## Abstract.

In this paper we introduce a Bayesian framework, which is flexible and explicit about the prior assumptions, for using model ensembles and observations together to constrain future climate change. The emergent constraint approach has seen broad application in recent years, including studies constraining the equilibrium climate sensitivity (ECS) using the Last Glacial Maximum (LGM) and the mid-Pliocene Warm Period (mPWP). Most of these studies were based on Ordinary Least Squares (OLS) fits between a variable of the climate state, such as tropical temperature, and climate sensitivity. Using our Bayesian method, and considering the LGM and mPWP separately, we obtain values of ECS of 2.7 K (1.1–4.8, 5–95 percentiles) using the PMIP2, PMIP3 and PMIP4 data sets for the LGM, and 2.4 K (0.4–5.0) with the PlioMIP1 and PlioMIP2 data sets for the mPWP. Restricting the ensembles to include only the most recent version of each model, we obtain 2.7 K (1.1–4.3) using the LGM and 2.4 K (0.4–5.1) using the mPWP. An advantage of the Bayesian framework is that it is possible to combine the two periods assuming they are independent, whereby we obtain a slightly tighter constraint of 2.6 K (1.1–3.9). We have explored the sensitivity to our assumptions in the method, including considering structural uncertainty, and in the choice of models, and this leads to 95% probability of climate sensitivity mostly below 5 and never exceeding 6 K. The approach is compared with other approaches based on OLS, a Kalman filter method and an alternative Bayesian method. An interesting implication of this work is that OLS-based emergent constraints on ECS generate tighter uncertainty estimates, in particular at the lower end, suggesting a higher bound by construction in case of weaker correlation. Although some fundamental challenges related to the use of emergent constraints remain, this paper provides a step towards a better foundation of their potential use in future probabilistic estimation of climate sensitivity.

## 1 Introduction

In recent years, researchers have identified a number of relationships between observational properties and a future climate change, which was not immediately obvious a priori, but which exists across the ensemble of global climate models (GCMs) (Allen and Ingram, 2002; Hall and Qu, 2006; Boé et al., 2009; Cox et al., 2018) participating in the Climate Model

Intercomparison Project (CMIP). These relationships are generally referred to as ‘emergent constraints’ as they emerge from the ensemble behaviour as a whole rather than from explicit physical analysis.

25 Such emergent constraints have been broadly used to constrain properties of the Earth’s climate system which are not easily or directly observable. These are usually presented in probabilistic terms, mostly based on Ordinary Least Squares (OLS) methods. For example, studies have explored the constraint on equilibrium climate sensitivity (ECS), which is the global mean equilibrium temperature after a sustained doubling of CO<sub>2</sub> over pre-industrial levels, using model outputs from the Paleoclimate Model Intercomparison Project (PMIP) (Hargreaves et al., 2012; Schmidt et al., 2014; Hopcroft and Valdes, 2015; Hargreaves and Annan, 2016). Because of their relatively strong temperature signal, paleoclimate states like the Last Glacial Maximum (LGM) and the mid-Pliocene Warm Period (mPWP) are often considered as promising constraints for the ECS (Hargreaves et al., 2012; Hargreaves and Annan, 2016), in particular at the high end.

35 Almost all emergent constraint studies have used OLS to establish the link between variables in the model ensembles. However, whether ECS or another climate parameter was investigated, the theoretical foundations for the calculations have not previously been clearly presented. An additional problem arising from this is the resulting difficulty in synthesising estimates of climate system properties generated by different statistical methods with different, and often not explicitly introduced, assumptions. These methods include OLS but also alternative Bayesian approaches such as estimates of the climate sensitivity using energy-balance models (Annan et al., 2011; Aldrin et al., 2012; Bodman and Jones, 2016).

40 Two recent papers have also addressed the question of emergent constraints in different ways. Bowman et al. (2018) presented a hierarchical statistical framework which went a long way to closing the gap in theoretical understanding of emergent constraints. Conceptually, it is very similar to a single step Kalman filter. Specifically, it uses the model distribution (approximated as a Gaussian) as a prior, which is then updated using the observation to a posterior. However, such prior and the underlying assumptions attached to it could be seen as a restrictive choice to impose on the climate sensitivity area of research. In particular, it is fairly difficult to generate posterior values which are outside of the prior range, even when the observation is outside the range covered by models. Because of that, it does not appear to correspond to the choice which is usually made, albeit implicitly.

50 Another Bayesian statistical interpretation of emergent constraints has been recently presented by Williamson and Sansom (2019) who extended the standard approach to account for more general sources of uncertainty including model inadequacy. A key aspect of their approach is that they set a prior on the observational constraint rather than the climate system parameter(s) that we are primarily interested in this study, i.e. the climate sensitivity. Thus, their prior predictive distribution for the climate system parameter is not immediately clear and may not be so easily specified as in the approach we explore and which is described below.

55 We present an alternative Bayesian linear regression approach in which the regression relationship is used as a likelihood model for the problem. This allows for the prior over the predictand to be defined separately from and entirely independently of the model ensemble and emergent constraint analysis. Thus the likelihood arising from the emergent constraint could be used to update a prior estimate of the predictand that arose from a different source.

In Section 2 we provide an overview of the concept of emergent constraints, the previous methods used for these analyses, introduce the Bayesian linear regression method as well as the models and data employed in the paper. Section 3 describes the results, starting with analysis of models and data from the Paleoclimate Intercomparison Project (PMIP) Phases 2 and 3 for the LGM and mPWP, that have previously been analysed for an emergent constraint on climate sensitivity (Schmidt et al., 2014; Hargreaves and Annan, 2016). We then incorporate some CMIP6/PMIP4 model outputs that have been made available to us for these periods to illustrate how these outputs fit into the same analysis. We also use the LGM and mPWP outputs to demonstrate how the method allows independent lines of evidence to be combined. Finally, we discuss the influences of the prior and of model inadequacy on climate sensitivity.

## 65 2 Methods

The general method, referred to as “emergent constraints”, suggests that if a relationship exists, in an ensemble of results from different climate models, between an observable model variable and another model variable that we seek to constrain (such as climate sensitivity) then an observation could be used to better constrain that variable. This idea has been used in climate science to forecast variables such as snow albedo feedback (Hall and Qu, 2006), sea ice extent (Boé et al., 2009; Notz, 2015), low-level cloud feedback (Brient et al., 2016), and to estimate the equilibrium climate sensitivity (Hargreaves et al., 2012; Schmidt et al., 2014; Cox et al., 2018). A summary of several different emergent constraints on climate sensitivity was made by Caldwell et al. (2018). This approach using emergent constraints is meaningful only if we believe that reality satisfies the same relationship, and it was not observed purely by chance in the model ensemble. There is a risk in searching for such relationships in a small ensemble that we may find examples which are coincidental, with no real predictive value (Caldwell et al., 2014). Spurious relationships could also be found because of model limitations (Fasullo and Trenberth, 2012; Grise et al., 2015; Notz, 2015).

In this study, we focus on the relationship between equilibrium climate sensitivity, defined here as  $S$ , and the temperature change in the tropics which is observed at the Last Glacial Maximum (LGM) and the mid-Pliocene Warm Period (mPWP), defined as  $T_{\text{tropical}}$ . We posit that a relationship between climate sensitivity and temperature change is physically plausible, as we expect the long-term quasi-equilibrium temperature to be mainly influenced by radiative forcing, and past model ensembles variations in climate sensitivity have been dominated by tropical feedbacks, mostly arising from low-level clouds (Bony et al., 2006; Vial et al., 2013). Furthermore, since mixing with the deep oceans happens mostly at high latitudes and equilibrating the deep ocean temperatures in a climate model takes several thousand years, there is the risk that the temperature in these regions have not yet equilibrated to the same extent in all models. This can cause high latitude temperature variations that are not related to climate sensitivity, but to how modelling centres conducted their experiments.

### 2.1 Ordinary Least Squares

The most widely-used approach to emergent constraint analysis is to find an observable phenomenon that exhibits some relationship to the parameter of interest, and use this as a predictor in a linear regression framework. The Ordinary Least Squares

(OLS) method has been widely used because of its simplicity, and so we also use it here as a benchmark for comparison with alternative statistical methods. In the context of constraining climate sensitivity, the parameter of interest (i.e. the ECS) is considered as a predicted variable (Hargreaves et al., 2012; Schmidt et al., 2014; Hargreaves and Annan, 2016). This may be written as

$$S = \alpha \times T_{\text{tropical}} + \beta + \epsilon \quad (1)$$

where  $S$  is the climate sensitivity,  $\alpha$  and  $\beta$  two unknown constants,  $T_{\text{tropical}}$  the temperature anomaly averaged over the tropical region for the given paleo-time interval, and  $\epsilon$  the residual term which is drawn from a Gaussian distribution  $N(0, \sigma)$  and which accounts for deviations from the linear fit. When we use this approach, the unknown constants of the linear fit are estimated via ordinary least squares (OLS) using the  $(T_{\text{tropical}}^i, S^i)$  pairs representing the model ensemble (here  $i$  indexes the models) and then the equation is used to predict the true value of  $S$  for the climate system, based on the observed value  $T_{\text{tropical}}^o$ . A confidence interval for the predictor variable can be generated by accounting for uncertainties in the fit and in the observed value as was demonstrated by Hargreaves et al. (2012). This procedure makes the assumption that reality satisfies the same regression relationship as the models, i.e. is likely to be at a similar distance from the line as the model points are.

Integrating the intrinsically frequentist OLS-based confidence intervals into a Bayesian framework is somewhat unclear. One issue is the misinterpretation of frequentist confidence intervals as Bayesian posterior credible intervals, where the former is the representation of a percentage of intervals to contain the fixed true value of the parameter, while Bayesian credible interval is the probability of the true value to be included within a given interval. For instance, if there is an observed  $T_{\text{tropical}} = 1$  K, with an assumed Gaussian observational uncertainty of  $\sigma = 0.25$  at one standard deviation, then stating that there is a close-to-95% probability of having the true value of the parameter within the interval 0.5–1.5 K is a Bayesian credible interval interpretation. However, the latter is a common interpretation of frequentist-based studies. This confusion has inherent drawbacks on the analysis of posterior outputs, as shown in various fields of science (Hoekstra et al., 2014) and more recently, for climate sensitivity computations (Annan and Hargreaves, 2019). Williamson and Sansom (2019) have presented a Bayesian interpretation of this approach using reference priors on  $\psi$ , as defined by Cox et al. (2018) as a metric of global mean temperature variability, and the regression coefficients. However, this approach does not appear to readily allow for the use of any arbitrary prior distribution for  $S$  which may either be desired for comparison with other research, or else have arisen through a previous unrelated analysis. The Bayesian linear regression approach that we introduce in the next section avoids these problems.

## 2.2 Bayesian Linear Regression

The (subjective) Bayesian paradigm is based on the premise that we use probability distributions to describe our uncertain beliefs concerning unknown parameters. We use Bayes' Theorem to update a prior probability distribution function (pdf) for the equilibrium climate sensitivity via

$$P(S|T_{\text{tropical}}) = \frac{P(T_{\text{tropical}}|S)P(S)}{P(T_{\text{tropical}})}, \quad (2)$$

120 where  $P(S|T_{\text{tropical}})$  is the posterior after conditioning on the data,  $P(S)$  is the prior and  $P(T_{\text{tropical}})$  is a normalisation constant. The likelihood  $P(T_{\text{tropical}}|S)$  is a function that takes any value of  $S$  and generates a probabilistic prediction of what we would expect to observe as  $T_{\text{tropical}}$  if that value was correct. The use of the Bayesian paradigm requires us to create such a function. Using the principles of emergent constraint analyses in which a linear relationship between these two parameters, which was seen in the GCM ensemble, is believed to apply also to reality, it is natural to use the regression relationship

$$125 \quad T_{\text{tropical}} = \alpha \times S + \beta + \epsilon. \quad (3)$$

Note that this reverses the rôles of predictor and predictand compared to the OLS-based approach (Eq. 1). The values of  $\alpha$ ,  $\beta$  and  $\sigma$ , where  $\sigma$  represents the standard deviation of  $\epsilon$  as  $\epsilon \in N(0, \sigma)$ , are estimated from the model ensemble via a Bayesian linear regression procedure, which requires priors to be defined over these parameters.

In this way, we create a statistical model, conditioned on the model ensemble, that can generate a predictive pdf for the tropical temperature change at the LGM or at the mPWP  $P(T_{\text{tropical}}|S)$ , for any given sensitivity. There is a structural difference  
130 between this approach and that of Eq. 1, in that here the residual uncertainties  $\epsilon \in N(0, \sigma)$  represent our inability to perfectly predict the tropical temperature anomaly arising from a given sensitivity, and are probabilistically independent of the latter rather than the former variable. The issue here is not a matter of which regression line is ‘correct’, but rather how, given the model ensemble, we can create a plausible likelihood model for  $P(T_{\text{tropical}}|S)$ .

135 The regression prediction for the temperature change as a function of sensitivity, together with the observed tropical temperature change as estimated through analysis of proxy data  $T_{\text{tropical}}^o$ , naturally leads to a likelihood function for the sensitivity of the climate system  $P(T_{\text{tropical}} = T_{\text{tropical}}^o|S)$ . That is, for a given sensitivity  $S$ , we can calculate the probability of the observation of tropical temperature that we have, as the composition of the predictive pdf for actual tropical temperature, together with the uncertain observation operator. In practice this is performed by a simple sampling algorithm.

140 A prior belief both on climate sensitivity ( $P(S)$ ), and on the parameters of the regression model, has to be assumed. There is no clearly uncontested choice for prior distribution for climate sensitivity. However, Annan and Hargreaves (2011) argued that a Cauchy distribution has a reasonable behaviour with a long tail to high values, but unlike the uniform prior, does not assign high probability to these values. Thus we adopt this prior for our main analyses. In section 3.5 we test the sensitivity of the results to this choice and compare the results obtained using Gamma and uniform prior distributions. Priors for the parameters  
145 of the regression model are chosen with reference to the specific experiment and are intended to represent our reasonable (albeit uncertain) expectation that models do indeed generate a regression relationship as described.

An additional issue, that was briefly mentioned above, is that we may like to consider the probability that reality is qualitatively and quantitatively distinct from all models. This issue, which was explicitly argued in the context of emergent constraint analysis by Williamson and Sansom (2019), seems reasonable since all models do share a theoretical heritage and certain limitations. However, this issue remains challenging to quantify. It has not been considered in most previous studies which also  
150 makes it difficult to compare. We investigate this issue in Section 3.6. Whilst the proposed resolution remains preliminary and although the concept is promising for understanding emergent constraints, we decide to omit it for the rest of the analysis to enable more direct comparisons with previous studies.

The Bayesian Linear Regression (BLR) method is more explicit than the standard OLS approach, as the prior assumptions  
155 have to be given by the user. This transparency leads to more freedom and control of the statistical model. Moreover, it is less  
sensitive to outliers as the prior on the regression coefficients provides a form of regularisation. This should result in lower  
variance in the results, particularly when, as in the examples studied here, we have small model ensembles.

Additionally, the Bayesian method allows the user to add multiple lines of evidence by sequentially updating the chosen prior  
for  $S$ . The method for combining independent constraints is reasonably simple, as it only requires us to calculate and store  
160 the posterior of the first emergent constraint analysed, and use this distribution as the prior for the second emergent constraint.  
Thus it is a direct form of sequential Bayesian updating. This process results in a posterior distribution which will generally be  
narrower than either of the two posteriors that would have been generated from either of the emergent constraints separately.  
Although it may be tempting to simply combine all emergent constraints in this way, it is necessary to also consider possible  
dependencies between the uncertainties in the different emergent constraints before this can be done with confidence (Annan  
165 and Hargreaves, 2017).

### 2.3 Kalman Filter

Bowman et al. (2018) recently presented a new interpretation of emergent constraint analysis. Their framework is essentially a  
two-dimensional Kalman Filtering approach in which the prior, represented by the model ensemble, is updated according to the  
observation, using the Kalman equation which approximates all distributions by a multivariate Gaussian. Here we only have  
170 two dimensions for the Gaussian, these being the scalar predictor (e.g. sensitivity) and predictand (e.g. tropical temperature  
change). While this approach is a natural and attractive option in many respects, it has the specific drawback of using the  
distribution of model samples as a prior. Existing literature on emergent constraints does not make this assumption and this  
could be seen as a limiting aspect of the method, as it implies that the model ensemble is already a credible predictor even  
before consideration of the observational constraint. Some implications of this approach are that the posterior estimate is equal  
175 to the model distribution in the case that no constraint exists, either because there is in fact no relationship between observation  
and predictand, or else when the observational uncertainty is excessively large. It is also difficult for the method to generate  
posterior estimates that include values significantly outside the model range, even in the case where the observed value is  
outside the model spread. We present results generated with a Kalman filter in Section 3.1 for comparison with our main  
analysis.

### 180 2.4 Climate Models and Data

The BLR method may be applied to any emergent constraint. In this study, we use the model outputs and data syntheses arisen  
from phases 2 and 3 of PMIP (Braconnot et al., 2007; Haywood et al., 2011; Harrison et al., 2014), summarised in Table 1. The  
Last Glacial Maximum (19–23 ka) corresponds to the period of the last ice age where ice sheets and sea ice had their maximum  
extent. Due to its temporal proximity, relative abundance of proxy data, and substantial radiative forcing anomaly, the LGM is  
185 widely considered one of the best paleoclimate intervals for testing global climate models and has been featured in all of the

PMIP consortium experiments. A representation of several model LGM simulations compared to the SAT reconstruction of Annan and Hargreaves (2013) is shown in Fig. 1–(a).

Previous results from PMIP2 showed a significant correlation between LGM tropical temperatures and climate sensitivity in the models (Hargreaves et al., 2012), although the equivalent calculation for the PMIP3 models found no significant correlation (Schmidt et al., 2014; Hopcroft and Valdes, 2015). These two similar sized ensembles with contrasting characteristics are a good test-bed for exploring the properties of the different methods. For the tropical temperature anomaly relative to pre-industrial we use a value from Annan and Hargreaves (2013), for 20° S to 30° N, a  $T_{\text{tropical}}^o$  of -2.2 K with a Gaussian observational uncertainty of  $\pm 0.7$  K (5–95% confidence interval). Several data compilations are presently in development as part of PMIP4, but these have yet to be integrated into a global temperature field so revising the temperature estimate from Annan and Hargreaves (2013) is a topic for future work.

Interest in the mPWP (2.97–3.29 million years ago) as a more direct analogy for future climate change, has grown during the past years. This is the most recent period with a sustained high level of greenhouse gases and concomitant warmth relative to the pre-industrial period, however, the data are more sparse and uncertain. In Fig. 1–(b), the sea-surface temperature anomaly of different climate models which performed a mPWP simulation is displayed, as well as the PRISM3 SST reconstruction (Dowsett et al., 2009). Previous results for this period from the PlioMIP experiment, which was part of PMIP3, indicated a fairly strong correlation between tropical temperature and climate sensitivity in the models, but the confidence with which this can be used to constrain climate sensitivity was low due to high uncertainty in various observationally derived components as well as various compromises in the way the protocol was formulated (Hargreaves and Annan, 2016). For the mPWP, a tropical temperature anomaly of  $0.8 \pm 1.6$  K (5–95% interval) is taken from Hargreaves and Annan (2016) for 30° S to 30° N, assuming the largest 5–95% uncertainty showed in that work. The reconstruction used here is the PRISM3 (Pliocene Research, Interpretation and Synoptic Mapping) SST anomaly field as described in Dowsett et al. (2009).

The Last Interglacial (127 ka, referred as lig127k in CMIP6) and the mid-Holocene (6 ka) are part of the PMIP simulations and also relatively warm climates. The forcings are, however, seasonal and regional in nature, mostly influencing the patterns of climate change. The global change in temperature and the global climate forcing are both very small, and this coupled with the large uncertainty in paleoclimate data makes these intervals poor candidates for constraining climate sensitivity. We do not explore these intervals further here.

Climate sensitivity has various definitions and there are also a number of different ways of approximating the value in climate models that have not been run to equilibrium. For PMIP3 LGM the model values are mostly based on the regression method of Gregory et al. (2004), but for the models which contributed to PMIP2 LGM and PlioMIP the exact definition and derivation used in each case is not always clear in the literature. In order to make comparisons with previous work, here we use the same values as those used in Hargreaves et al. (2012), Schmidt et al. (2014) and Hargreaves and Annan (2016) with two exceptions to ensure that only one value of sensitivity is used for identical versions of the same model across different experiments. Specifically, for FGOALS-g2 we use the value of 3.37 K (Yoshimori, pers. comm.) for both PMIP3 LGM and PMIP3 PlioMIP, and for HadCM3 we use 3.3 K (Randall et al., 2007) for both PMIP2 LGM and PMIP3 PlioMIP. Previous values used by Hargreaves and Annan (2016) for PMIP3 PlioMIP were 3.7 K for FGOALS-g2 (Zheng et al., 2013) and 3.1 K

for HadCM3 (Haywood et al., 2013). These changes are minor compared to the ensemble range of climate sensitivity and thus, they have no significant effect on the posterior outputs.

In addition to the already published results from PMIP2 and PMIP3 we add to our ensembles the results that are currently available from PMIP4 in section 3.3. While the LGM protocol (Kageyama et al., 2017) remains very similar to that in previous iterations of PMIP, the mPWP protocol (Haywood et al., 2016) has more significant differences which address several of the limitations of the previous version. Most importantly, PlioMIP2 seeks to represent a specific quasi-equilibrium climate state in the past rather than representing an amalgamation of different warm peak climates as had been the case for PlioMIP1. A priori we are therefore less confident about combining the results from PlioMIP1 and PlioMIP2 and do so mostly to indicate where the new models lie in the ensemble and to highlight the potential for future research in this area once more model results based on the PlioMIP2 protocol become available.

### 3 Applications and Results

In order to apply the Bayesian Linear Regression and compute the likelihood  $P(T_{\text{tropical}}|S)$ , several priors have to be established as initial conditions. Specifically, for both the LGM and the mPWP we use Eq. 3 as the basis for our likelihood function. The prior expectations of the three unknown parameters  $\alpha$ ,  $\beta$  and the standard deviation of the residual  $\epsilon$ , referred to as  $\sigma$ , need to be defined. The relative complexity of the likelihood function with three a priori unknown parameters requires the use of a sampling method for computational efficiency. In this study, we use the Markov Chain Monte Carlo (MCMC) method NUTS as described by Hoffman and Gelman (2014). The NUTS method is also included in the MCMC python package PyMC3 (Salvatier et al., 2016) which is applied here. Other MCMC methods which have been tested, such as Metropolis sampling or Hamiltonian Monte Carlo, give equivalent results.

Depending on the strength of the correlation among the dataset, one could expect a sensitivity of the regression to the choice of prior parameters. In the following sections, we first describe the physical arguments behind the choice of priors over  $\alpha$ ,  $\beta$  and  $\sigma$ , and then present the outputs of the BLR for both the PMIP2 and PMIP3 dataset of the LGM and the PlioMIP1 dataset of the mPWP. Then, we include the CMIP6 data in the BLR framework for both paleo intervals, and present an approach of combining the two emergent constraints. Finally, we explore the sensitivity of the BLR approach to the choice of priors over the climate parameter of choice (i.e. the climate sensitivity) and to the hypothetical inadequacy of climate models.

#### 3.1 The Last Glacial Maximum

From consideration of energy balance arguments and fundamental physical properties, such as the response of Earth to an increase of  $\text{CO}_2$ , we have a prior expectation of a relationship between sensitivity and global LGM temperature anomaly (e.g. Lorius et al., 1990), and model experiments of Hargreaves et al. (2007) as well as simple physical arguments about the spatial distribution of forcing suggest that this relationship may be most clearly visible when we focus on the tropical region. While the total negative forcing at the LGM is roughly twice as large as the positive forcing that would be caused by a doubling of  $\text{CO}_2$ , the temperature response at low latitudes is generally expected to be lower than the global mean, due to polar amplification and

the related presence of high latitude ice sheets. Thus we might reasonably expect the tropical temperature change at the LGM to be roughly equal to the global temperature rise under a doubling of CO<sub>2</sub>. It would also be unexpected if the correlation had the opposite sign to that based on simple energy balance arguments, such that a more sensitive model had a lower temperature change at the LGM. However we cannot justify imposing a precise constraint on the slope and therefore our choice of prior for  $\alpha$  is  $N(-1, 1)$ . As for  $\beta$ , we expect the regression line to pass close to the origin, as a model with no sensitivity to CO<sub>2</sub> would probably have little response to any other forcing changes, especially in the tropical region where the influence of ice sheets is remote. However, we do not expect a precise fit to the origin and therefore, the prior chosen for  $\beta$  is  $N(0, 1)$ . Finally, we chose a wide prior for  $\sigma$ , a Half Cauchy with a scale parameter of 5. The Cauchy is fairly close to uniform for values smaller than the scale parameter, decaying gradually for higher values.

Deviations from the regression line may be due to different efficacies of other forcing components, especially ice sheets or dust. To take into account the uncertainty on the strength of the response, we performed two additional analyses where the prior response was smaller ( $\alpha$  defined as  $N(-0.5, 1)$ ) and larger ( $\alpha$  defined as  $N(-2, 1)$ ). We do not see much difference in the results using the three priors over  $\alpha$ : the difference is approximately 0.2 K of climate sensitivity for both the upper and lower percentiles quoted, giving us confidence in our choice of  $N(-1, 1)$ . The computed 5–95% posterior climate sensitivity ranges for different values of  $\alpha$  are summarised in Table 2.

The MCMC algorithm samples the posterior distribution of regression parameters which is represented by the ensemble of predictive regression lines in Fig. 2. This ensemble is used to infer the climate sensitivity following the Bayesian inference approach using the geological reconstruction of the LGM tropical temperature. The posterior distributions are computed using a truncated-at-zero Cauchy prior with a peak of 2.5 and a scale of 3, which corresponds to a wide 5–95% prior interval of 0.5–28.7 K. Such a prior was used previously by Annan et al. (2011) because it has a long tail, allowing for a substantial probability of having high climate sensitivity while still maintaining some preference for more moderate values. Additionally, the Cauchy prior has a finite integral, unlike the uniform distribution (which is sometimes referred as an "improper prior" for this reason). However, the sensitivity of Bayesian statistics to the choice of prior has often been noted. Thus, two alternative priors, including the widely used uniform prior, and their corresponding posterior distributions, are investigated in Section 3.5.

To test the robustness of the method and also to compare it with the statistical methods used in previous studies, three cases are investigated in which we use different combinations of the available model ensembles. The results are shown in Fig. 2 and Table 2.

For the PMIP2 ensemble, the correlation between tropical temperature and climate sensitivity was found to be reasonably strong and in this study the resulting 90% range for inferred climate sensitivity is 1.0–4.5 K (Fig. 2–(b)). The range is slightly better constrained at the lower end than the 0.5–4 K from Hargreaves et al. (2012), however we have used the revised value for the LGM tropical anomaly of  $-2.2 \pm 0.7$  K rather than the value of  $-1.8 \pm 0.7$  K that was used by Hargreaves et al. (2012).

When all the models of PMIP2 and PMIP3 (see Table 1) were considered jointly the correlation became weaker and the corresponding 5–95% range generated by the BLR method is 0.7–4.8 K (Fig. 2–(d)). Schmidt et al. (2014) obtained 1.6–4.5 K using a similar ensemble although in that case multiple results obtained from the same modelling centre were combined by

averaging. Using the OLS method on our ensemble we obtain 1.8–4.3 K. The BLR method generates a wider range here, as the correlation is weaker and the prior starts to influence the posterior.

290 Finally, we consider the PMIP3 models in isolation. For this ensemble no correlation is found so for the BLR method the result is heavily dependent on our prior assumptions. We obtain a 5–95% range here of 0.7–5.5 K (Fig. 2–(f)). Applying the OLS method on the PMIP3 dataset gives a 5–95% range of 2.2–4.7 K. As previously argued for the combination of PMIP2 and PMIP3, the OLS produces a tighter posterior range. It is also close to the range of the initial ensemble because of the lack of correlation for this dataset.

295 The Kalman filtering approach presented by Bowman et al. (2018) has not previously been used for emergent constraint analyses in paleoclimate research. Thus, we also use this method to explore both PMIP2 and the combination of PMIP2 and PMIP3 (Fig. 3). With the same geological reconstruction value, and a prior 5–95% range (based on the PMIP2 GCM ensemble) of 1.8–4.6 K, a posterior range of 1.3–4.6 K is inferred. By combining the PMIP2 and PMIP3 models, the prior 5–95% range becomes 2.0–4.5 K and the posterior range is 1.6–4.5 K. The increase in lower bound in these calculations is the largest change compared to our Bayesian linear regression method. However, this is strongly forced by the underlying assumptions of a Kalman filter (Section 2.3) which uses the model ensemble as a prior, making it difficult to compute a posterior range outside  
300 of the model range, in particular when the observed value is considered as excessively uncertain.

### 3.2 The mid-Pliocene Warm Period

As for the LGM, priors parameters have to be defined to perform the BLR with the mPWP data. In principle these may be different to those used for the LGM experiment but in practice we have adopted the same priors for our base case, apart from  
305 the obvious sign change for  $\alpha$ . Regarding the slope term  $\alpha$ , the total positive forcing of the mPWP is not as large as the negative forcing of the LGM. Therefore, it seems reasonable to expect a roughly similar slope in the regression. We performed the same sensitivity experiments as for the LGM, with three different priors over alpha:  $N(1, 1)$ ,  $N(0.5, 1)$ ,  $N(2, 1)$ . There was only a small difference between the results using the three priors: the differences at the 5th percentile being less than 0.1 K and the differences at the 95th percentile being approximately 0.3 K (see Table 2). Regarding  $\beta$  and  $\sigma$ , there is no physical reason  
310 for them to be substantially different than the ones chosen for the LGM. Indeed, although the mPWP is a warm climate, it should also be expected that there is little temperature change to other forcing if the climate sensitivity is null. Thus, a  $N(0, 1)$  prior for  $\beta$  is selected and the same prior for  $\sigma$  as for the LGM analysis is chosen.

The Bayesian inference method applied above for the LGM model outputs is now applied on the mPWP model outputs (Fig. 4). With less abundant models and less well-constrained temperature data, we prefer to assume large uncertainties in the  
315 mPWP SST reconstruction ( $0.8 \pm 1.6$  K, 5–95% confidence). We adopt the Cauchy prior on climate sensitivity as for the LGM analysis (5–95% interval of 0.5–28.7 K) and compute a 5–95% interval for the ECS of 0.5–5.0 K for the PlioMIP1 dataset. Similar to the results for the LGM, the OLS method (Hargreaves and Annan, 2016) resulted in a slightly narrower 5–95% range than the BLR method (1.3–4.2 K, assuming 1.6 K of uncertainty on the data).

### 3.3 Inclusion of CMIP6 / PMIP4 data

320 The ongoing PMIP4 experiments have produced LGM and mPWP (PlioMIP2) simulations. Here we add those results to our ensembles. There are two model runs available for the LGM and three for the mPWP (see Table 2).

For the LGM we have previously combined the PMIP2 and PMIP3 results, and the protocol for PMIP4 is not very different. If we combine all three ensembles we obtain a 5–95% range for the ECS of 0.8–4.7 K using the BLR method (Fig. 5–(b)). The ensemble size is now 16, but we note that this includes several models coming from the same modelling centres.  
325 Past studies have investigated the proximity of models with hierarchical trees (Masson and Knutti, 2011; Knutti et al., 2013) and the influence of their dependency on statistical methods (Annan and Hargreaves, 2017). Thus, although we believe such dependencies exist in the ensemble, it is in reality difficult to quantify and correct for this. How to deal with this possible duplication of information is therefore a subjective decision. In Schmidt et al. (2014) it was taken into account by averaging the results from models from the same modelling centre. Here we take an alternative approach of including only the latest version  
330 of each model. This gives an ensemble size of 9 models (Fig. 6–(a)) and a rather well-constrained 5–95% climate sensitivity range of 1.1–4.3 K with the BLR method (Fig. 6–(b)).

For PlioMIP and PlioMIP2 the situation is a little more complex as the protocol has been redesigned to represent a specific interglacial state rather than a generic warm climate, referred to as a "time slab" in the PlioMIP protocol. Thus there could be a different regression relationship for these two ensembles. However, when we plot the PlioMIP1 ensemble members (Fig. 5–(d))  
335 we see that they do not look different to the PlioMIP2 ensemble members. The straight combination of PlioMIP1 and PlioMIP2 gives an ensemble range of 12 models and we computed a 5–95% range of 0.4–5.0 K (Fig. 5–(d)). Including only the most recent versions of models results in an ensemble size of 9 models (Fig. 6–(c)) and generates a merely identical 5–95% climate sensitivity range of 0.4–5.1 K with the mPWP simulation (Fig. 6–(d)).

### 3.4 Combining multiple constraints

340 As described in section 2.4, the mPWP and the LGM are very different climates. If the observational data are generated by unrelated analyses, we may be able to consider the two lines of evidence to be independent, and combine them using Bayes theorem to create a new posterior which is likely to be narrower than that arising from either analysis alone. Assuming that the uncertainties arising from the mPWP and the LGM analyses are independent of each other may be plausible as the proxy reconstructions use different observations and analyses to estimate both the tropical temperatures and the other variables that  
345 act as boundary conditions for the model experiments. Moreover, modelling uncertainties that influence the regression analysis are expected to arise from rather different sources, such as the response to ice sheets and a cold climate in one case, versus the influence of a warmer climate in the other. Having said that, model biases influencing the simulation of one climate change may also influence the other, which means that if similar models occur in both ensembles, this could lead to dependencies. Using Bayes theorem to combine the constraints means that it is not necessary for the same set of models to be used for each  
350 ensemble but, as we can see from Table 1, a few models do occur in both ensembles.

It is straightforward to first compute the posterior estimate of  $S$  from the LGM analysis as previously described, and then use this as a prior for the mPWP analysis. Priors over the regression coefficients are considered independent between the two analyses. Because of the issues discussed above, we perform an analysis using both ensembles of latest model versions in the LGM and the mPWP as described in section 3.3. The posterior of the LGM is used as the prior for the mPWP analysis and the resulting posterior from this process has a narrower 5–95% interval for  $S$  of 1.1–3.9 K (Fig. 7).

### 3.5 Alternative Priors on sensitivity

A major strength of the Bayesian analysis developed here is the way that the prior on the parameter of interest, here climate sensitivity, can easily be specified independently of all other aspects of the analysis. A uniform prior for  $S$  has been widely used (e.g. Tomassini et al., 2007; Aldrin et al., 2012). However, it has also been argued that such prior could give an unrealistically high probability to high climate sensitivity (Annan and Hargreaves, 2011). Here we test our method with the commonly-used uniform prior  $U[0;10]$  which has a 5–95% range of 0.5–9.5 K. The resulting posterior 5–95% range for climate sensitivity is 0.8–5.0 K when analysing the LGM PMIP2 models only, and 0.6–5.4 K with the LGM PMIP2 and PMIP3 models together. These posteriors are wider than the ranges previously computed with a Cauchy prior, particularly for the case of combining PMIP2 and PMIP3 where the correlation is rather weak, meaning that the prior has a relatively higher influence. These results are shown in Fig. 8. Due to the questions which have arisen over the use of a uniform prior and the fact that it has an infinite integral, we also perform a comparison with an alternative prior which features a decaying tail and a finite integral. For this purpose, a Gamma prior is chosen with a shape parameter of 2 and a scale of 2, which corresponds to a similar 5–95% prior range of 0.7–9.5 K. The posterior computed 5–95% range is 1.0–4.5 K for LGM PMIP2 models and 0.9–4.8 K for the combination of PMIP2 and PMIP3, which is very close to the one computed with the Cauchy prior. Although the Bayesian paradigm will inevitably involve such subjective choices, the sensitivity of the results to a sensible choice of prior appears to be low as long as a reasonable correlation exists in the ensemble.

### 3.6 Model Inadequacy

As previously explored and described by Williamson and Sansom (2019), we investigate the probability that all models deviate from reality to a certain extent, mainly because of computational limitations and their shared technical heritage. Statistically, this issue is best described by the terminology that while the models are considered ‘exchangeable’ with each other, they are not exchangeable with reality. Williamson and Sansom (2019) provide further discussion on this point. In our methodology, this can simply be accounted for by considering that the regression prediction of  $S$  for reality has a larger residual than that arising for the models themselves:

$$T_{\text{tropical}}^t = \alpha \times S^t + \beta + \epsilon^*, \quad (4)$$

where the superscript  $t$  indicates here that we are referring to the truth (i.e. the real climate system) and  $\epsilon^*$  has the distribution  $N(0, \sigma^*)$  for some  $\sigma^* > \sigma$ . There can be various reasons why such an inadequacy, represented as  $\epsilon^*$  in Eq. 4, may be thought to exist. Models all share a common heritage and theoretical basis, which is certainly incomplete even if not substantially

wrong, and computational constraints limit their performance. Particularly in the paleoclimate context, there may be biases in the experimental protocol and differences in number of feedbacks included in the different model systems, e.g. interactive  
385 vegetation and prognostic dust. Such errors would lead to reality being some distance from the model regression line, even if the models were otherwise perfect. Such issues are pertinent to both the LGM, where there are significant uncertainties relating to dust and vegetation effects, and the mPWP where even the GHG forcing is somewhat uncertain, and furthermore where the older simulations are designed as a general representation of interglacial warm periods rather than a specific quasi-equilibrium climate state.

390 However, while we may anticipate reality deviating further from the regression line, it is difficult to quantify such deviation. Here, we perform two sensitivity tests where we define  $\sigma^* = 2\sigma$ , that is to say the distribution for the residual term  $\epsilon^*$  is defined as  $N(0,2\sigma)$  for our predictions. We consider that this corresponds to a rather large inadequacy term. To compare with our previous analysis, we investigate the effect of the model inadequacy using the data set of PMIP2 and PMIP3 combined for the case of the LGM, and the data set of PlioMIP1 for the case of the mPWP, and present them in Fig. 9. For the LGM, the  
395 5–95% posterior range computed after doubling  $\sigma$  is 0.5–5.8 K (Fig. 9–(b)), while the 5–95% posterior range for the mPWP is 0.5–5.4 K (Fig. 9–(d)). When we consider the ‘latest model version’ approach outlined in Section 3.3 and take the same approach of doubling the estimated residual, the 5–95% posterior ranges increase to 0.7–5.1 K for the LGM and a 5–95% posterior range of 0.4–5.7 K for the mPWP. Thus these sensitivity tests typically add around half a degree to the upper bound obtained, while having much less influence on the lower bounds in these examples.

#### 400 4 Conclusions

Past climates are relevant sources of information on the properties of the climate system, specifically the equilibrium climate sensitivity, due to the quasi-equilibrium changes in response to external forcing, which are of similar magnitude to the projected future climate changes. In this study, we have described a new statistical method based on Bayesian inference to approach the question of emergent constraints. We believe this method provides a reasonable representation within the Bayesian paradigm  
405 of the underlying structure of emergent constraint principles. This Bayesian method is designed to be as explicit and flexible as possible. Previous work using Ordinary Least Squares usually applied implicit assumptions. Because of these assumptions, OLS tends to generate tight posterior ranges, particularly on the lower end and when the correlation is rather weak.

By applying the method to the LGM tropical temperature model ensemble used in Schmidt et al. (2014), which included 14 models from the PMIP2 and PMIP3 generations, we estimate the climate sensitivity to be 2.6 K (0.7–4.8, 5–95 percentiles).  
410 Similarly, applying the method to the mPWP tropical temperature data set of Hargreaves and Annan (2016) gives a climate sensitivity of 2.4 K (0.5–5.0), but with the more uncertain ensemble of models which contributed to PlioMIP1.

With the new generation of climate models, the LGM and mPWP analyses have been widened by the addition of several CMIP6 model outputs. By adding the PMIP4 LGM simulations, we computed a 5–95% interval for climate sensitivity of 0.8–4.7 K. We performed the same analysis by combining PlioMIP1 and PlioMIP2 models and obtained a 5–95% interval of

415 0.4–5.0 K. However, these results come with some caveats attached. In particular, combining the two model generations of the mPWP could lead to biased results, since the experimental protocol substantially changed in PlioMIP2.

An alternative approach is to consider solely the latest version of each model. By doing this we reduce expected redundancy in the ensemble, and so improve our confidence in the result, despite the smaller ensemble sizes. This leads to a more tightly-constrained climate sensitivity of 2.7 (1.1–4.3) for the LGM simulations, and a less well-constrained sensitivity 2.4 (0.4–5.1)  
420 for the mPWP simulations. Our experiment considering a substantial model inadequacy term resulted in an increase of up to a degree in the upper bounds presented here, though this aspect is as yet poorly understood and quantified.

Our results obtained by analysing the LGM or the mPWP in isolation are consistent with results obtained by other statistical methods used in previous studies. The differences between the way the information is obtained from the paleo record for the mPWP and the LGM and the different dominant climate features of the intervals suggest it may be reasonable to consider  
425 these estimates to be statistically independent, given climate sensitivity. It is then possible to combine them within the same Bayesian framework to compute a narrower range of climate sensitivity. By doing so, we evaluated the climate sensitivity to be 2.6 K (1.1–3.9). Nevertheless, this approach requires independence between the different combined emergent constraints.

It is, in principle, straightforward to include other independent emergent constraints into our Bayesian framework. As well as evidence from historical or present day analyses, other past climates are starting to be explored by modellers and may be  
430 potential candidates for future analyses, such as the Eocene, the Miocene and the last deglaciation. Over the next couple of years we expect new outputs for models from CMIP6 and new data analyses to become available, which will enable these preliminary analyses to be compared with results from expanded LGM and mPWP ensembles and improved data estimates.

*Code and data availability.* The Python codes used for the different statistical methods are available from the Bolin Centre Code Repository at <https://git.bolin.su.se/bolin/renoult-2020> (<https://doi.org/10.5281/zenodo.3611069>). The data of the PMIP2 models can be obtained by  
435 asking the corresponding modelling groups. The data of the PMIP3 and CMIP6 models can be downloaded from the ESGF Portal at CEDA, located at <https://esgf-index1.ceda.ac.uk/>. The data of the PlioMIP1 models can be downloaded from Redmine at the School of Earth and Environment of the University of Leeds, located at <https://www.see.leeds.ac.uk/redmine/public/>. For username and password, email Alan Haywood ([a.m.Haywood@leeds.ac.uk](mailto:a.m.Haywood@leeds.ac.uk)). The PRISM3 SST reconstruction can be downloaded from the PRISM/PlioMIP web page, located under “Experiment 1 AGCM version 1.0, Preferred Data” at [http://geology.er.usgs.gov/egpsc/prism/prism\\_1.23/prism\\_pliomip\\_data.html](http://geology.er.usgs.gov/egpsc/prism/prism_1.23/prism_pliomip_data.html),  
440 files PRISM3\_SST\_v1.1.nc and PRISM3\_modern\_SST.nc. The LGM SAT geological reconstruction can be downloaded from the Supplementary material of Annan and Hargreaves (2013), currently located at <http://www.clim-past.net/9/367/2013/cp-9-367-2013-supplement.zip>. For data of CMIP6 models which are not yet published on ESGF, please refer to the corresponding modelling groups.

*Author contributions.* The BLR method was conceived by JDA and JCH. TM put the project together. The code for the Bayesian framework and for the OLS was written by MR. The code for the Kalman Filter was written by JDA. The statistical analysis were performed by MR. The  
445 climate sensitivities of the CMIP6 models were computed by CF. The manuscript was written by MR, JDA, JCH, NS and TM. RO provided the LGM outputs of MIROC-ES2L. UM and MLK provided the LGM outputs of MPI-ESM1.2-LR.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* We are very grateful for the extensive work of the scientists involved in the different PMIPs and their efforts to publish and share their data with us. We acknowledge the Bolin Centre for Climate Research at Stockholm University for giving us access to  
450 the code repository which allows to freely share our codes. We acknowledge the STFC Centre for Environmental Data Analysis (CEDA)  
in collaboration with the InfraStructure for the European Network for Earth System Modelling (IS-ENES) and the Natural Environment  
Research Council via the National Centre for Atmospheric Science (NCAS) for making available on the ESGF portal the CMIP5 and CMIP6  
dataset. We acknowledge Alan Haywood and Richard Rigby for giving us access to the PlioMIP1 dataset. We acknowledge the Statistical  
Research Group at the Department of Mathematics at Stockholm University and its director Jan-Olov Persson for his useful comments.

**Figure 1.** Latitudinal distribution of temperature changes relative to pre-industrial for both simulated climates for various climate models and a proxy reconstruction. Dashed lines are models of the CMIP5 generation, while thick lines are models from the CMIP6 generation. All model distributions correspond to 100-year zonal averages when possible; certain CMIP5 PlioMIP1 models were averaged over 30 years. (a), SAT change of the LGM. The thick black line is a wide ensemble proxy reconstruction taken from Annan and Hargreaves (2013). (b), SST change of the mPWP. The thick black line is the wide ensemble proxy reconstruction PRISM3 described by Dowsett et al. (2009).

**Table 1.** Models, tropical temperature ( $T_{\text{tropical}}$ ) outputs and Climate Sensitivity ( $S$ ) used in this study

\*For the LGM simulations (generations PMIP2, PMIP3 and PMIP4), the tropical average was defined between 20° S and 30° N, where the correlation was computed as the highest with climate sensitivity (Hargreaves et al., 2012). For the mPWP simulations (generations PlioMIP1 and PlioMIP2), the tropical average was defined between 30° S and 30° N (Hargreaves and Annan, 2016). All temperature values are defined as changes compared to pre-industrial.

\*\*Latest version of a model that was kept for the approach described in Section 3.3.

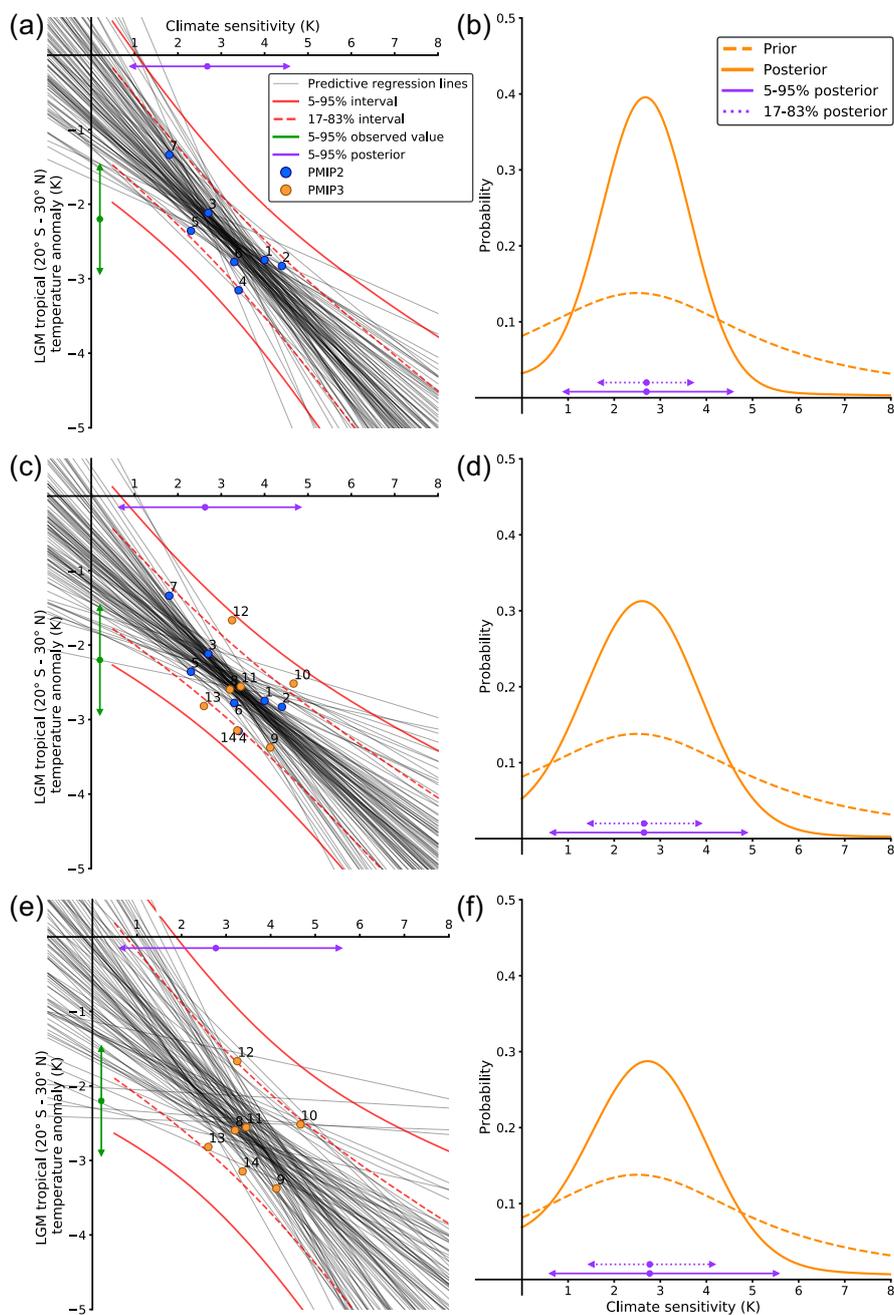

<sup>1</sup>Calculated using the Gregory method on 150 years of output making it consistent with the values of Andrews et al. (2012).

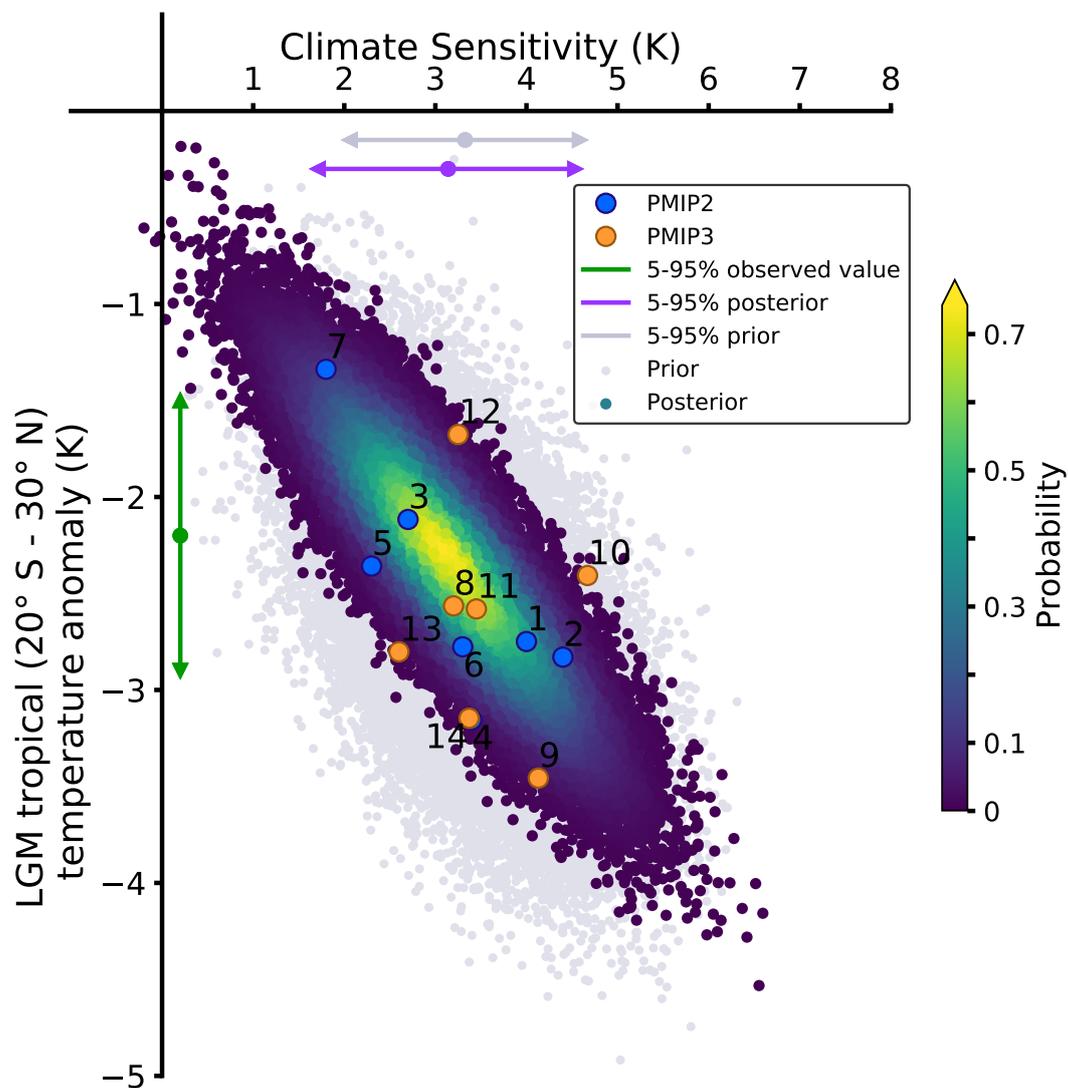

**Table 2.** Summary of the methods and computed posterior sensitivities.

Experiment	Method*	5–95% prior (K)	5–95% $T_{\text{tropical}}^o$ (K)	Median (K)	5–95% posterior (K)
LGM PMIP2	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.7	1.0–4.5
LGM PMIP2	BLR Gamma prior	0.7–9.5	-2.9 – -1.5	2.6	1.0–4.5
LGM PMIP2	BLR Uniform prior	0.5–9.5	-2.9 – -1.5	2.7	0.8–5.0
LGM PMIP2	OLS predicted CS	n/a	-2.9 – -1.5	2.8	1.5–4.1
LGM PMIP2	Kalman filter	1.8–4.6	-2.9 – -1.5	2.9	1.3–4.6
LGM PMIP2	BLR $\alpha$ prior mean=-2	0.5–28.7	-2.9 – -1.5	2.7	1.0–4.4
LGM PMIP2	BLR $\alpha$ prior mean=-0.5	0.5–28.7	-2.9 – -1.5	2.7	0.9–4.6
LGM PMIP2+PMIP3	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.6	0.7–4.8
LGM PMIP2+PMIP3	BLR Gamma prior	0.7–9.5	-2.9 – -1.5	2.6	0.9–4.8
LGM PMIP2+PMIP3	BLR Uniform prior	0.5–9.5	-2.9 – -1.5	2.7	0.6–5.4
LGM PMIP2+PMIP3	OLS predicted CS	n/a	-2.9 – -1.5	3.0	1.8–4.3
LGM PMIP2+PMIP3	Kalman filter	2.0–4.5	-2.9 – -1.5	3.1	1.6–4.5
LGM PMIP2+PMIP3	BLR $\alpha$ prior mean=-2	0.5–28.7	-2.9 – -1.5	2.6	0.8–4.7
LGM PMIP2+PMIP3	BLR $\alpha$ prior mean=-0.5	0.5–28.7	-2.9 – -1.5	2.6	0.7–4.8
LGM PMIP2+PMIP3	BLR Model inadequacy	0.5–28.7	-2.9 – -1.5	2.8	0.5–5.8
LGM PMIP3	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.8	0.7–5.5
LGM PMIP3	OLS predicted CS	n/a	-2.9 – -1.5	3.4	2.2–4.7
LGM PMIP2+PMIP3+PMIP4	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.7	0.8–4.7
LGM "Latest" models	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.7	1.1–4.3
LGM "Latest" models	BLR Model inadequacy	0.5–28.7	-2.9 – -1.5	2.7	0.7–5.1
mPWP PlioMIP1	BLR Cauchy prior	0.5–28.7	-0.8 – 2.4	2.4	0.5–5.0
mPWP PlioMIP1	BLR $\alpha$ prior mean=2	0.5–28.7	-0.8 – 2.4	2.4	0.5–4.8
mPWP PlioMIP1	BLR $\alpha$ prior mean=0.5	0.5–28.7	-0.8 – 2.4	2.4	0.5–5.1
mPWP PlioMIP1	BLR Model inadequacy	0.5–28.7	-0.8 – 2.4	2.5	0.5–5.4
mPWP PlioMIP1+PlioMIP2	BLR Cauchy prior	0.5–28.7	-0.8 – 2.4	2.4	0.4–5.0
mPWP "Latest" models	BLR Cauchy prior	0.5–28.7	-0.8 – 2.4	2.4	0.4–5.1
mPWP "Latest" models	BLR Model inadequacy	0.5–28.7	-0.8 – 2.4	2.5	0.4–5.7
mPWP and LGM, "Latest" models	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.6	1.1–3.9
mPWP and LGM, with CMIP6	BLR Cauchy prior	0.5–28.7	-2.9 – -1.5	2.5	0.8–4.1

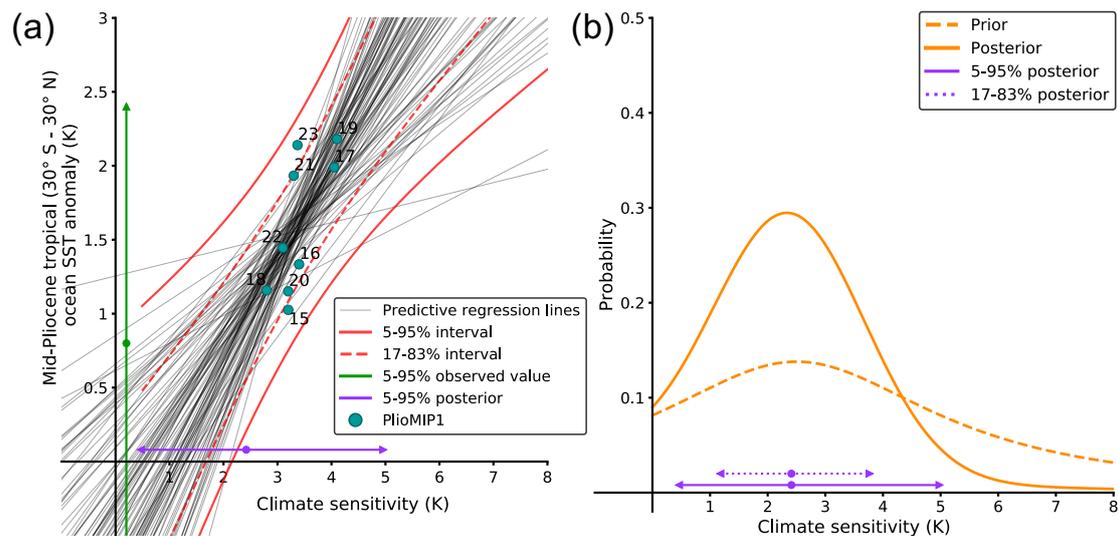

\*BLR: Bayesian Linear Regression. OLS: Ordinary Least Squares. Truncated-at-zero Cauchy prior: peak=2.5, scale=3. Gamma prior: peak=2, scale=2. Uniform prior: bounded 0–10. The "Latest" models ensembles are those created from the most recent versions of each model (see Section 3.3).

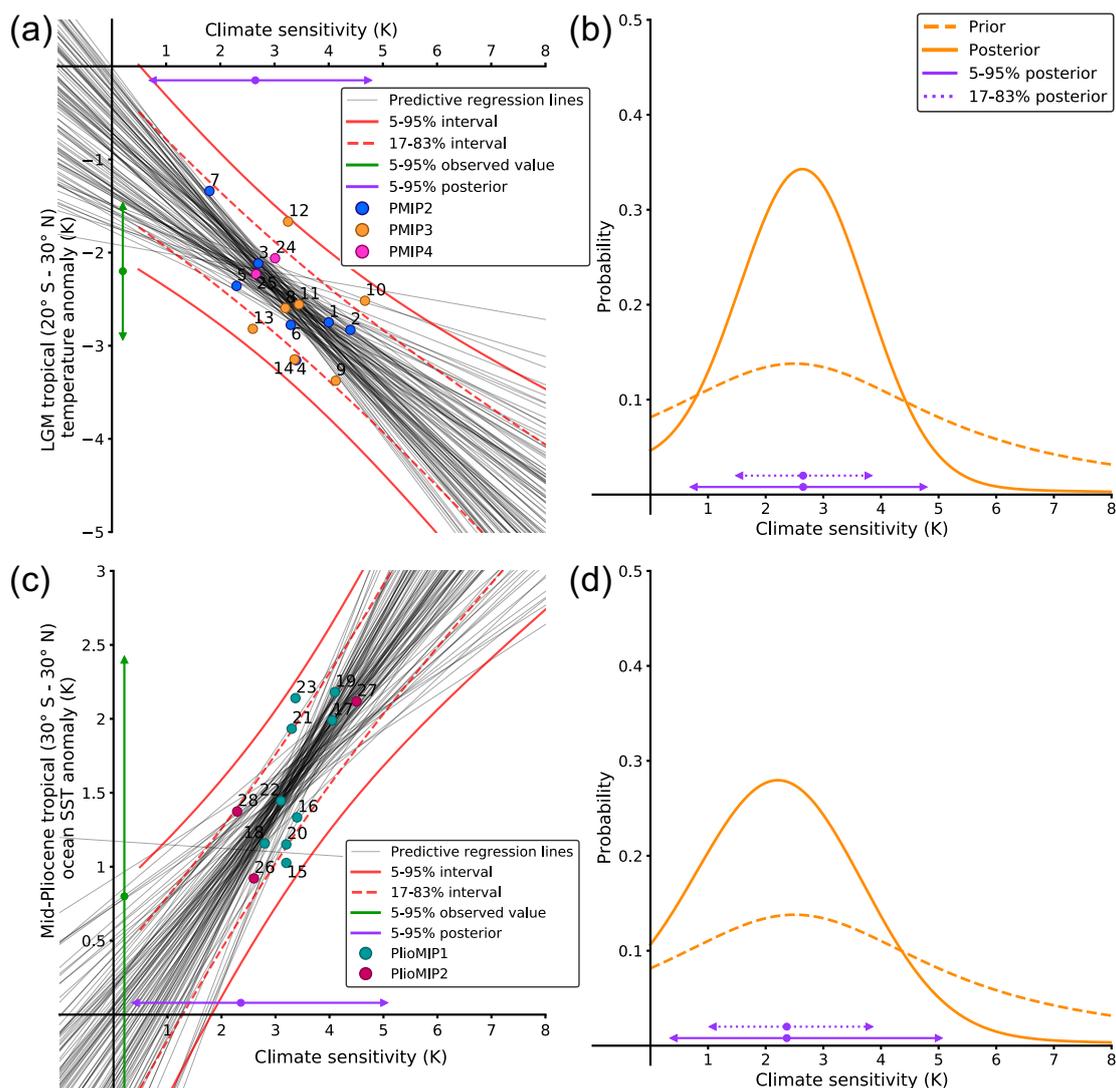

**Figure 2.** LGM northern tropical (20° S–30° N) temperature versus climate sensitivity for the PMIP2 and PMIP3 models. On the left, predictive regression lines sampled with the MCMC method. On the right, corresponding posterior climate sensitivity computed with a Cauchy prior and inferred from a geological reconstruction taken from Hargreaves et al. (2012). (a) and (b), analysis done on the PMIP2 dataset; (c) and (d), analysis done on the PMIP2 and PMIP3 combined dataset; (e) and (f), analysis done on the PMIP3 dataset. The numbers on each point refer to the models used as listed in Table 1.

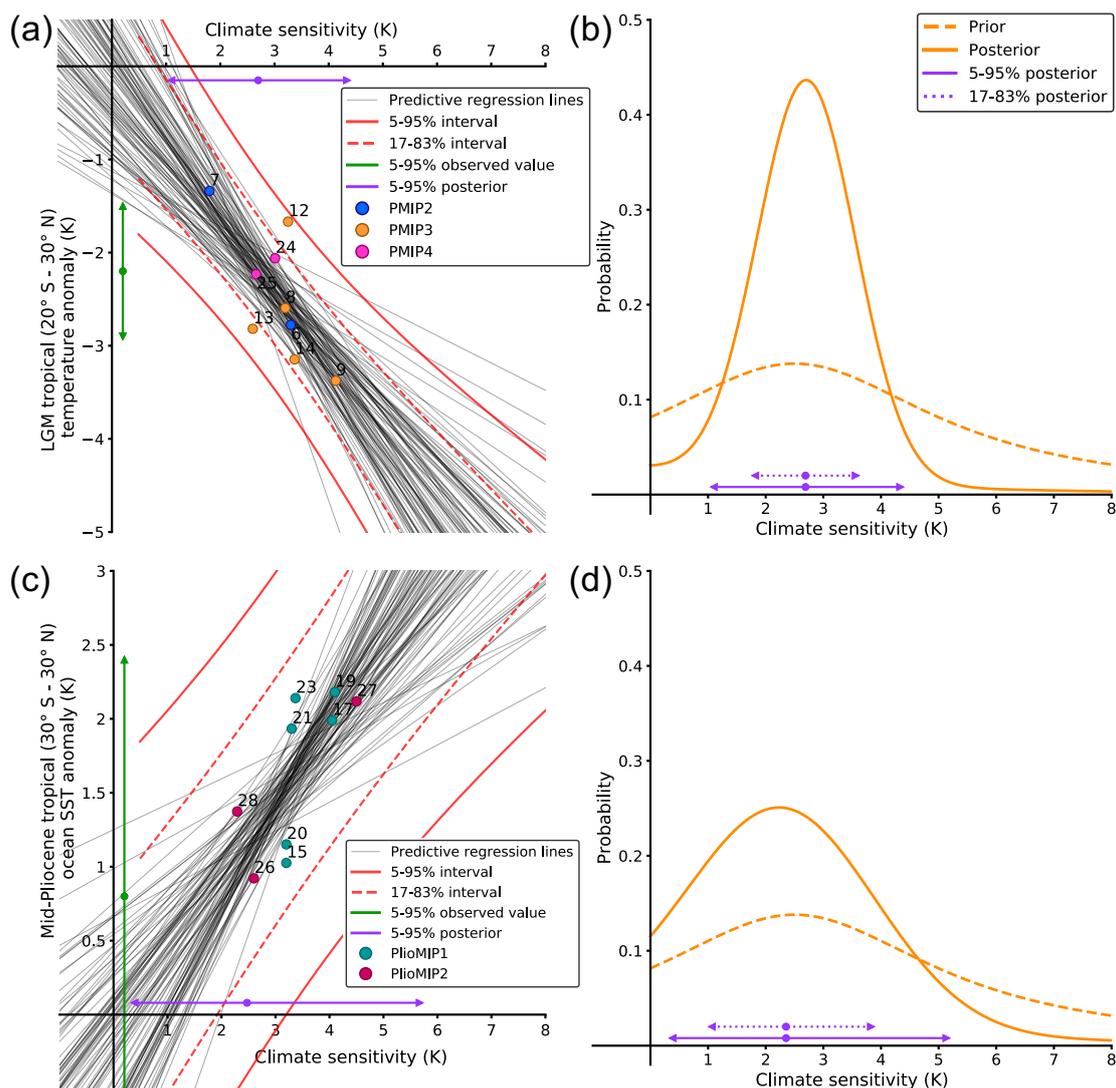

**Figure 3.** LGM northern tropical (20° S–30° N) temperature versus climate sensitivity of the PMIP2 and PMIP3 models. The Kalman filtering is applied on the ensemble of both PMIP2 and PMIP3.

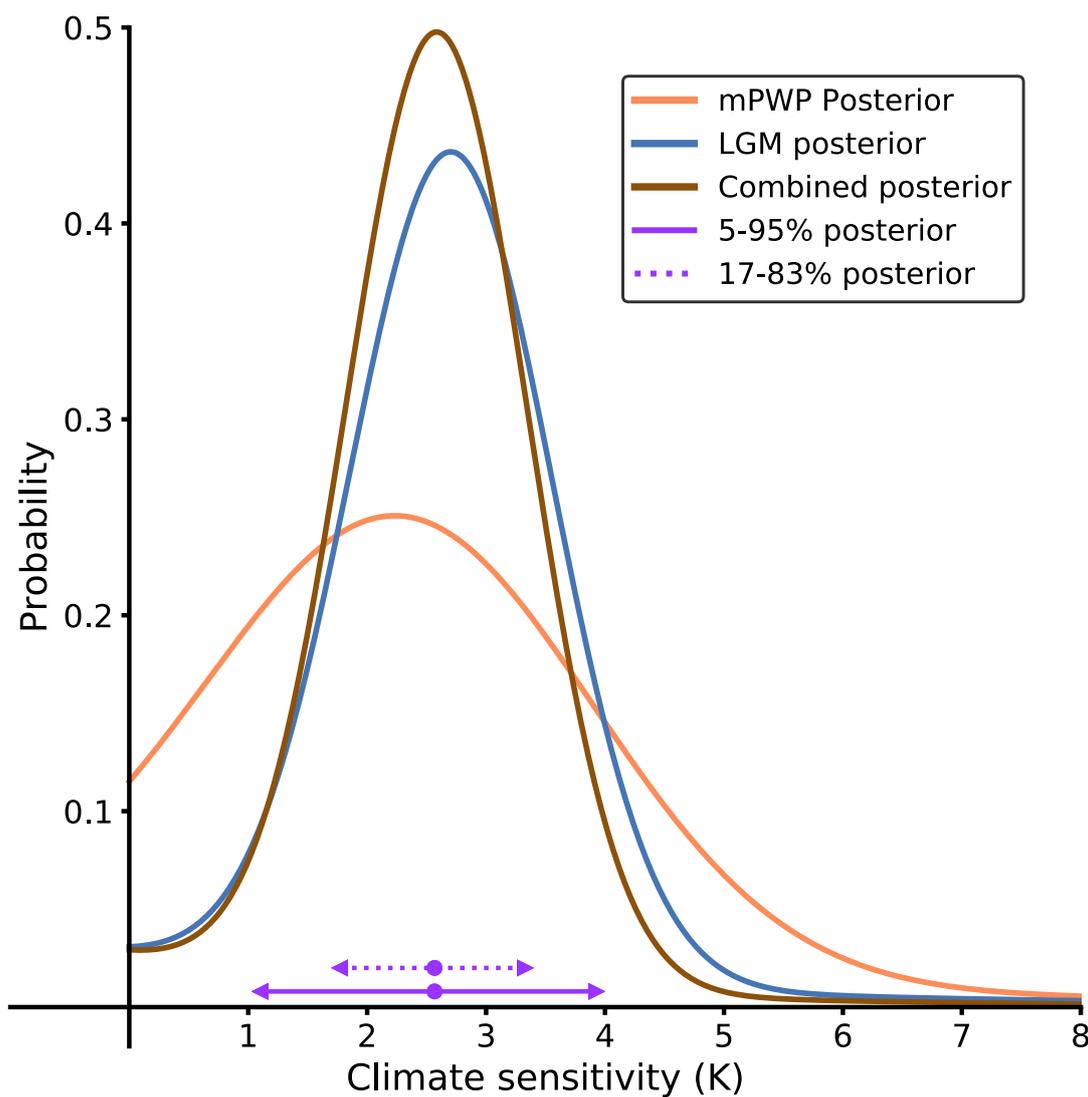

**Figure 4.** mPWP tropical (30° S–30° N) temperature versus climate sensitivity of the PlioMIP1 models. (a), predictive regression lines sampled with a MCMC method. (b), corresponding posterior climate sensitivity computed with a Cauchy prior and inferred from a geological reconstruction taken from Dowsett et al. (2009). The numbers on each point refer to the models used as listed in Table 1.

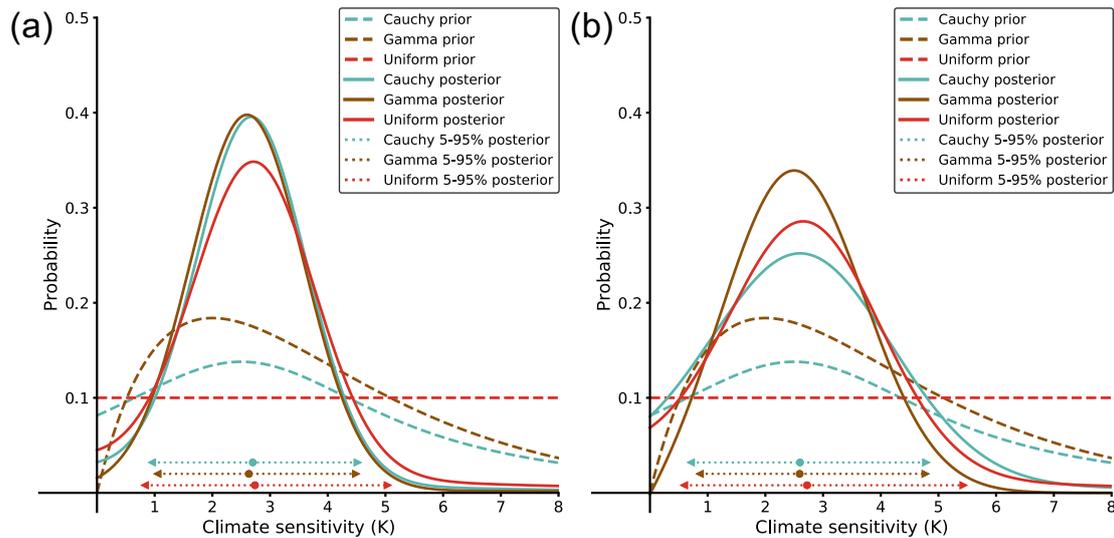

**Figure 5.** Inclusion of the CMIP6 models into the Bayesian method for the LGM and the mPWP. (a), LGM northern tropical (20° S–30° N) temperature versus climate sensitivity of the PMIP2, PMIP3 and PMIP4 models and (b), inferred climate sensitivity. (c), mPWP tropical (20° S–30° N) temperature versus climate sensitivity of the PlioMIP1 and PlioMIP2 models and (d), inferred climate sensitivity. For both inferences, the prior used is a Cauchy distribution defined with a peak of 2.5 and a scale of 3.

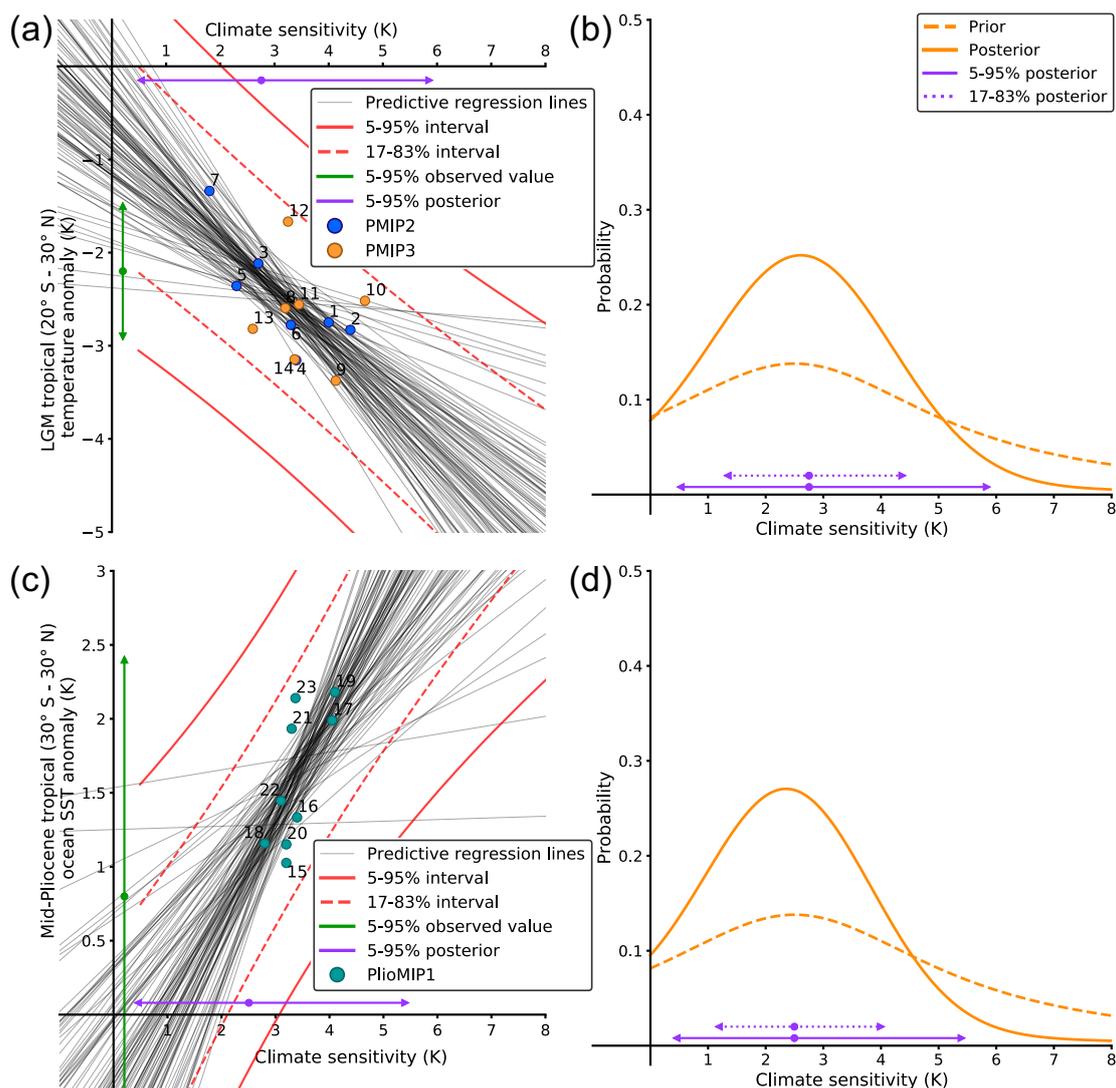

**Figure 6.** Application of the BLR method to an ensemble of the latest version of each model. (a), LGM northern tropical (20° S–30° N) temperature versus climate sensitivity of the PMIP2, PMIP3 and PMIP4 models and (b), inferred climate sensitivity. (c), mPWP tropical (20° S–30° N) temperature versus climate sensitivity of the PlioMIP1 and PlioMIP2 models and (d), inferred climate sensitivity. For both inferences, the prior used is a Cauchy distribution defined with a peak of 2.5 and a scale of 3.

**Figure 7.** Posterior distribution of climate sensitivity computed with a Cauchy prior by combining two assumed independent emergent constraints. The method does not explicitly use both posteriors of the LGM and the mPWP, but use the LGM posterior as the mPWP prior. However, the resulting combined posterior will usually be narrower than the two independent posteriors. For the LGM, the posterior is computed by using the latest model versions of PMIP, including PMIP4. For the mPWP, the posterior is computed by using the latest model versions of PlioMIP, including PlioMIP2.

**Figure 8.** Posterior distributions computed with different priors and dataset. (a), posteriors computed with the PMIP2 dataset (strong correlation). (b), posteriors computed with the PMIP2 and PMIP3 dataset combined (weak correlation). The Cauchy prior is defined with a peak of 2.5 and a scale of 3; The Gamma prior is defined with a peak of 2 and a scale of 2; The Uniform prior is bounded between 0 and 10.

**Figure 9.** Doubling the value of  $\sigma$  as defined by  $\sigma^*$  to investigate model inadequacy. (a), LGM northern tropical (20° S–30° N) temperature versus climate sensitivity of the PMIP2 and PMIP3 models and (b), inferred climate sensitivity. (c), mPWP tropical (20° S–30° N) temperature versus climate sensitivity of the PlioMIP1 models and (d), inferred climate sensitivity. For both inferences, the prior used is a Cauchy distribution defined with a peak of 2.5 and a scale of 3.
