences (i.e., with absolute value greater than the interannual standard deviation over the last 50 years in both 125ka and 115ka) are shown. The green and purple lines correspond to 50% sea ice extent at 115ka and 125ka, respectively. The black (blue) thick lines depict regions affected by a deepening (shallowing) of the mixed layer depth (with difference superior of 100m depth) at 125ka compared to 115ka.

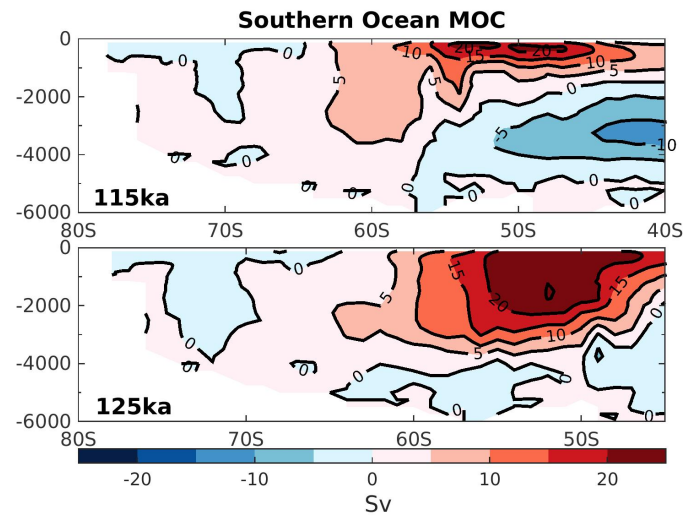

Figure 2. Southern Ocean global overturning stream function in Sverdrup (Sv) for the experiment at 115ka (top panel) and 125ka (bottom panel). Red colors represent water masses moving clockwise and reverse for blue colors.

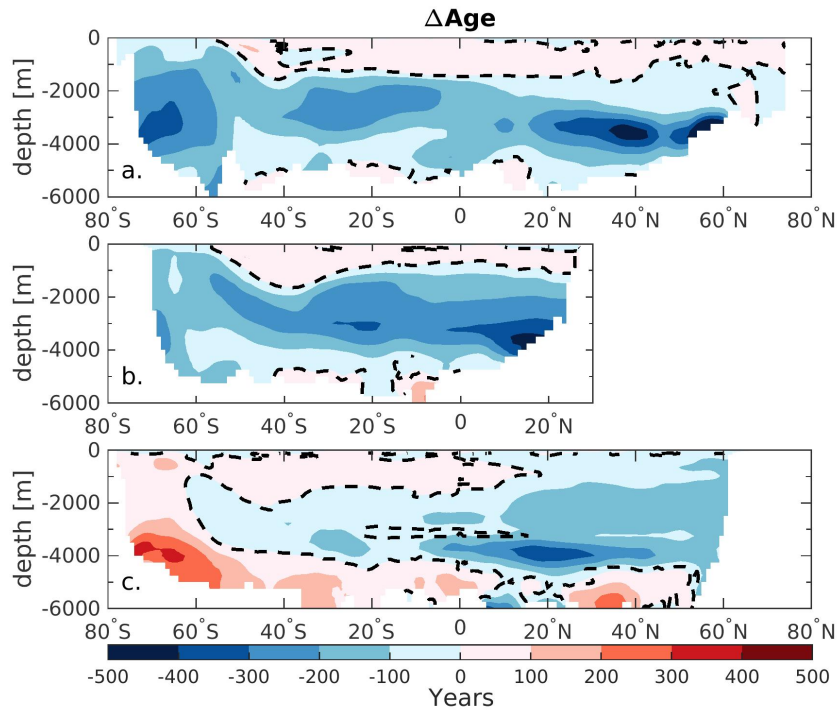

Figure 3. Zonally averaged section of the difference in water mass age (ΔAge) between 125ka and 115ka in (a) the Atlantic Ocean, (b) the Indian Ocean and (c) the Pacific Ocean. The dashed-lines display $\Delta Age = 0$.

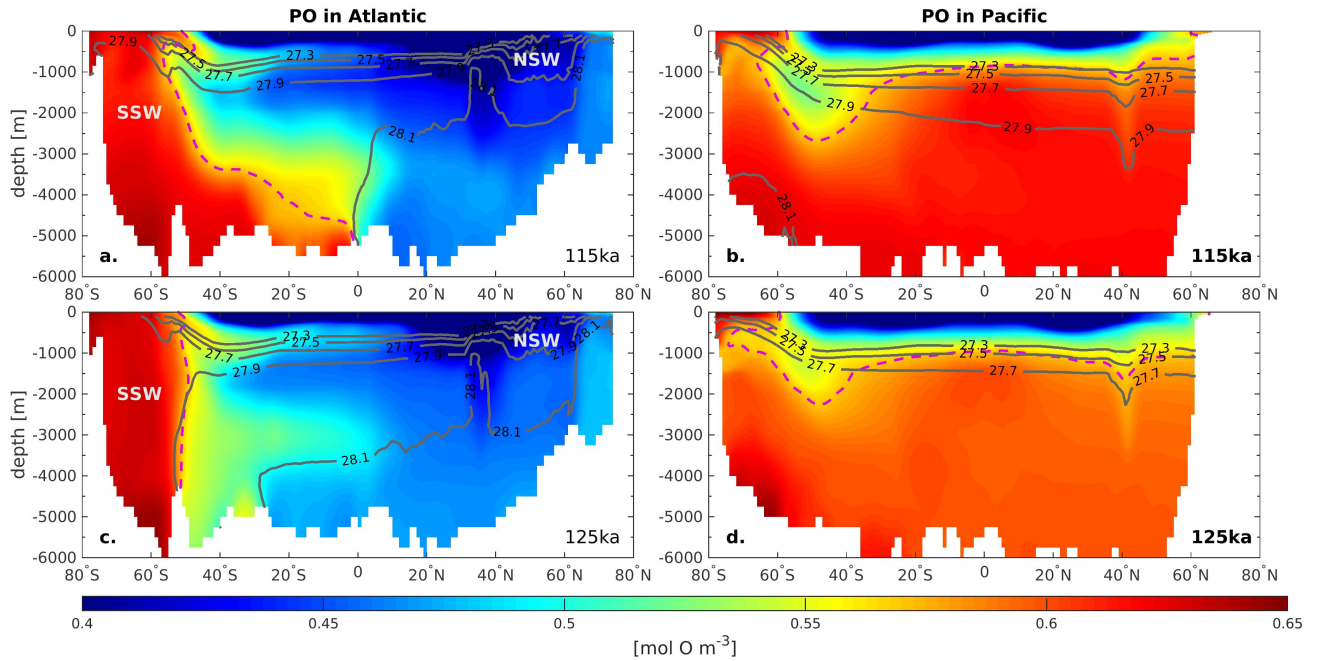

Figure 4. Zonally averaged section of PO as defined by Broecker (1974) in (a,c) the Atlantic Ocean at 115ka and 125ka, respectively, and (b,d) the Pacific Ocean at 115ka and 125ka, respectively. The light purple dashed-lines delimit the water influenced by the SSW from NSW. The dark gray solid-lines depict the neutral density [kg m^{-3}].

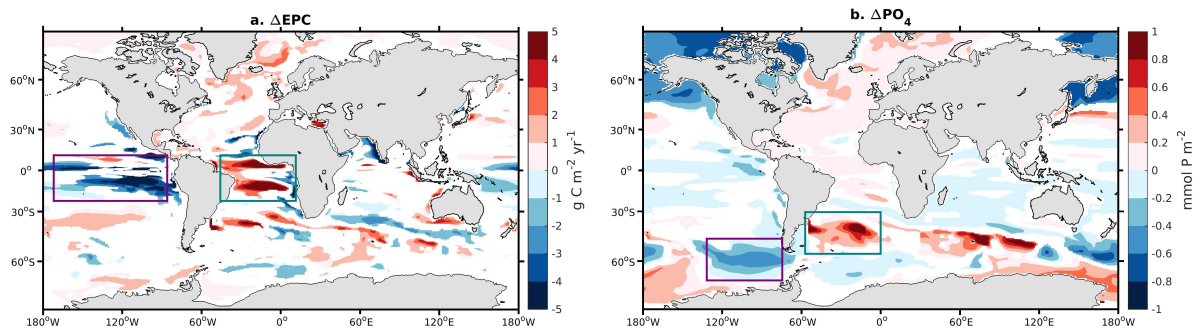

Figure 5. Difference in (a) export production of carbon at 100 m depth (ΔEPC) and (b) phosphate at the surface (ΔPO_4) between 125ka and 115ka. When the absolute value of the difference is below the standard deviation over the last 50 years at 125ka and 115ka, the value returns a NaN. Purple and turquoise rectangles highlight the two 'ocean tunnels' linking the sinking/upwelling regions of southern sourced intermediate waters in our model.

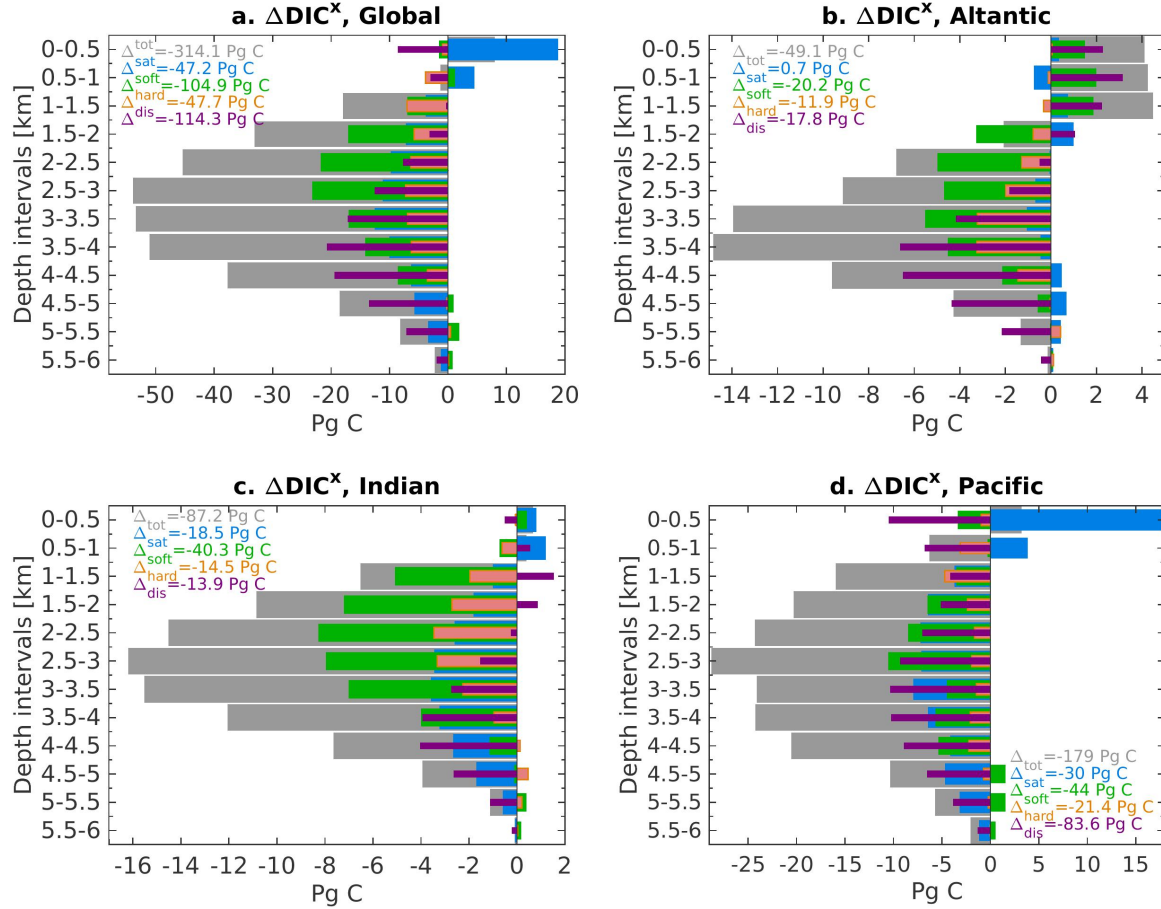

Figure 6. DIC differences between 125ka and 115ka (ΔDIC^x) in (a) Global Ocean, (b) Atlantic, (c) Indian and (d) Pacific basins. The ΔDIC^x is averaged over a 500 m depth interval where 'x' refers to the different components of the DIC. The ΔDIC^{tot} is represented by the gray bars and is decomposed into its 4 components ΔDIC^{sat} (blue), ΔDIC^{soft} (green), ΔDIC^{carb} (orange) and ΔDIC^{dis} (purple). The sum throughout the water column of each components is given by the legend.

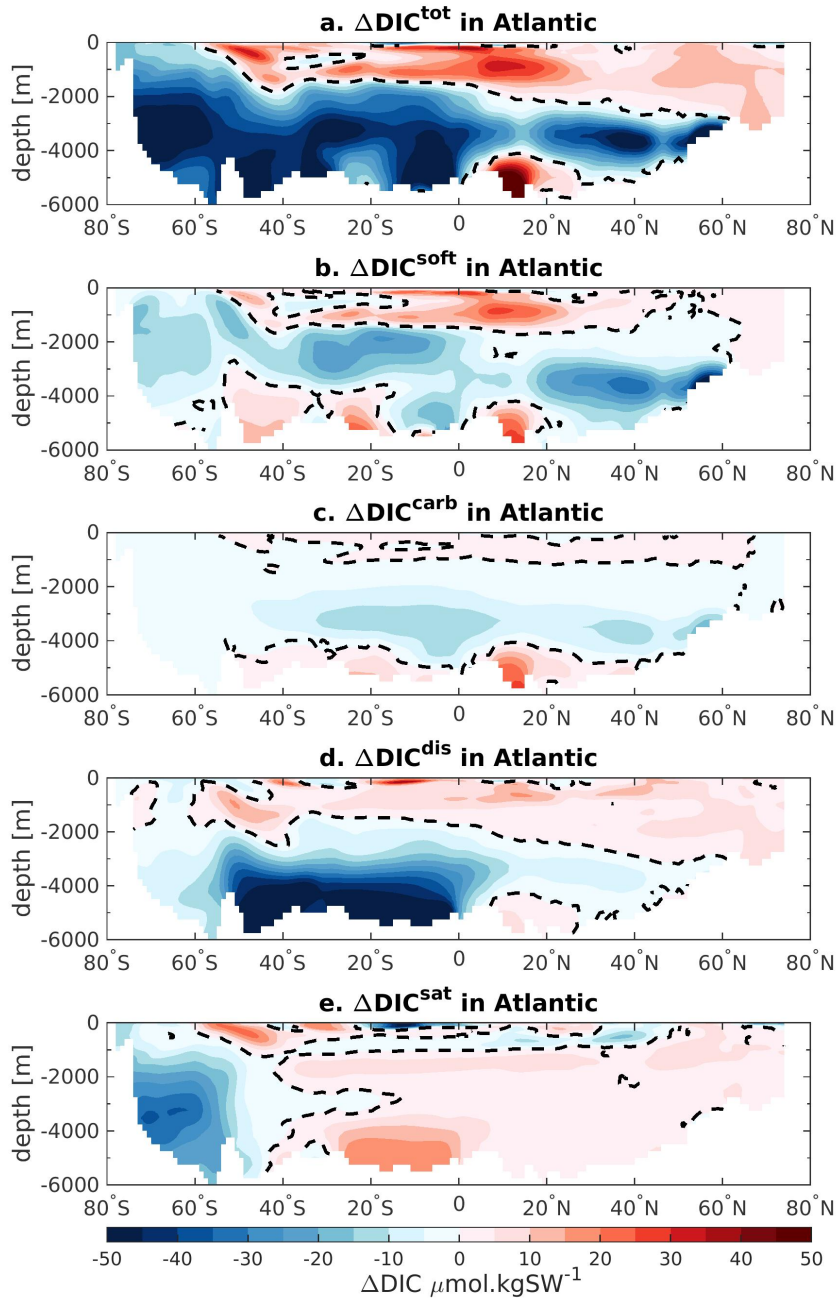

Figure 7. Atlantic zonally averaged section of the difference in (a) $\Delta\text{DIC}^{\text{tot}}$, (b) $\Delta\text{DIC}^{\text{soft}}$, (c) $\Delta\text{DIC}^{\text{carb}}$, (d) $\Delta\text{DIC}^{\text{dis}}$ and (e) $\Delta\text{DIC}^{\text{sat}}$ between 125ka and 115ka. The black dashed-lines represent the zero values.

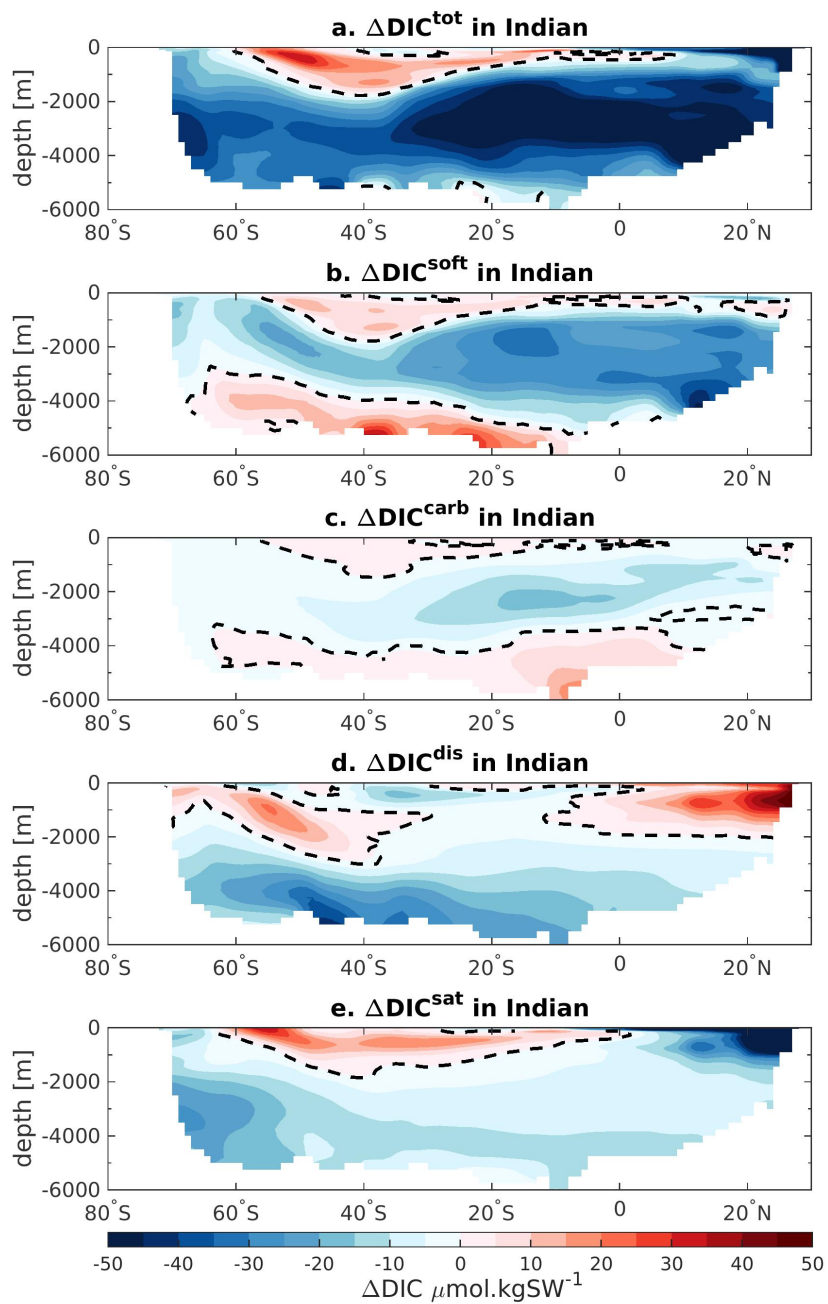

Figure 8. Same as Fig. 7 for the Indian Ocean.

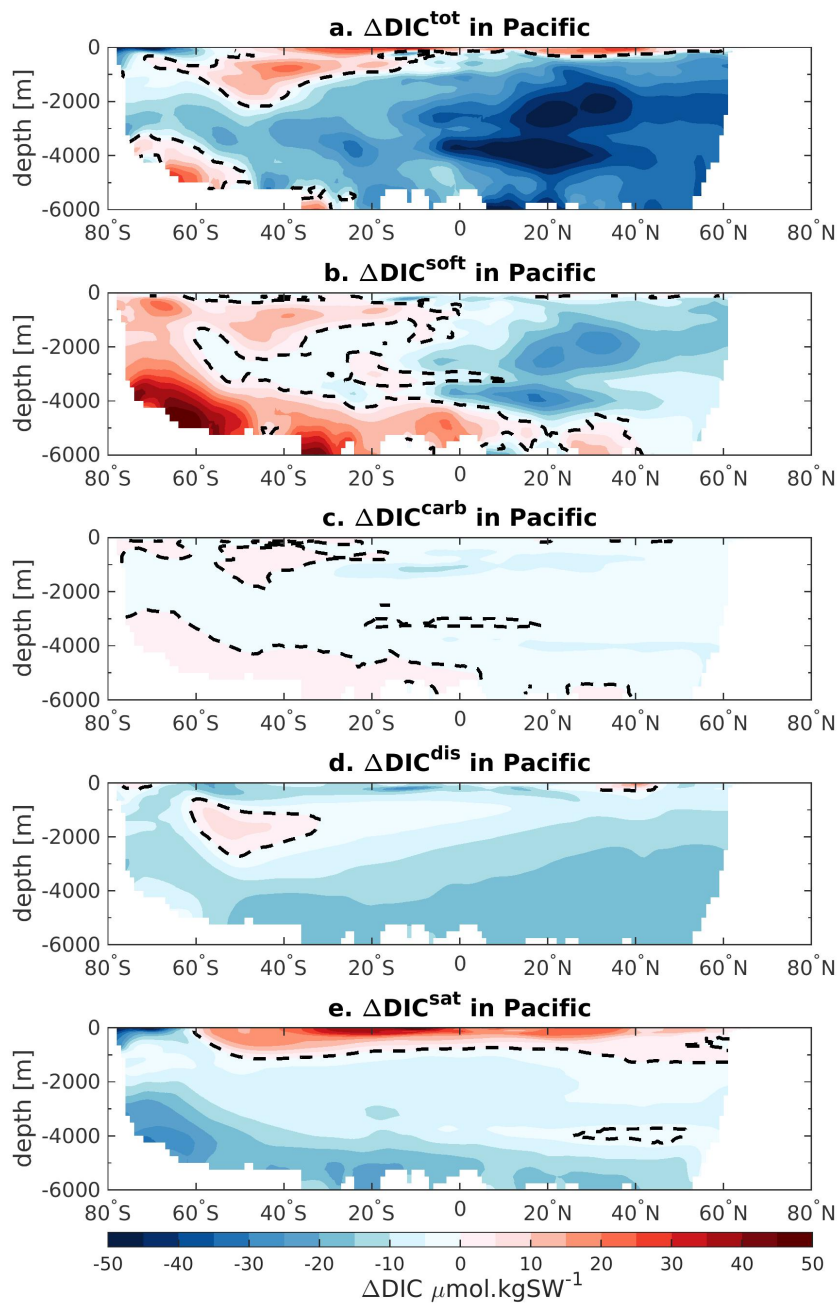

Figure 9. Same as Fig. 7 for the Pacific Ocean.
