Abstract. As a continuation of the Pliocene Model Intercomparison Project (PlioMIP), PlioMIP Phase
2 (PlioMIP2) coordinates a wide selection of different climate model experiments aimed at further
improving our understanding of the climate and environments during the late Pliocene with updated
boundary conditions. Here we report on PlioMIP2 simulations carried out by the two versions of the
15 Norwegian Earth System Model (NorESM), NorESM-L and NorESM1-F, with updated boundary
conditions derived from the Pliocene Research, Interpretation and Synoptic Mapping version 4
(PRISM4). The two NorESM versions both produce warmer and wetter Pliocene climate. Relative to
the pre-industrial period, the simulated Pliocene global mean surface air temperature is 2.1°C higher
with NorESM-L and 1.7°C higher with NorESM1-F, respectively, and the corresponding global mean
20 sea surface temperature enhances by 1.5°C and 1.2°C. The simulated precipitation for the Pliocene
increases by 0.14 mm day⁻¹ globally in both model versions, with large responses in the tropics and
especially in monsoon regions. In the simulated warmer and wetter Pliocene world, Atlantic meridional
overturning circulation (AMOC) become deeper and stronger, with the maximum AMOC levels
increasing by ~9% (with NorESM-L) and ~15% (with NorESM1-F), while the meridional overturning
25 circulation slightly strengthens in the Pacific and Indian Oceans. Although the two models produce
similar Pliocene climates, they also generate some differences, in particular for the Southern Ocean,
which should be investigated through the PlioMIP2 in the future. As compared to PlioMIP1, the
simulated Pliocene warming with NorESM-L is weaker in PlioMIP2, but otherwise show very similar

responses.

1 Introduction

The mid-Pliocene warm period (mPWP, 3.0–3.3 million years ago), a warm and stable interval in the Earth's geological history with paleogeography configurations and greenhouse gas concentrations similar to today, provides an interesting case study for understanding possible warm climates in our future. During the mPWP, the estimated global mean temperature was about 2–3 °C higher than at present (e.g., Dowsett et al., 2009, 2010a). The global mean sea level was higher with a peak of 22±10 meters than today (Miller et al., 2012). Due to warm sea surface temperatures, the Arctic Ocean experienced seasonally sea ice free conditions (Cronin et al., 1993; Dowsett et al., 2010b; Robinson, 2009; Clotten et al., 2018). Ice sheets were smaller over western Antarctica and Greenland and the vegetation belts were displaced poleward (Salzmann et al., 2008; Dowsett et al., 2010b).

The warm mPWP climate has been simulated with a suite of models under the framework of Pliocene Model Intercomparison Project phase 1 (PlioMIP1), forced with the boundary conditions from PRISM version 3 (PRISM3) (Dowsett et al., 2010a; Haywood et al., 2013). According to these simulations, the simulated global annual mean surface temperature during the mPWP was 1.8–3.6 °C above pre-industrial levels (Haywood et al., 2010, 2013, 2016a). The high atmospheric CO₂ level (405ppmv) dominated the majority of warming in tropical regions, while clear-sky albedo was mainly responsible for a stronger warming at high latitudes (Hill et al. 2014). Furthermore, the Hadley Cell became weaker and shifted poleward (Sun et al., 2013). Westerlies (Li et al., 2015) and global tropical cyclones (Yan et al., 2016) migrated poleward. Also, according to the models, the East Asian summer monsoon intensified in the Pliocene warm climate (Zhang, R. et al., 2013), and the global monsoon system generally brought more precipitation into the expanded monsoon regions (Li et al., 2018). The simulated Arctic sea ice was less extensive and thinner than it is in modern times (Howell et al., 2016). The simulated Atlantic meridional overturning circulation (AMOC) and the associated ocean heat transport were similar to those of the pre-industrial period (Zhang, Z. et al., 2013a). Despite the generally consistent features of the simulations, a large model-data mismatch in terms of the warming magnitude remained at the northern high latitudes (e.g., Atlantic, Arctic Ocean, and Asia) (Dowsett et al., 2013; Haywood et al., 2013).

To better understand the warm mPWP climate and to better constrain the model-data mismatch,

PlioMIP phase 2 (PlioMIP2) was launched in 2016. The modelling strategy adopted in PlioMIP2 has been revised to establish a more well-balanced methodology for model-data comparisons. Instead of focusing on the time window between 3.0 and 3.3 Ma, PlioMIP2 identified the time slice of 3.205 Ma centered on an interglacial peak (marine isotope stage KM5c) as the key target for the model-data comparison (Haywood et al., 2016b). The updated boundary conditions taken from PRISM4 (Dowsett et al., 2013; Salzmann et al., 2013; Haywood et al., 2016b) are used in PlioMIP2.

In this study, we present PlioMIP2 simulations with two different versions of the NorESM, NorESM-L (Zhang et al., 2012) and NorESM1-F (Guo et al., 2019). In the following sections, we first introduce the two model versions and our experimental design. Next, we present the simulated results in section 4 and discussions in section 5. Finally, the last section gives the summary and conclusions.

2 Model descriptions

The NorESM is developed based on the structure of the Community Climate System Model version 4 (CCSM4) from the National Centre for Atmospheric Research (Gent et al., 2011). In the model, the atmospheric component is the Oslo version of CAM4 (CAM4-Oslo), which implements an advanced scheme for interactions between aerosol and clouds (Kirkevåg et al., 2013). The oceanic component is the Miami Isopycnic Coordinate Ocean Model (MICOM) (Bleck and Smith, 1990; Bleck et al., 1992; Bentsen et al., 2013), with several improvements. To limit model complexity and speed up model integration, both NorESM-L and NorESM1-F use the standard, prescribed aerosol chemistry of CAM4 rather than that of CAM4-Oslo.

2.1 NorESM-L

NorESM-L is developed for paleoclimate simulations (Zhang et al., 2012). The atmospheric component has a horizontal resolution of T31 (~3.75°) and 26 vertical levels. The ocean component employs a bipolar grid with a horizontal resolution of nominal 3° and uses 30 isopycnic vertical layers (Table 1). NorESM-L was used to simulate the Pliocene climate in PlioMIP1 (Zhang et al., 2012). Further information on NorESM-L is documented in Zhang et al. (2012).

2.2 NorESM1-F

NorESM1-F is assembled for long time simulations with relatively high resolutions and improved

process representations and climate performance compared to the CMIP5 version of the NorESM (Guo et al., 2019). In the model, the atmosphere component uses a horizontal resolution of 1.9° latitude and 2.5° longitude and uses 26 vertical levels. The ocean component employs a tripolar grid with a nominal 1° horizontal resolution (Table 1). NorESM1-F provides reasonable simulations of sea ice and AMOC (Guo et al., 2019). There are also several important improvements on how precipitation is simulated, e.g., improvements in seasonality, reduced wet bias, and mitigation of the common double-ITCZ problem. Further details on the model performance of NorESM1-F can be found in Guo et al. (2019).

3 Experimental designs

3.1 Pre-industrial control experiment

According to the PlioMIP2 protocol (Haywood et al., 2016b), we use modern geographic boundary conditions, including modern land-sea mask, topography, and ice sheets and vegetation for year 1850, in the pre-industrial control experiments (Table 2). For NorESM-L, we set atmospheric CO_2 , N_2O , and CH_4 levels to the pre-industrial values of 280 ppmv, 270 ppbv, and 760 ppbv, respectively. The orbital parameters apply values for year 1950. For NorESM1-F, the default pre-industrial atmospheric CO_2 , N_2O , and CH_4 levels are 284.7 ppmv, 275.68 ppbv, and 791.6 ppbv, respectively.

The pre-industrial experiment with NorESM-L was run for 2200 years, and the experiment with NorESM1-F was run for 2000 years. Climatological means of the last 100 years were analyzed in this study.

3.2 Pliocene experiment

Following PlioMIP2 experimental guidelines (Haywood et al., 2016b), we close the Hudson Bay, Bering Strait, and straits through the Canadian Arctic Archipelago in the Pliocene land-sea configuration. The atmospheric CO_2 concentration is set to 400 ppmv. Atmospheric N_2O and CH_4 concentrations, the solar constant, and orbital parameters are identical to pre-industrial values (Table 2).

We use the “anomaly method” recommended in PlioMIP2 to create the paleogeography for the Pliocene experiment. We first calculate differences between the PRISM4 Pliocene and PRISM4 modern topography and interpolate these to a T31 resolution for NorESM-L and to a $1.9^\circ \times 2.5^\circ$ resolution for NorESM1-F. Then, we add the interpolated topography anomalies to modern topography in the pre-industrial experiment.

To create vegetation in the Pliocene experiment, we first interpolate PRISM4 Pliocene vegetation to the resolution for NorESM-L and for NorESM1-F. Then, we convert biome vegetation types to LSM (Land System Model) vegetation types following the procedure outlined by Rosenbloom (2009). Lakes for the Pliocene are prescribed by adding the PRISM4 lake area anomaly to modern conditions.

5 Pliocene soil conditions remain the same as the pre-industrial conditions.

With NorESM-L, the Pliocene experiment was run for 1200 years. With NorESM1-F, the Pliocene experiment was first spun up for 2000 years with atmospheric CO₂ concentration set to 400 ppmv, and then run for 500 years forced with all Pliocene boundary conditions. Climatological means of the last 100 years were used for analysis.

10 4 Results

4.1 Surface air temperature

Relative to the pre-industrial experiments, the simulated Pliocene climate is warmer according to both NorESM versions (Fig. 1). The global annual mean surface air temperature (SAT) increases by 1.7°C and 2.1°C under the NorESM1-F and NorESM-L Pliocene simulations, respectively. In particular,

15 stronger warming appears at high latitudes (Fig. 1 and Table 3). The simulated Pliocene annual mean SAT increases by 3.2°C (NorESM1-F) and 7.6°C (NorESM-L) at the northern high latitudes and by 5.2°C (NorESM1-F) and 4.9°C (NorESM-L) at the Southern high latitudes. Weak cooling appears in tropical Africa, India, northeastern Asia, northern Australia, and southern Pacific close to western Antarctica, under the NorESM1-F and NorESM-L Pliocene simulations (Fig. 1a, b).

20 Changes in seasonal SAT follow a similar pattern as those of the annual SAT. The two models generate strong seasonal warming in circumpolar-Arctic regions, e.g., Hudson Bay, the Canadian Arctic Archipelago, and Greenland in the Pliocene experiment. However, NorESM-L produces larger Pliocene seasonal warming over the Southern Ocean and Antarctica than NorESM1-F.

4.2 Precipitation

25 The simulated Pliocene global mean annual precipitation increases by 0.14 mm day⁻¹ according to the two NorESM versions (Fig. 2). The mean annual precipitation increases largely in the tropical regions and especially in monsoon regions of, North Africa, Asia, and Australia. In subtropical regions, the zonal mean annual precipitation does not change markedly or slightly decreases. The changes in

seasonal precipitation generally follow the pattern of annual precipitation. Both models suggest that the ITCZ shifts northward in the Atlantic and in Africa in the boreal summer, but does not change considerably in the boreal winter.

4.3 Sea surface temperature

5 Both NorESM1-F and NorESM-L simulate higher sea surface temperatures (SSTs) in the Pliocene experiments compared to pre-industrial experiments (Fig. 3). The simulated Pliocene global mean annual SST is 1.2°C (NorESM1-F) and 1.5°C (NorESM-L) higher than pre-industrial level (Fig. 3 and Table 3). Large increases in SST appear at the high latitudes of both hemispheres (Fig. 3 and Table 3). The simulated Pliocene annual mean SST increases by 2.4°C (NorESM1-F) and 2.1°C (NorESM-L) in
10 the middle and high latitudes of the North Atlantic (north of 30°N) and by 1.4°C (NorESM1-F) and 2.4°C (NorESM-L) in the Southern Ocean. A slight cooling occurs in the Southern Pacific close to western Antarctica according to the Pliocene experiments for both NorESM model versions. The seasonal change in SST is largely consistent with the annual pattern.

4.4 Sea surface salinity

15 Changes in sea surface salinity from the Pliocene experiments differ notably between NorESM1-F and NorESM-L. The global mean SSS decreases by 0.34 g kg⁻¹ in the NorESM1-F Pliocene simulation, while it increases by 0.16 g kg⁻¹ according to the NorESM-L Pliocene simulation (Fig. 4). With NorESM1-F, Pliocene sea surface salinity generally decreases in most oceans, except for the Baffin Bay, the Labrador Sea, and the North Atlantic subpolar regions. With NorESM-L, Pliocene sea surface
20 salinity slightly increases in most oceans while it decreases in the Indian Ocean and in the Arctic.

4.5 Sea ice

The simulated Pliocene sea ice with NorESM1-F and NorESM-L is reduced both in terms of its thickness and its extent (Fig. 5). In the Northern Hemisphere, the simulated Pliocene sea ice thickness in the Arctic Ocean is reduced by 0.5 to 1 m in March, and by more than 1 m in September. In
25 September, NorESM1-F simulates an almost ice-free Arctic in the Pliocene experiment, while sea ice remains in the central Arctic according to the NorESM-L Pliocene simulation. In March, sea ice becomes thinner while still covering most of the Arctic Ocean in both models. In the Southern Hemisphere, although both models generate retreated sea ice extents for the Southern Ocean,

NorESM-L simulates the larger sea ice responses. The Southern Ocean becomes almost ice-free specifically in March according to the NorESM-L Pliocene simulation.

4.6 Meridional overturning circulation

The simulated Pliocene AMOC becomes stronger and deeper in both models compared to the pre-industrial climate. With NorESM1-F, the maximum AMOC is 28.1 Sv in the Pliocene experiment, increasing by about 15% (Fig. 6 and Table 4). With NorESM-L, the simulated maximum AMOC is 23.3 Sv in the Pliocene experiment, which is 2 Sv (about 9%) larger than that in the pre-industrial experiment. Both models suggest that the vertical extent of the AMOC cell penetrates deeper during the Pliocene relative to the pre-industrial period (Fig. 6 and Table 4). Compared to the pre-industrial period, Pliocene sea surface salinity increases in Baffin Bay, the Labrador Sea, and the North Atlantic subpolar gyre in both models (Fig. 4), reducing the surface stratification and tending to favor more open ocean convection, thereby potentially contributing to the strengthened AMOC.

In the Pacific and Indian Ocean, meridional overturning circulation is slightly stronger in the Pliocene experiments than that in the pre-industrial experiments. As for the shallower circulation in the Northern Pacific subtropical gyre, the maximum of the circulation is increased by 1.0 Sv with NorESM1-F (22.3 Sv for the pre-industrial experiment vs. 23.3 Sv for the Pliocene experiment) and by 0.9 Sv with NorESM-L (30.7 Sv for the pre-industrial experiment vs. 31.6 Sv for the Pliocene experiment) (Fig. 6 and Table 4). As for the deeper circulation associated with Pacific Deep Water, the strength is increased by 0.8 Sv with NorESM1-F (–13.6 Sv for the pre-industrial experiment vs. –14.6 Sv for the Pliocene experiment) and by 4.6 Sv with NorESM-L (–17.0 Sv for the pre-industrial experiment vs. –21.6 for in the Pliocene experiment) (Fig. 6 and Table 4). In the Pliocene experiments, both NorESM versions simulate an extended northward penetration of deep water.

5 Discussions

5.1 NorESM1-F vs. NorESM1-L

Although the two versions of the NorESM simulate similar Pliocene climates, they still exhibit some differences. The most significant differences appear in the Southern Ocean (Fig. 1). SST increase over the Southern Ocean is ~1°C larger with NorESM-L than with NorESM1-F in the Pliocene experiments. This difference between the two model versions can likely be associated with different

responses in ocean heat transport and sea ice. Simulated Pliocene southward ocean heat transport to the Southern Ocean is reduced according to NorESM1-F, but increased according to NorESM-L (Fig. 7). The reduction in the Southern Ocean sea ice extent is more pronounced for NorESM-L than it is according to NorESM1-F (Fig. 5). Pliocene (austral summer) sea ice is nearly absent according to 5 NorESM-L, while it still covers part of the Southern Ocean according to NorESM1-F. The presence of less sea ice, reducing albedo and allowing more active ocean-atmosphere interactions, contributes to the higher levels of Southern Ocean warming in the Pliocene experiment simulated with NorESM-L.

NorESM-L also simulates increased ventilation for the Southern Ocean, while NorESM1-F does not. As is indicated by the changes in salinity, sea water over the Southern Ocean becomes less 10 stratified according to the NorESM-L Pliocene simulation (Fig. 8). The weakened ocean stratification allows the Southern Ocean to be well ventilated. As a result, the simulated Pliocene deep water is much younger in the Southern Ocean (Fig. S1). This well-ventilated Southern Ocean also appears from the PlioMIP1 Pliocene simulation with NorESM-L (Zhang, Z. et al., 2013b). However, with NorESM1-F, simulated Pliocene Southern Ocean stratification appears similar to that simulated in the pre-industrial 15 experiment.

5.2 PlioMIP1 vs. PlioMIP2

With NorESM-L, the simulated Pliocene surface temperatures in PlioMIP2 are slightly cooler than those simulated in PlioMIP1. Simulated increases in global annual mean SAT and SST are 1.1°C and 0.43°C less in PlioMIP2 than those generated in PlioMIP1 (Fig. 9). At the northern middle and high 20 latitudes, the simulated increases in annual mean SAT (SST) are 1.7°C and 5.0°C (1.0°C and 0.7°C) weaker, respectively, in PlioMIP2 than in PlioMIP1 (Fig. 9, and Table 5). Simulated weaker levels of Pliocene warming also appears in the PlioMIP2 experiment with HadCM3, according to which the Pliocene annual mean SAT is 0.4°C cooler in PlioMIP2 (Hunter et al., 2019) than in PlioMIP1 (Bragg et al., 2012). However, MRI-CGCM2.3, CCSM4, and IPSL-CM5A all simulate a larger warming in the 25 Pliocene experiments in PlioMIP2 (Kamae et al., 2016; Chandan et al., 2017; Tan et al., 2019) than those in PlioMIP1 (Contoux et al. 2012; Kamae and Ueda, 2012; Rosenbloom et al., 2013).

The simulated weaker Pliocene warming is attributable to the modified boundary conditions used in PlioMIP2. Relative to PlioMIP1, the Pliocene atmospheric CO₂ is less by 5 ppmv in PlioMIP2 (400 ppmv in PlioMIP2 vs. 405 ppmv in PlioMIP1). The slight reduction of Pliocene atmospheric CO₂ is not

likely to induce significant effect on the simulated Pliocene warming weakness. Compared to PlioMIP1, the seaways at the northern high latitudes (including the Bering Strait and Canadian Arctic Archipelago straits) are closed under the PlioMIP2 boundary conditions. Previous sensitivity investigations have demonstrated that the closure of the Bering Strait favors the formation of North Atlantic deep water and the intensification of AMOC by reducing freshwater transport from the Pacific to the Arctic Ocean and the North Atlantic (e.g., Hu et al., 2010; Brierley and Fedorov, 2016; Otto-Bliesner et al., 2017). On the contrary, the closure of Canadian Arctic Archipelago Straits tends to weaken AMOC, by increasing fresh water transport through the Fram Strait and thereby leading to the freshening and subsequent cooling of the Labrador and Greenland-Iceland-Norwegian Seas (Otto-Bliesner et al., 2017). However, the combined effects of closing these two seaways are complicated and appear to be model dependent. For example, with the Bering Strait and Canadian Arctic Archipelago Straits closed together, Pliocene ocean surface warming in the North Atlantic high latitudes is enhanced under the CCSM4 (Otto-Bliesner et al., 2017) and IPSL-CM5A simulations (Tan et al., 2019), but is weakened according to NorESM-L.

6 Conclusions

In this study, we used two versions of the NorESM (NorESM-L and NorESM1-F) to carry out core experiments designed in PlioMIP2, with boundary conditions derived from PRISM4. Relative to the pre-industrial period, the simulated Pliocene global mean SAT is 2.1°C higher according to NorESM-L and 1.7°C higher according to NorESM1-F. The simulated Pliocene global mean SST is 1.5°C warmer according to NorESM-L and 1.2°C warmer according to NorESM1-F. Compared to NorESM1-F, the simulated Pliocene warming is larger with NorESM-L. In both model versions, Pliocene global mean precipitation increases by 0.14 mm/day. Strong precipitation responses occur in tropical regions and especially in monsoon regions, and, the ITCZ shifts northward in the Atlantic and in Africa in the boreal summer. According to the Pliocene experiments of both NorESM versions, AMOC becomes stronger and deeper, and meridional overturning circulation strengthens slightly in the Pacific and Indian Oceans. Although the two models simulate similarly warm climates for the Pliocene, they also produce some differences and especially for the Southern Ocean. NorESM-L simulates increased ventilation in the Pliocene Southern Ocean, while NorESM1-F does not. Compared to the climate simulated with NorESM-L in PlioMIP1, the Pliocene warming simulated in PlioMIP2 (with the

updated PRISM4 boundary conditions) is slightly less pronounced. A comparison of Pliocene climates simulated with NorESM-L in PlioMIP1 and PlioMIP2 shows a weaker warming in PlioMIP2. The Pliocene global mean SAT and SST are 1.1°C and 0.43°C lower, respectively, in PlioMIP2 than those in PlioMIP1. Sensitivity experiments testing the impacts of boundary conditions modification made from
5 PlioMIP1 to PlioMIP2, i.e., the effects of closing ocean gateways in the northern high latitudes, will be helpful in casting further light on these model discrepancies.

Data availability. All PlioMIP2 boundary conditions are available on the USGS PlioMIP2 web page (https://geology.er.usgs.gov/egpsc/prism/7_pliomip2.html). Climatological averages of the two NorESM versions will be uploaded to the PlioMIP2 data repository later (<sftp://see-gw-01.leeds.ac.uk>).

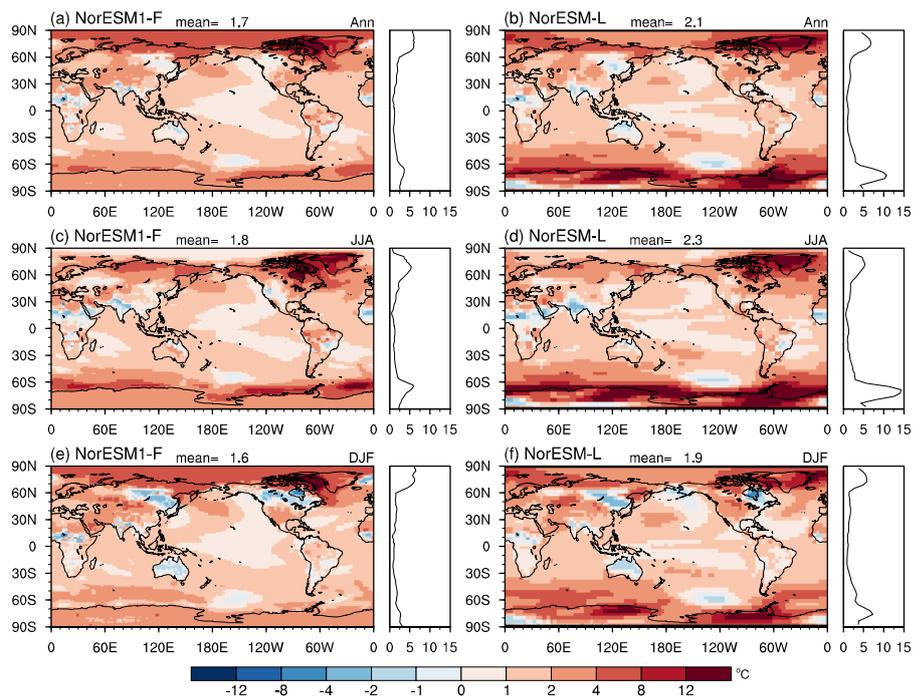

Figure 1. The difference in climatological surface air temperatures (units: °C) between Pliocene and pre-industrial experiments according to NorESM1-F (left panel) and NorESM-L (right panel) for the annual mean (a and b), boreal summer (c and d), and boreal winter (e and f). The zonal mean is shown to the right of each plot.

5

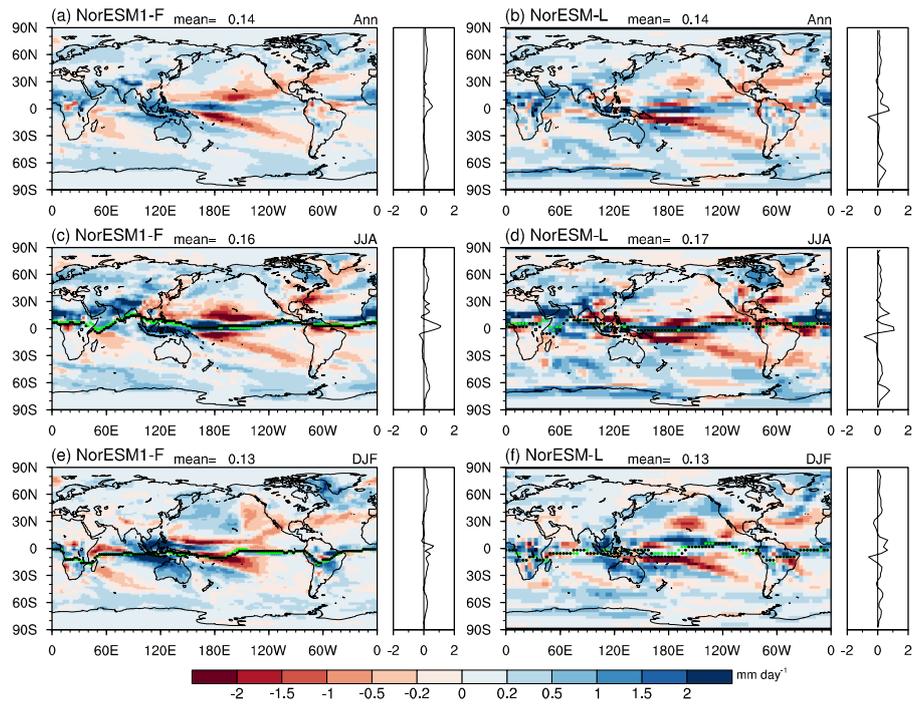

Figure 2. Same as Figure 1 but for precipitation (units: mm day^{-1}). The black and green dots in c, d, e, and f indicate the positions of ITCZ in the pre-industrial and Pliocene experiments, respectively, as defined by Braconnot et al. (2007).

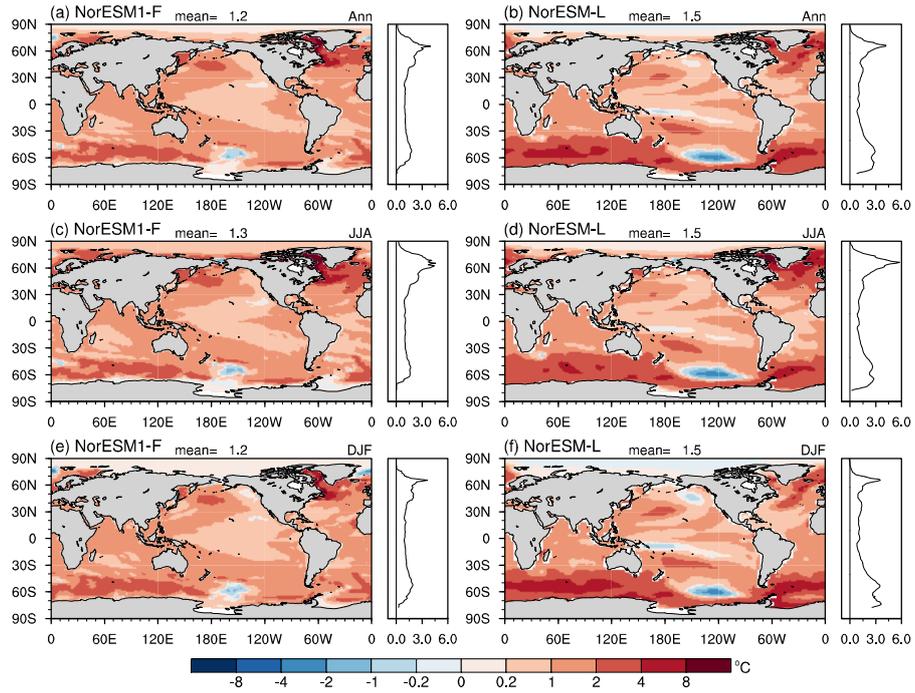

Figure 3. Same as Figure 1 but for sea surface temperature (units: °C).

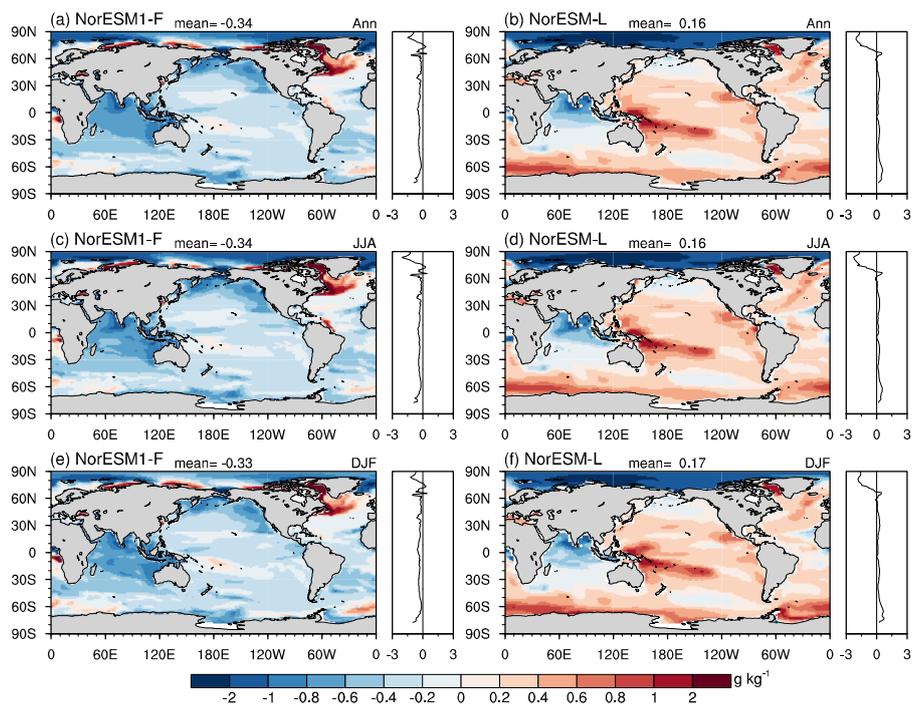

Figure 4. Same as Figure 1 but for sea surface salinity (units: g kg^{-1}).

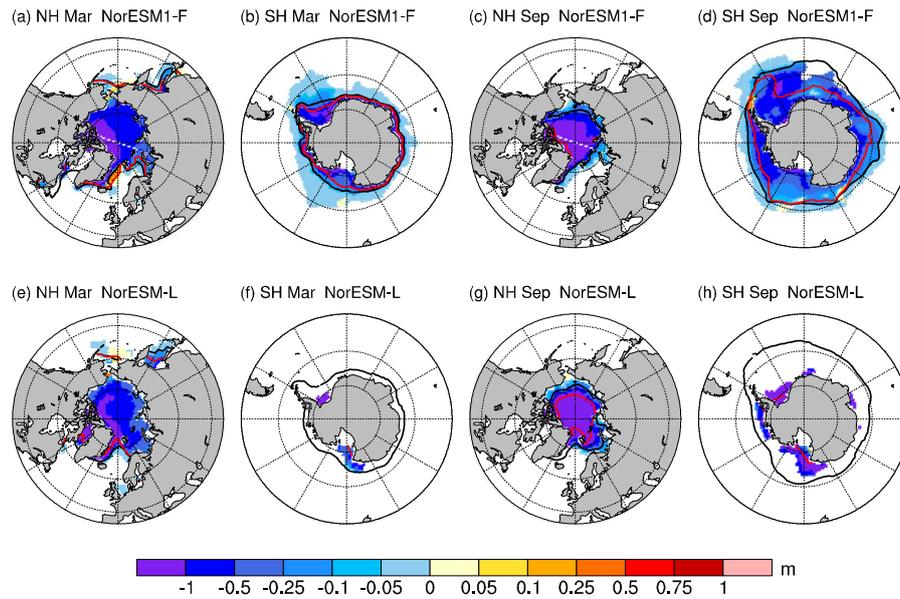

Figure 5. The difference in climatological sea ice thickness (shading, units: m) between the Pliocene and pre-industrial experiments according to NorESM1-F (top panel) and NorESM-L (bottom panel) for March (a, b, e, and f) and September (c, d, g, and h). The red and black lines represent 15 % sea ice concentration in the Pliocene and pre-industrial experiments, respectively.

5

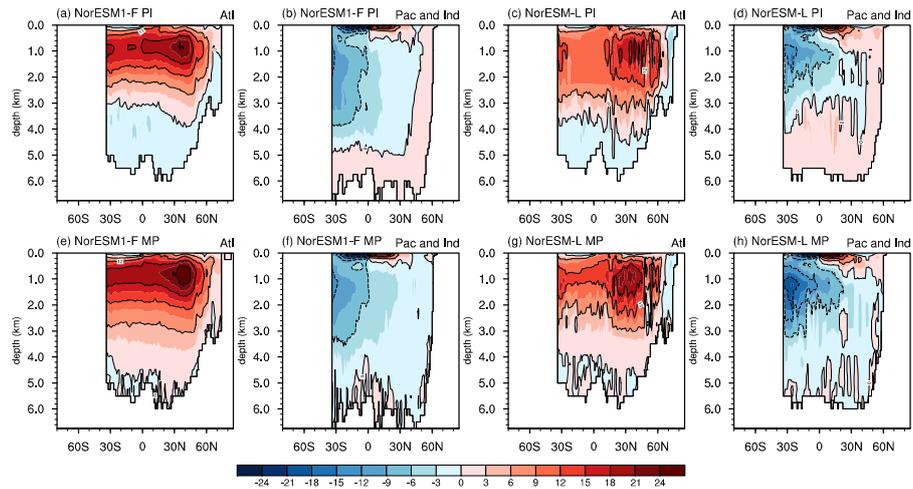

Figure 6. Climatological meridional overturning stream functions (units: Sv) derived from the NorESM1-F (left two panels) and NorESM-L (right two panels) Pliocene and pre-industrial experiments conducted on the Atlantic Basin (a, c, e, and g) and the Pacific and Indian Ocean Basin (b, d, f, and h).

5

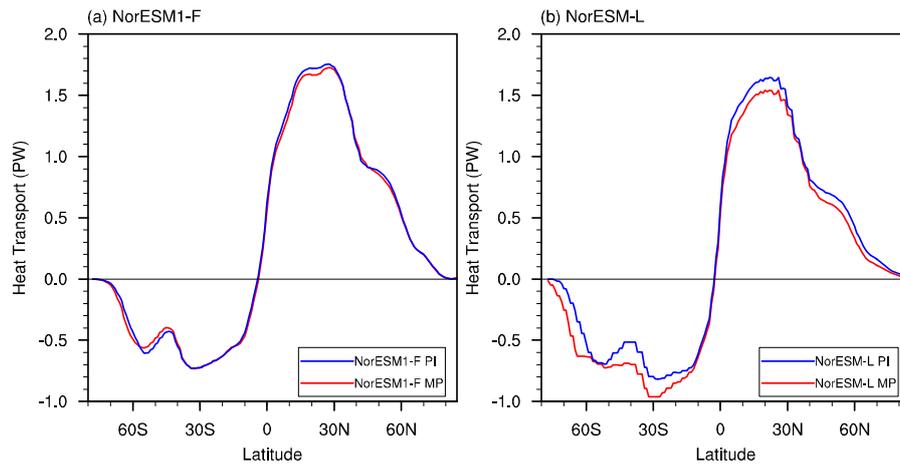

Figure 7. Climatological global meridional ocean heat transport (units: PW) derived from the Pliocene (red line) and pre-industrial (blue line) experiments according to NorESM1-F (a) and NorESM-L (b).

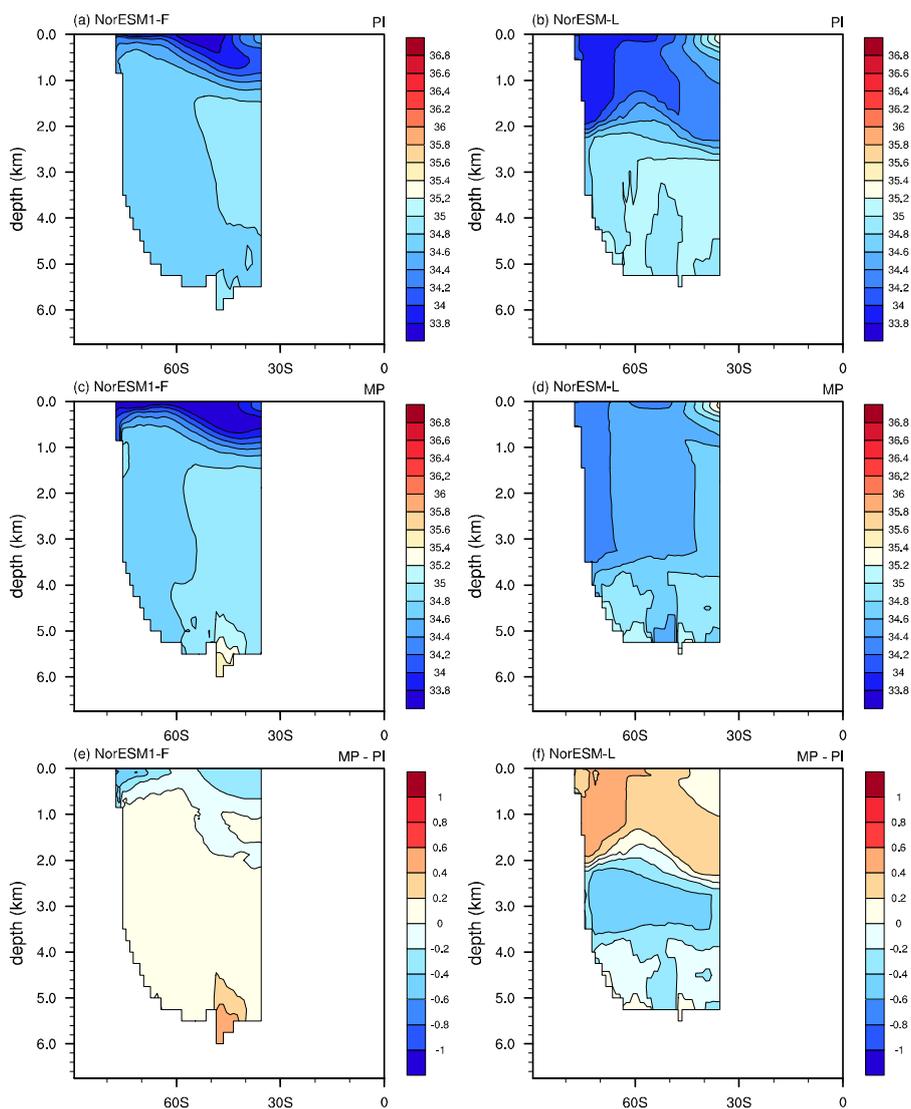

Figure 8. Climatological Southern Ocean salinity (units: g kg^{-1}) derived from the pre-industrial (a and b) and Pliocene (c and d) experiments, and their differences (e and f) according to NorESM1-F (left panel) and NorESM-L (right panel).

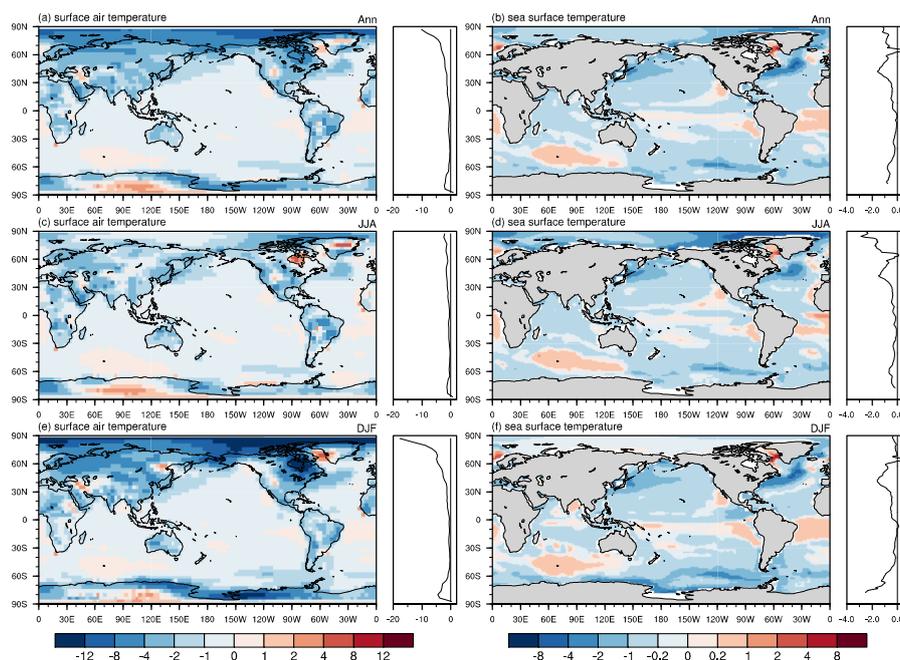

Figure 9. Anomalies of surface air temperature change (left panel) and sea surface temperature change (right panel) (units: °C) between PlioMIP2 and PlioMIP1 (PlioMIP2 minus PlioMIP1) according to NorESM-L for the annual means (a and b), boreal summer (c and d), and boreal winter (e and f). The zonal mean is shown to the right of each plot.

5

Table 1. The model description.

Model version	Atmosphere	Ocean	Reference
NorESM-L	T31, ~3.75 ° 26 levels in the vertical	bipolar grid g37, ~ 3 °	Zhang et al., 2012
NorESM1-F	1.9 × 2.5 ° 26 levels in the vertical	tripolar grid ~1 °	Guo et al., 2019

Table 2. Boundary conditions for the pre-industrial and the Pliocene experiments.

	Pre-industry		Pliocene	
	NorESM-L	NorESM1-F	NorESM-L	NorESM1-F
Land-sea mask/Bathymetry	Local modern		PRISM	
Topography and ice sheet height	Local modern		Anomalies + local modern	
Vegetation and ice sheet cover	Local pre-industrial		PRISM vegetation	
CO ₂ (ppmv)	280	284.7	400	400
N ₂ O (ppbv)	270	275.68	270	275.68
CH ₄ (ppbv)	760	791.6	760	791.6
CFCs	0	0	0	0
Orbital parameters	Year 1950			
Total integration (yr)	2200	2000	1200	500*
Averaging period	Last 100 yr			

*After 2000 years spin-up with atmospheric CO₂ concentration set to 400 ppmv, the experiment is integrated for another 500 years forced with all Pliocene boundary conditions.

5

Table 3. Regional averaged annual and seasonal anomalies between the Pliocene and pre-industrial experiments according to NorESM1-F and NorESM-L in PlioMIP2 for surface air temperature (SAT), precipitation, and sea surface temperature (SST).

Region	SAT (ANN/JJA/DJF, °C)		precipitation (ANN/JJA/DJF, mm day ⁻¹)		SST (ANN/JJA/DJF, °C)	
	NorESM1-F	NorESM-L	NorESM1-F	NorESM-L	NorESM1-F	NorESM-L
SH high-latitude (60°S–90°S)	3.2/4.6/2.1	7.6/10.3/4.7	0.20/0.25/0.14	0.27/0.38/0.15	1.0/0.92/1.2	2.6/2.5/2.9
SH middle-latitude (30°S–60°S)	1.6/1.7/1.5	2.3/2.2/2.4	0.09/0.11/0.09	0.16/0.18/0.13	1.5/1.4/1.6	2.2/2.1/2.5
SH low-latitude (30°S–0°)	1.1/1.2/0.99	1.1/1.2/1.0	0.09/-0.03/0.24	0.03/-0.07/0.10	1.0/1.0/1.1	1.1/1.1/1.1
NH low-latitude (0°–30°N)	1.1/0.92/1.1	1.1/0.92/1.2	0.22/0.36/0.07	0.24/0.36/0.16	1.0/1.0/1.0	1.0/1.0/1.1
NH middle-latitude (30°N–60°N)	1.9/2.1/1.6	1.7/1.9/1.6	0.11/0.16/0.10	0.11/0.14/0.14	1.7/2.0/1.5	1.5/1.7/1.2
NH high-latitude (60°N–90°N)	5.2/4.4/4.9	4.9/4.5/3.9	0.18/0.09/0.21	0.13/0.13/0.12	1.5/2.4/0.9	1.4/2.2/0.77

Table 4. Meridional overturning circulation in the Atlantic Ocean (AMOC) and the Pacific and Indian Oceans (PMOC).

Meridional Overturning Circulation	NorESM1-F			NorESM-L		
	PI	MP	%	PI	MP	%
AMOC maximum (Sv)	24.5	28.1	15	21.3	23.3	9
AMOC upper cell averaged depth (m)	~3200	~4700	47	~3700	~4800	30
PMOC maximum above 500m, North of 5° N (Sv)	22.3	23.3	4	30.7	31.6	3
PMOC minimum below the 500m (Sv)	-13.6	-14.4	6	-17.0	-21.6	27

The strength of shallower circulation in the subtropical gyre of the North Pacific is represented by the PMOC maximum north of 5° N above 500 m. The strength of Pacific Deep Water is represented by the PMOC minimum measured below the 500 m.

5

Table 5. Similar as table 3, but for anomalies simulated according to NorESM-L between PlioMIP1 and PlioMIP2.

Region	SAT (ANN/JJA/DJF, °C)		P (ANN/JJA/DJF, mm day ⁻¹)		SST (ANN/JJA/DJF, °C)
