12 ABSTRACT

13 During past geological times, the Earth experienced several intervals of global warmth, but their driving
14 factors remain equivocal. A careful appraisal of the main processes controlling past warm events is essential to
15 inform future climates and ultimately provide decision makers with a clear understanding of the processes at
16 play in a warmer world. In this context, intervals of greenhouse climates, such as the thermal maximum of the
17 Cenomanian-Turonian (~94 Ma) during the Cretaceous period, are of particular interest. Here we use the IPSL-
18 CM5A2 Earth System Model to unravel the forcing parameters of the Cenomanian-Turonian greenhouse climate.
19 We perform six simulations with an incremental change in five major boundary conditions in order to isolate
20 their respective role on climate change between the Cenomanian-Turonian and the preindustrial. Starting with a
21 preindustrial simulation, we implement the following changes in boundary conditions: (1) the absence of polar
22 ice sheets, (2) the increase in atmospheric $p\text{CO}_2$ to 1120 ppm, (3) the change of vegetation and soil parameters,
23 (4) the 1% decrease in the Cenomanian-Turonian value of the solar constant and (5) the Cenomanian-Turonian
24 paleogeography. Between the preindustrial simulation and the Cretaceous simulation, the model simulates a
25 global warming of more than 11°C. Most of this warming is driven by the increase in atmospheric $p\text{CO}_2$ to 1120
26 ppm. Paleogeographic changes represent the second major contributor to global warming, whereas the
27 reduction in the solar constant counteracts most of geographically-driven warming. We further demonstrate that
28 the implementation of Cenomanian-Turonian boundary conditions flattens meridional temperature gradients
29 compared to the preindustrial simulation. Interestingly, we show that paleogeography is the major driver of the
30 flattening in the low- to mid-latitudes, whereas $p\text{CO}_2$ rise and polar ice sheet retreat dominate the high-latitude
31 response.

32 1. INTRODUCTION

33 The Cretaceous period is of particular interest to understand drivers of past greenhouse climates
34 because intervals of prolonged global warmth (O'Brien et al. 2017, Huber et al. 2018) and elevated atmospheric
35 CO₂ levels (Wang et al., 2014), possibly similar to future levels, have been documented in the proxy record. The
36 thermal maximum of the Cenomanian-Turonian (CT) interval (94 Ma) represents the acme of Cretaceous
37 warmth, during which one of the most important carbon cycle perturbations of the Phanerozoic occurred: the
38 oceanic anoxic event 2 (OAE2; Jenkyns, 2010; Huber et al., 2018). Valuable understanding of what controls large-
39 scale climate processes can hence be drawn from investigations of the mechanisms responsible for the CT
40 thermal maximum and carbon cycle perturbation.

41 Proxy-based reconstructions and model simulations of sea-surface temperatures (SST) for the CT reveal
42 that during OAE2 the equatorial Atlantic was 4-6° warmer than today (Norris et al., 2002; Bice et al., 2006; Pucéat
43 et al., 2007; Tabor et al., 2016), and possibly even warmer than that (6-9° - Forster et al., 2007). This short and
44 abrupt episode of major climatic, oceanographic, and global carbon cycle perturbations occurred at the CT
45 Boundary and was superimposed on a long period of global warmth (Jenkyns, 2010). The high latitudes were also
46 much warmer than today (Herman and Spicer, 2010; Spicer and Herman, 2010), as was the abyssal ocean which
47 experienced bottom temperatures reaching up to 20°C during the CT (Huber et al., 2002; Littler et al., 2011;
48 Friedrich et al., 2012). Paleobotanical studies suggest that the atmosphere was also much warmer (Herman and
49 Spicer, 1996), with high-latitude temperatures up to 17°C higher than today (Herman and Spicer, 2010) and
50 possibly reaching annual means of 10-12°C in Antarctica (Huber et al., 1999).

51 The steepness of the equator-to-pole gradient is still a matter of debate, in particular because of
52 inconsistencies between data and models as the latter usually predict steeper gradients than those
53 reconstructed from proxy data (Barron, 1993; Huber et al., 1995; Heinemann et al., 2009; Tabor et al., 2016).
54 Models and data generally agree, however, that Cretaceous sea-surface temperature (SST) gradients were
55 reduced compared to today (Sellwood et al., 1994; Huber et al., 1995; Jenkyns et al., 2004; O'Brien et al., 2017;
56 Robinson et al., 2019).

57 The main factor generally considered responsible for the Cretaceous global warm climate is the higher
58 atmospheric CO₂ concentration (Barron et al., 1995; Crowley and Berner, 2001; Royer et al., 2007; Wang et al.,
59 2014; Foster et al., 2017). This has been determined by proxy-data reconstructions of the Cretaceous *p*CO₂ using
60 various techniques, including analysis of paleosols δ¹³C (Sandler and Harlavan, 2006; Leier et al., 2009; Hong and

61 Lee, 2012), liverworts $\delta^{13}\text{C}$ (Fletcher et al., 2006) or phytane $\delta^{13}\text{C}$ (Damsté et al., 2008; Van Bentum et al., 2012)
62 and leaf stomata analysis (Barclay et al., 2010; Mays et al., 2015; Retallack and Conde, 2020). Modelling studies
63 have also focused on estimating Cretaceous atmospheric CO_2 levels (Barron et al., 1995; Poulsen et al., 2001,
64 2007; Berner, 2006; Bice et al., 2006; Monteiro et al., 2012) in an attempt to refine the large spread in values
65 inferred from proxy data (from less than 900 ppm to over 5000 ppm). The typical atmospheric $p\text{CO}_2$
66 concentration resulting from these studies for the CT averages around a long-term value of 1120 ppm (Barron et
67 al., 1995; Bice and Norris, 2003; Royer, 2013; Wang et al., 2014), e.g., four times the preindustrial value (280 ppm
68 = 1 P.A.L : "Preindustrial Atmospheric Level"). Atmospheric $p\text{CO}_2$ levels are, however, known to vary on shorter
69 timescales during the period, in particular during OAE2. It has indeed been suggested that this event may have
70 been caused by a large increase in atmospheric $p\text{CO}_2$ concentration, possibly reaching 2000 ppm or even higher,
71 because of volcanic activity in large igneous provinces (Kerr and Kerr, 1998; Turgeon and Creaser, 2008; Jenkyns,
72 2010). The proxy records suggest that the $p\text{CO}_2$ levels may have dropped down to 900 ppm after carbon
73 sequestration into organic-rich marine sediments (Van Bentum et al., 2012).

74 Paleogeography is also considered as a major driver of climate change through geological times (Crowley
75 et al., 1986; Gyllenhaal et al., 1991; Goddérís et al., 2014; Lunt et al., 2016). Several processes linked to
76 paleogeographic changes have been shown to impact Cretaceous climates. These processes include albedo and
77 evapotranspiration feedbacks from paleovegetation (Otto-bliesner and Upchurch, 1997), seasonality due to
78 continental break-up or presence of epicontinental seas (Fluteau et al., 2007), atmospheric feedbacks due to
79 water cycle modification (Donnadieu et al., 2006), Walker and Hadley cells changes after Gondwana break-up
80 (Ohba and Ueda, 2011), or oceanic circulation changes due to gateways opening (Poulsen et al., 2001, 2003).
81 Other potential controlling factors include the time-varying solar constant (Gough, 1981), whose impact on
82 Cretaceous climate evolution was quantified by Lunt et al. (2016), and changes in the distribution of vegetation,
83 which has been suggested to drive warming, especially in the high-latitudes with a temperature increase of up to
84 4°-10°C in polar regions (Otto-bliesner and Upchurch, 1997; Brady et al., 1998; Upchurch, 1998; Deconto et al.,
85 2000; Hunter et al., 2013).

86 Despite all these studies, there is no established consensus on the relative importance of each of the
87 controlling factors on the CT climate. In particular, the primary driver of the Cretaceous climate has been
88 suggested to be either $p\text{CO}_2$ or paleogeography. Early studies suggested a negligible role of paleogeography on
89 global climate compared to the high CO_2 concentration (Barron et al., 1995) whereas others suggested that CO_2

90 was not the primary control (Veizer et al., 2000) or that the impact of paleogeography on climate was as
91 important as a doubling of $p\text{CO}_2$ (Crowley et al., 1986). More recent modeling studies have also suggested that
92 paleogeographic changes could affect global climate (Poulsen et al., 2003; Donnadieu et al., 2006; Fluteau et al.,
93 2007) but their impact remain debated (Ladant and Donnadieu, 2016; Lunt et al., 2016; Tabor et al., 2016). For
94 example, the simulations of Lunt et al. (2016) support a key role of paleogeography at the regional rather than
95 global scale, and show that the global paleogeographic signal is cancelled by an opposite trend due to changes in
96 the solar constant. Tabor et al. (2016) also suggest important regional climatic impacts of paleogeography, but
97 argue that CO_2 is the main driver of the Late Cretaceous climate evolution. In contrast, Ladant and Donnadieu
98 (2016) find a large impact of paleogeography on the global mean Late Cretaceous temperatures; their signal is
99 roughly comparable to a doubling of atmospheric $p\text{CO}_2$. Finally, the role of paleovegetation is also uncertain as
00 some studies show a major role at high-latitude (Upchurch, 1998; Hunter et al., 2013), whereas a more recent
01 study instead suggests limited impact at high latitudes ($<2^\circ\text{C}$) with a cooling effect at low latitudes under high
02 $p\text{CO}_2$ values (Zhou et al., 2012).

03 In this study, we investigate the forcing parameters of CT greenhouse climate by using a set of
04 simulations run with the IPSL-CM5A2 Earth System Model. We perform six simulations, using both preindustrial
05 and CT boundary conditions, where we incrementally modify the preindustrial boundary conditions to that of the
06 CT. The changes are as follows: (1) the removal of polar ice sheets, (2) an increase in $p\text{CO}_2$ to 1120 ppm, (3) the
07 change of vegetation and soil parameters, (4) a 1% reduction in the value of the solar constant, and (5) the
08 implementation of Cenomanian-Turonian paleogeography. We particularly focus on processes driving warming
09 or cooling of atmospheric surface temperatures after each change in boundary condition change to study the
10 relative importance of each parameter in the CT to preindustrial climate change. We also investigate how the SST
11 gradient responds to boundary condition changes to understand the evolution of its steepness between the CT
12 and the preindustrial.

13

14 2. MODEL DESCRIPTION & EXPERIMENTAL DESIGN

15 2.1 IPSL-CM5A2 MODEL

16 IPSL-CM5A2 is an updated version of the IPSL-CM5A-LR earth system model developed at IPSL (Institut
17 Pierre-Simon Laplace) within the CMIP5 framework (Dufresne et al., 2013). It is a fully-coupled Earth System
18 Model, which simulates the interactions between atmosphere, ocean, sea ice, and land surface. The model

19 includes the marine carbon and other key biogeochemical cycles (C, P, N, O, Fe and Si - See Aumont et al., 2015).
20 Its former version, IPSL-CM5A-LR, has a rich history of applications, including present-day and future climates
21 (Aumont and Bopp, 2006; Swingedouw et al., 2017) as well as preindustrial (Gastineau et al., 2013) and
22 paleoclimate studies (Kageyama et al., 2013; Contoux et al., 2015; Bopp et al., 2017; Tan et al., 2017; Sarr et al.,
23 2019). It was also part of IPCC AR5 and CMIP5 projects (Dufresne et al., 2013). IPSL-CM5A-LR has also been used
24 to explore links between marine productivity and climate (Bopp et al., 2013; Le Mézo et al., 2017; Ladant et al.,
25 2018), vegetation and climate (Contoux et al., 2013; Woillez et al., 2014), and topography and climate (Maffre et
26 al., 2018), but also the role of nutrients in the global carbon cycle (Tagliabue et al., 2010) or the variability of
27 oceanic circulation and upwelling (Ortega et al., 2015; Swingedouw et al., 2015). Building on recent technical
28 developments, IPSL-CM5A2 provides enhanced computing performances compared to IPSL-CM5A-LR, allowing
29 thousand year-long integrations required for deep-time paleoclimate applications or long-term future projections
30 (Sepulchre et al., 2019). It thus reasonably simulates modern-day and historical climates (despite some biases in
31 the tropics), whose complete description and evaluation can be found in Sepulchre et al., 2019.

32 IPSL-CM5A2 is composed of the LMDZ atmospheric model (Hourdin et al., 2013), the ORCHIDEE land
33 surface and vegetation model (including the continental hydrological cycle, vegetation, and carbon cycle; Krinner
34 et al., 2005) and the NEMO ocean model (Madec, 2012), including the LIM2 sea-ice model (Fichefet and
35 Maqueda, 1997) and the PISCES marine biogeochemistry model (Aumont et al., 2015). The OASIS coupler (Valcke
36 et al., 2006) ensures a good synchronization of the different components and the XIOS input/output parallel
37 library is used to read and write data. The LMDZ atmospheric component has a horizontal resolution of 96x95,
38 (equivalent to 3.75° in longitude and 1.875° in latitude) and 39 uneven vertical levels. ORCHIDEE shares the same
39 horizontal resolution whereas NEMO – the ocean component – has 31 uneven vertical levels (from 10 meters at
40 the surface to 500 meters at the bottom), and a horizontal resolution of approximately 2°, enhanced to up to 0.5°
41 in latitude in the tropics. NEMO uses the ORCA2.3 tripolar grid to overcome the North Pole singularity (Madec
42 and Imbard, 1996).

43 44 2.2 EXPERIMENTAL DESIGN 45

46 Six simulations were performed for this study: one preindustrial control simulation, named piControl, and
47 five simulations for which the boundary conditions were changed one at a time to progressively reconstruct the

48 CT climate (see Table 1 for details). The scenarios are called 1X-NOICE (with no polar ice sheets), 4X-NOICE (no
49 polar ice sheets + pCO₂ at 1120 ppm), 4X-NOICE-PFT-SOIL (previous changes + implementation of idealized Plant
50 Functional Types (PFTs) and mean parameters for soil), 4X-NOICE-PFT-SOIL-SOLAR (previous changes + reduction
51 of the solar constant) and 4X-CRETACEOUS (previous changes + CT paleogeography). The piControl simulation
52 has been run for 1800 years and the five others for 2000 years in order to reach near-surface equilibrium (see
53 Fig.1).

54

55 2.2.1 BOUNDARY CONDITIONS

56

57 As most evidence suggests the absence of permanent polar ice sheets during the CT (MacLeod et al.,
58 2013; Ladant and Donnadieu, 2016; Huber et al., 2018), we remove polar ice sheets in our simulations (except in
59 piControl) and we adjust topography to account for isostatic rebound resulting from the loss of the land ice
60 covering Greenland and Antarctica (See Supplementary Figure 1). Ice sheets are replaced with brown bare soil
61 and the river routing stays unchanged.

62 In the 4X simulations (i.e., all except piControl and 1X-NOICE), pCO₂ is fixed to 1120 ppm (4 P.A.L), a value
63 reasonably close to the mean suggested by a recent compilation of CT pCO₂ reconstructions (Wang et al., 2014).

64 In the 4X-NOICE-PFT-SOIL simulation, the distribution of the 13 standard PFTs defined in ORCHIDEE is
65 uniformly reassigned along latitudinal bands, based on a rough comparison with the preindustrial distribution of
66 vegetation, in order to obtain a theoretical latitudinal distribution usable for any geological period. The list of
67 PFTs and associated latitudinal distribution and fractions are described in Supplementary Table 1. Mean soil
68 parameters, i.e., mean soil color and texture (rugosity), are calculated from preindustrial maps (Zobler, 1999;
69 Wilson and Henderson-sellers, 2003) and uniformly prescribed on all continents. The impact of these idealized
70 PFTs and mean parameters is discussed in the results.

71 The 4X-NOICE-PFT-SOIL-SOLAR simulation is initialized from the same conditions as 4X-NOICE-PFT-SOIL
72 except that the solar constant is reduced to its CT value (Gough, 1981). We use here the value of 1353.36 W/m²
73 (98.9% of the modern solar luminosity, calculated for an age of 90 My).

74 The 4X-CRETACEOUS simulation, finally, incorporates the previous modifications plus the implementation
75 of the CT paleogeography. The land-sea configuration used here is that proposed by Sewall (2007), in which we
76 have implemented the bathymetry from Müller (2008) (see Fig. 2). These bathymetric changes are done to
77 represent deep oceanic topographic features, such as ridges, that are absent from the Sewall paleogeographic

78 configuration. In this simulation, the mean soil color and rugosity as well as the theoretical latitudinal PFTs
79 distribution are adapted to the new land-sea mask and the river routing is recalculated from the new topography.
80 We also modify the tidally driven mixing associated with dissipation of internal wave energy for the M2 and K1
81 tidal components from present day values (de Lavergne et al., 2019). The parameterization used for simulations
82 with the modern geography follows Simmons et al. (2004), with refinements in the modern Indonesian Through
83 Flow (ITF) region according to Koch-Larrouy et al. (2007). To create a Cenomanian-Turonian tidal dissipation
84 forcing, we calculate an M2 tidal dissipation field using the Oregon State University Tidal Inversion System
85 (OTIS, Egbert et al., 2004; Green and Huber, 2013). The M2 field is computed using our Cenomanian-Turonian
86 bathymetry and an ocean stratification taken from an unpublished equilibrated Cenomanian-Turonian simulation
87 realized with the IPSLCM5A2 with no M2 field. In the absence of any estimation for the CT, we prescribe the K1
88 tidal dissipation field to 0. In addition, the parameterization of Koch-Larrouy et al. (2007) is not used here
89 because the ITF does not exist in the Cretaceous.

02

The piControl and 1X-NOICE simulations are initialized with conditions from the Atmospheric Model Intercomparison Project (AMIP) which were constrained by realistic sea surface temperature (SST) and sea ice from 1979 to near present (Gates et al., 1999). In an attempt to reduce the integration time required to reach near-equilibrium, the initial conditions of simulations with 4 PAL are taken from warm idealized conditions (higher SST and no sea ice) adapted from those described in Lunt et al. (2017). The constant initial salinity field is set to 34.7 PSU and ocean temperatures are initialized with a depth dependent distribution (see Sepulchre et al., GMD 2020, in review). In waters deeper than 1000 m, the temperature, $T=10^{\circ}\text{C}$, whereas at depths shallower than 1000 m it follows

$$T = 10 + \left(\frac{1000 - \text{depth}}{1000} \right) * 25 \cos(\text{latitude}) \quad (1)$$

203 *Table 1 : Description of the simulations. The parameters in bold indicate the specific change for the corresponding simulation. Simulations are run for 2000 years, except piControl which is run*
 204 *for 1000 years.*

205

206 3. RESULTS

207 The simulated changes between the preindustrial (piControl) and the CT (4X-CRETACEOUS)
208 simulations can be decomposed into five components based on our boundary condition changes: (1)
209 Polar ice sheet removal (Δ_{ice}), (2) pCO_2 (ΔCO_2), (3) PFT and Soil parameters ($\Delta PFT-SOIL$), (4) Solar
210 constant (Δ_{solar}) and (5) Paleogeography (Δ_{paleo}). Each contribution to the total climate change can
211 be calculated by a linear factorization (Broccoli and Manabe, 1987; Von Deimling et al., 2006), which
212 simply corresponds to the anomaly between two consecutive simulations. The choice of applying a
213 linear factorization approach was made due to computing time and cost. We appreciate that another
214 sequence of changes could lead to different intermediate states and could modulate the intensity of
215 warming or cooling associated to each change. The computational costs would be too high for this
216 study to explore this further here; it is an interesting problem that we leave for a future investigation.
217 The results presented in the following are averages calculated over the last 100 simulated years.

219 3.1 GLOBAL CHANGES

220 The progressive change of parameters made to reconstruct the CT climate induces a general
221 global warming (Table 2, Fig. 3). The annual global atmospheric temperature at 2 meters above the
222 surface (T2M) rises from 13.25°C to 24.35 °C between the preindustrial and CT simulations. All
223 changes in boundary conditions generates a warming signal on a global scale, with the exception of
224 the decrease in solar constant which generates a cooling. Most of the warming is due to the fourfold
225 increase in atmospheric pCO_2 , which alone increases the global mean temperature by 9°C.
226 Paleogeographic changes also represent a major contributor to the warming, leading to an increase in
227 T2M of 2.6°C. In contrast, the decrease in solar constant leads to a cooling of 1.8°C at the global scale.
228 Finally, changes in the soil parameters and PFTs, as well as the retreat of polar caps, have smaller
229 impacts, leading to increases in global mean T2M of 0.8°C and 0.5°C respectively.

230 Temperature changes exhibit different geographic patterns (Fig. 4) depending on which
231 parameter is changed. These patterns range from global and uniform cooling (Δ_{solar} – Fig 4e) to a
232 global, polar-amplified, warming (ΔpCO_2 – Fig 4c), as well as heterogeneous regional responses (Δ_{ice} or
233 Δ_{paleo} – Fig 4b and 4f). In the next section, we describe the main patterns of change and the main
234 feedbacks arising.

237
238

239 3.2 The major contributor to global warming - ΔCO_2

240 As mentioned above, the fourfold increase in $p\text{CO}_2$ leads to a global warming of 9°C (Table 3,
241 Fig. 3) between the 1X-NOICE and the 4X-NOICE simulations. The whole Earth warms, with an
242 amplification located over the Arctic and Austral oceans and a warming generally larger over
243 continents than over oceans (Fig 4c). The warming is due to a general decrease of planetary albedo
244 and of the atmosphere's emissivity (see Supplementary Figure 2). The decrease in the atmosphere's
245 emissivity is directly driven by the increase in CO_2 , and thus greenhouse trapping in the atmosphere. It
246 is also amplified by an increase in high-altitude cloudiness (defined as cloudiness at atmospheric
247 pressure < 440 hPa) over the Antarctic continent (Fig 5a, b). The decrease in planetary albedo is due to
248 two major processes. First, a decrease of sea ice and snow cover (especially over Northern
249 Hemisphere continents and along the coasts of Antarctica), leading to surface albedo decrease,
250 explains the warming amplification over polar oceans and continents. Second, a decrease in low-
251 altitude cloudiness (defined as cloudiness at atmospheric pressure > 680 hPa) at all latitudes except
252 over the Arctic (Fig 5a, b) leads to an increase in absorbed solar radiation.

253 The contrast in the atmospheric response over continents and oceans is due to the impact of
254 the evapo-transpiration feedback. Oceanic warming drives an increase in evaporation, which acts as a
255 negative feedback and moderates the warming by consuming more latent heat at the ocean surface.
256 In contrast, high temperatures resulting from continental warming tend to inhibit vegetation
257 development, which acts as positive feedback and enhances the warming due to reduced
258 transpiration and reduced latent heat consumption.

259

260 3.3 Boundary conditions with the smallest global impact – Δice , $\Delta\text{PFT-SOIL}$, Δsolar

261 The removal of polar ice sheets in the 1X-NOICE simulation leads to a weak global warming of
262 0.5°C but a strong regional warming observed over areas previously covered by the Antarctic and
263 Greenland ice sheets (Fig 4a, b). This signal is due to the combination of a decrease in elevation (i.e.,
264 lapse rate feedback – Supplementary Figure S3) and in surface albedo, which is directly linked to the

265 shift from a reflective ice surface to a darker bare soil surface. Unexpected cooling is also simulated in
266 specific areas, such as the margins of the Arctic Ocean and the southwestern Pacific. These contrasted
267 climatic responses to the impact of ice sheets on sea surface temperatures are consistent with
268 previous modeling studies (Goldner et al., 2014; Knorr and Lohmann, 2014; Kennedy et al., 2015).
269 Their origin is still unclear but changes in winds in the Southern Ocean, due to topographic changes
270 after polar ice sheet removal, may locally impact oceanic currents, deep-water formation, and thus
271 oceanic heat transport and temperature distribution. In the Northern Hemisphere, the observed
272 cooling over Eurasia could be linked to stationary wave feedbacks following changes in topography
273 after Greenland ice sheet removal (Supplementary Figure S4; see also Maffre et al., 2018).

274 The change in soil parameters and the implementation of theoretical zonal PFTs in the 4X-
275 NOICE-PFT-SOIL simulation drive a warming of 0.8 °C. This warming is essentially located above arid
276 areas, such as the Sahara, Australia, or Middle East, and polar latitudes (Antarctica/Greenland) (Fig
277 4d), and is mostly caused by the implementation of a mean uniform soil color, which drives a surface
278 albedo decrease over deserts that normally have a lighter color. The warming at high-latitudes is
279 linked to vegetation change: bare soil that characterizes continental regions previously covered with
280 ice is replaced by boreal vegetation with a lower surface albedo. The presence of vegetation at such
281 high-latitudes is consistent with high-latitude paleobotanical data and temperature records during the
282 Cretaceous (Otto-bliesner and Upchurch, 1997; Herman and Spicer, 2010; Spicer and Herman, 2010).

283 Finally, the change in solar constant from 1365 W/m² to 1353 W/m² (Gough 1981) directly
284 drives a cooling of 1.8 °C evenly distributed over the planet (Fig 4e).

285

286 3.4 The most complex response - Δ paleogeography

287 The paleogeographic change drives a global warming of 2.6 °C. This is seen year-round in the
288 Southern Hemisphere, while the Northern Hemisphere experiences a warming during winter and
289 cooling during summer compared to the 4X-NI-PFT-SOIL-SOLAR simulation (Fig 6). These temperature
290 changes are linked to a general decrease in planetary albedo and/or emissivity, although the Northern
291 Hemisphere sometimes exhibits increased albedo, due to the increase in low-altitude cloudiness. This
292 increase in albedo is compensated by a strong atmosphere emissivity decrease during winter but not
293 during summer, which leads to the seasonal pattern of cooling and warming (Supplementary Figure
294 S5).

295 The albedo and emissivity changes are linked to atmospheric and oceanic circulation
296 modifications driven by four major features of the CT paleogeography (Fig 2):

- 297 (1) Equatorial oceanic gateway opening (Central American Seaway/Neotethys)
- 298 (2) Polar gateway closure (Drake/Tasman)

299 (3) Increase in oceanic area in the North Hemisphere (Fig 2)

300 (4) Decrease in oceanic area in the South Hemisphere (Fig 2)

301

302 In the CT simulation, we observe an intensification of the meridional surface circulation and
303 extension towards higher latitudes compared to the simulation with the modern geography (Fig8a-b),
304 as well as an intensification of subtropical gyres, especially in the Pacific (Supplementary Figure S6),
305 which are responsible for an increase in poleward oceanic heat transport (OHT – Fig 8c). Such
306 modifications can be linked to the opening of equatorial gateways that creates a zonal connection
307 between the Pacific, Atlantic and Neotethys oceans (Enderton and Marshall, 2008; Hotinski and
308 Toggweiler, 2003) and that leads to the formation of a strong circumglobal equatorial current (Fig 7b) .
309 This connection permits the existence of stronger easterly winds that enhance equatorial upwelling
310 and drive increased export of water and heat from low latitudes to polar regions. In the Southern
311 Hemisphere, the Drake Passage is only open to shallow flow, and the Tasman gateway has not yet
312 formed. The closure of these zonal connections leads to the disappearance of the modern Antarctic
313 Circumpolar Current (ACC) during the Cretaceous (Fig 7c-d). Notwithstanding, the observed increase
314 in southward OHT between 40° and 60°S (Fig 8c) is explained by the absence of significant zonal
315 connections in the Southern Ocean, which allows for the buildup of polar gyres in the CT simulation
316 (Supplementary Figure S6).

317 The increase in OHT is associated with a meridional expansion of high sea-surface
318 temperatures leading to an intensification of evaporation between the tropics and a poleward shift of
319 the ascending branches of the Hadley cells. The combination of these two processes results in a
320 greater injection of moisture into the atmosphere between the tropics (Supplementary Figure S7).
321 Consequently, the high-altitude cloudiness increases and spreads towards the tropics, leading to an
322 enhanced greenhouse effect. This process is the main driver of the intertropical warming (Herweijer et
323 al., 2005; Levine and Schneider, 2010; Rose and Ferreira, 2013).

324 The atmosphere's response to the paleogeographic changes in the mid- and high-latitudes is
325 different in the Southern and Northern Hemispheres because the ocean to land ratio varies between
326 the CT configuration and the modern. In the Southern Hemisphere, the reduced ocean surface area in
327 the CT simulation (Fig 2) limits evaporation and moisture injection into the atmosphere, which in turn
328 leads to a decrease in relative humidity and low-altitude cloudiness (Supplementary Fig S8) and
329 associated year-round warming due to reduced planetary albedo. In the Northern Hemisphere,
330 oceanic surface area increases (Fig 2) and results in a strong increase in evaporation and moisture
331 injection into the atmosphere. Low-altitude cloudiness and planetary albedo increase and lead to
332 summer cooling, as discussed above (Fig 6). During winter an increase in high-altitude cloudiness leads
333 to an enhanced greenhouse effect and counteracts the larger albedo. This high-altitude cloudiness

334 increase is consistent with the simulated increase in extratropical OHT (Fig. 8). Mid-latitude
335 convection and moist air injection into the upper troposphere is consequently enhanced and
336 efficiently transported poleward (Rose and Ferreira, 2013; Ladant and Donnadieu, 2016). In addition,
337 increased continental fragmentation in the CT paleogeography relative to the preindustrial decreases
338 the effect of continentality (Donnadieu et al. 2006) because thermal inertia is greater in the ocean
339 than over continents.

340

341 3.5 Temperature Gradients

342 3.5.1 Ocean

343 The mean annual global SST increases as much as 9.8°C (from 17.9°C to 27.7 °C) across the
344 simulations. The SST warming is slightly weaker than that of the mean annual global atmospheric
345 temperature at 2m discussed above, and most likely occurs because of evaporation processes due to
346 the weaker atmospheric warming simulated above oceans compared to that simulated above
347 continents. Unsurprisingly, as for the atmospheric temperatures, $p\text{CO}_2$ is the major controlling
348 parameter of the ocean warming (7°C), followed by paleogeography (4.5°C) and changes in the solar
349 constant (2.3°C), although the latter induces a cooling rather than a warming. PFT and soil parameter
350 changes and the removal of polar ice sheets have a minor impact at the global SST (0.6 °C and 0°C
351 respectively). It is interesting to note the increased contribution of paleogeography to the simulated
352 SST warming compared to its contribution to the simulated atmospheric warming, which is probably
353 driven by the major changes simulated in surface ocean circulation (Fig. 7).

354 Mean annual SST in the preindustrial simulation reach $\sim 26^\circ\text{C}$ in the tropics (calculated as the
355 zonal average between 30°S and 30°N) and $\sim -1.5^\circ\text{C}$ at the poles (beyond 70°N - Fig 9a). In this work,
356 we define the meridional temperature gradients as the linear temperature change per 1° of latitude
357 between 30° and 80° . The gradients in the piControl experiment then amount to $0.45^\circ\text{C}/^\circ\text{latitude}$ and
358 $0.44^\circ\text{C}/^\circ\text{latitude}$ for the Northern and Southern Hemispheres, respectively. In the CT simulation, the
359 mean annual SST reach $\sim 33.3^\circ\text{C}$ in the tropics, and $\sim 5^\circ\text{C}$ and 10°C in the Arctic and Southern Ocean
360 respectively, and the simulated CT meridional gradients are $0.45^\circ\text{C}/^\circ\text{latitude}$ and $0.39^\circ\text{C}/^\circ\text{latitude}$ for
361 the Northern and Southern Hemispheres, respectively.

362 The progressive flattening of the SST gradient can be visualized by superimposing the zonal
363 mean temperatures of the different simulations and by adjusting them at the Equator (Fig 9b). Two
364 major observations can be drawn from these results. First, paleogeography has a strong impact on the
365 low-latitudes ($< 30^\circ$ of latitude) SST gradient because it widens the latitudinal band of relatively
366 homogeneous warm tropical SST as a result of the opening of equatorial gateways. Second, poleward
367 of 40° in latitude, the paleogeography and the increase in atmospheric $p\text{CO}_2$ both contribute to the

368 flattening of the SST gradient with a larger influence from paleogeography than from atmospheric
369 $p\text{CO}_2$.

370

371 3.5.2 Atmosphere

372 In the preindustrial simulation, mean tropical atmospheric temperatures reach $\sim 23.6^\circ\text{C}$
373 whereas polar temperatures (calculated as the average between 80° and 90° of latitude) in the
374 Northern and Southern Hemispheres reach around -16.8°C and -37°C respectively. The northern
375 meridional temperature gradient is $0.69^\circ\text{C}/^\circ\text{latitude}$ while the southern latitudinal temperature
376 gradient is $1.07^\circ\text{C}/^\circ\text{latitude}$ (Fig 9c). This significant difference is explained by the very negative mean
377 annual temperatures over Antarctica linked to the presence of the ice sheet.

378 In the CT simulation, mean tropical atmospheric temperatures reach $\sim 32.3^\circ\text{C}$ whereas polar
379 temperatures reach $\sim 3.4^\circ\text{C}$ in the Northern Hemisphere and $\sim -0.5^\circ\text{C}$ in the Southern Hemisphere,
380 thereby yielding latitudinal temperature gradients of $0.49^\circ\text{C}/^\circ\text{latitude}$ and $0.54^\circ\text{C}/^\circ\text{latitude}$,
381 respectively. The gradients are reduced compared to the preindustrial because the absence of year-
382 round sea and land ice at the poles drives leads to far higher polar temperatures.

383 As for the SST gradients, we plot atmospheric meridional gradients by adjusting temperature
384 values so that temperatures at the Equator are equal for each simulation (Fig 9d). This normalization
385 reveals that the mechanisms responsible for the flattening of the gradients are different for each
386 hemisphere. In the Southern Hemisphere high-latitudes ($> 60^\circ$ of latitude), three parameters
387 contribute to reducing the equator-to-pole temperature gradient in the following order of
388 importance: removal of polar ice sheets, paleogeography and increase in atmospheric $p\text{CO}_2$. In
389 contrast, the reduction in the gradient steepness in the Northern Hemisphere high-latitudes is
390 exclusively explained by the increase in atmospheric $p\text{CO}_2$. In the low- and mid-latitudes, this
391 temperature gradient reduction is essentially explained by paleogeography in the Southern
392 Hemisphere and by a similar contribution of paleogeographic changes and increase in atmospheric
393 $p\text{CO}_2$ in the Northern Hemisphere.

394 4. DISCUSSION

395

396 4.1 CENOMANIAN-TURONIAN MODEL/DATA COMPARISON

397 The results predicted by our CT simulation can be compared to reconstructions of
398 atmospheric and oceanic paleotemperatures inferred from proxy data (Fig 10a, b). Our SST data
399 compilation is modified version of Tabor et al (2016), with additional data from more recent studies
400 (see our Supplementary data). We also compiled atmospheric temperature data obtained from

401 paleobotanical and paleosoil studies (see Supplementary data for the complete database and
402 references).

403 The Cretaceous equatorial and tropical SST have long been believed to be similar or even
404 lower than those of today (Sellwood et al., 1994; Crowley and Zachos, 1999; Huber et al., 2002), thus
405 feeding the problem of “tropical overheating” systematically observed in General Circulation Model
406 simulations (Barron et al., 1995; Bush et al., 1997; Poulsen et al., 1998). This incongruence was based
407 on the relatively low tropical temperatures reconstructed from foraminiferal calcite (25-30°C, Fig. 9a),
408 but subsequent work suggested that these were underestimated because of diagenetic alteration
409 (Pearson et al., 2001; Pucéat et al., 2007). Latest data compilations including temperature
410 reconstructions from other proxies, such as TEX86, have provided support for high tropical SST in the
411 Cenomanian-Turonian (Tabor et al., 2016; O’Brien et al., 2017) and our tropical SST are mostly
412 consistent with existing paleotemperature reconstructions (Fig. 10a). In the mid-latitudes (30-60°),
413 proxy records infer a wide range of possible SST, ranging from 10°C to more than 30°C. Simulated
414 temperatures in our CT simulation reasonably agree with these reconstructions if seasonal variability,
415 represented by local monthly maximum and minimum temperatures (grey shaded areas, Fig 10a), is
416 considered. This congruence would imply that a seasonal bias may exist in temperatures
417 reconstructed from proxies, which is suggested in previous studies (Sluijs et al., 2006; Hollis et al.,
418 2012; Huber, 2012; Steinig et al., 2020) but still debated (Tierney, 2012). There are unfortunately only
419 a few high-latitudes SST data points available, which render the model-data comparison difficult. In
420 the Northern Hemisphere, the presence of crocodylian fossils (Vandermark et al., 2007) in the
421 northern Labrador Sea (~70° of latitude) imply mean annual temperature of at least 14°C and
422 temperature of the coldest month of at least 5°C. In comparison, simulated temperatures at the same
423 latitude in the adjacent Western Interior Sea are very similar (13.5 °C for the annual mean and 7.9 °C
424 for the coldest month). In the Southern Hemisphere, mean annual SST calculated from foraminiferal
425 calcite at DSDP sites 511 and 258 are between 25° and 28°C (Huber et al., 2018). Simulated annual SST
426 reach a monthly maximum of 28°C around the location of site DSDP 258. We speculate that a seasonal
427 bias in the foraminiferal record may represent a possible cause for this difference; alternatively, local
428 deviations of the regional seawater $\delta^{18}\text{O}$ from the globally assumed -1‰ value may also reduce the
429 model-data discrepancy (Zhou et al., 2008; Zhu et al., 2020).

430 To our knowledge, atmospheric temperature reconstructions from tropical latitudes are not
431 available. In the mid-latitudes (30-60°), simulated atmospheric temperatures in the Southern
432 Hemisphere reveal reasonable agreement with data whereas Northern Hemisphere mean zonal
433 temperatures in our model are slightly warmer than that inferred from proxies (Fig 10b). At high-
434 latitudes, the same trend is observed for atmospheric temperatures as it is for SST with data indicating
435 higher temperatures than the model in both the Southern and Northern Hemispheres. This inter-

436 hemispheric symmetry in model-data discrepancy could indicate a systematic cool bias of the
437 simulated temperatures.

438 4.2 RECONSTRUCTED LATITUDINAL TEMPERATURE GRADIENTS

439 The simulated northern hemisphere latitudinal SST gradient of ($\sim 0.45^{\circ}\text{C}/^{\circ}\text{latitude}$) is in good
440 agreement with those reconstructed from paleoceanographic data in the Northern Hemisphere
441 ($\sim 0.42^{\circ}\text{C}/^{\circ}\text{latitude}$) whereas it is much larger in the Southern Hemisphere ($\sim 0.39^{\circ}\text{C}/^{\circ}\text{latitude}$ vs
442 $\sim 0.3^{\circ}\text{C}/^{\circ}\text{latitude}$) (Fig 11). This overestimate of the latitudinal gradient holds for the atmosphere as
443 well, as gradients inferred from data are much lower (North= $0.2^{\circ}\text{C}/^{\circ}\text{latitude}$ and
444 South= $0.18^{\circ}\text{C}/^{\circ}\text{latitude}$) than simulated gradients (North= $0.49^{\circ}\text{C}/^{\circ}\text{latitude}$ and
445 South= $0.55^{\circ}\text{C}/^{\circ}\text{latitude}$), although the paucity of Cenomanian-Turonian continental temperatures
446 proxy data is likely to significantly bias this comparison.

447 In the following, we compare our simulated gradients to those obtained in previous deep time
448 modelling studies using recent earth system models. Because Earth system models studies focusing on
449 the Cenomanian-Turonian are limited in numbers, we include simulations of the Early Eocene (~ 55
450 Ma), which is another interval of global climatic warmth (Lunt et al., 2012a, 2017) (Fig. 11). The
451 simulated SST latitudinal gradients range from $0.32^{\circ}\text{C}/^{\circ}\text{latitude}$ to $0.55^{\circ}\text{C}/^{\circ}\text{latitude}$ (Lunt et al., 2012;
452 Tabor et al., 2016; Zhu et al., 2019; Fig. 11) and the atmospheric latitudinal gradients from
453 $0.33^{\circ}\text{C}/^{\circ}\text{latitude}$ to $0.78^{\circ}\text{C}/^{\circ}\text{latitude}$ (Huber and Caballero, 2011; Lunt et al., 2012; Niezgodzki et al.,
454 2017; Upchurch et al., 2015; Zhu et al., 2019; Fig. 11). For a single model and a single set of boundary
455 conditions (Cretaceous or Eocene), the lowest latitudinal gradient is obtained for the highest $p\text{CO}_2$
456 value. However, when comparing different studies with the same model (Cretaceous vs Eocene using
457 the ECHAM5 model; Lunt et al., 2012a; Niezgodzki et al., 2017) it is not the case: the South
458 Hemisphere atmospheric gradient obtained for the Eocene with the ECHAM5 model is always lower
459 than those obtained for the Cretaceous with the same model, regardless of the $p\text{CO}_2$ value (Fig. 11
460 and Supplementary Data). These results show the major role of boundary conditions (in particular
461 paleogeography) in defining the latitudinal temperature gradient. IPSL-CM5A2 predicts SST and
462 atmosphere gradients that are well within the range of other models of comparable resolution and
463 complexity. Models almost systematically simulate larger gradients than those obtained from data
464 (Fig. 11, see also Huber, 2012). The reasons behind this incongruence are debated (Huber, 2012) but
465 highlight the need for more data and for challenging the behavior of complex earth system models, in
466 particular in the high latitudes. Studies have demonstrated that models are able to simulate lower
467 latitudinal temperature gradients under specific conditions such as anomalously high CO_2
468 concentrations (Huber and Caballero, 2011), modified cloud properties and radiative
469 parameterizations (Upchurch et al., 2015; Zhu et al., 2019) or lower paleo elevations and/or more

470 extensive wetlands (Hay et al., 2019). Finally, from a proxy perspective, it has been suggested that a
471 sampling bias could exist, with a better record of temperatures during the warm season at high
472 latitudes and during the cold season in low latitudes (Huber, 2012). Such possible biases would help
473 reduce the model-data discrepancy, in particular for atmospheric temperatures (Fig 10b), as high-
474 latitude reconstructed temperatures are more consistent with simulated summer temperatures
475 whereas the consistency is better with simulated winter temperatures in the mid- to low-latitudes, but
476 further work is required to unambiguously demonstrate the existence of these biases.

477

478 4.3 PRIMARY CLIMATE CONTROLS

479

480 The earliest estimates of climate sensitivity (or the temperature change under a doubling of
481 the atmospheric $p\text{CO}_2$) predicted a 1.5 to 4.5°C temperature increase, with the most likely scenario
482 providing an increase of 2.5°C (Charney et al., 1979; Barron et al., 1995; Sellers et al., 1996; IPCC,
483 2014). Our modelling study predicts an atmospheric warming of 11.1°C for the CT. The signal is
484 notably due to a 9°C warming in response to the fourfold increase in $p\text{CO}_2$, which converts to an
485 increase of 4.5°C for a doubling of $p\text{CO}_2$ (assuming a linear response). This climate sensitivity agrees
486 with the higher end of the range of previous estimates (Charney et al., 1979; Barron et al., 1995;
487 Sellers et al., 1996; IPCC, 2014). However, our simulated climate sensitivity could be slightly lower as
488 the simulations are not completely equilibrated (Fig. 1). The latest generation of Earth system models
489 used in deep-time paleoclimate also show an increasingly higher climate sensitivity to increased CO_2
490 (Hutchinson et al., 2018; Golaz et al., 2019; Zhu et al., 2019), suggesting that the sensitivity could have
491 been underestimated in earlier studies. For example, the recent study of Zhu (2019), using an up-to-
492 date parameterization of cloud microphysics in the CESM1.2 model, proposes an Eocene Climate
493 Sensitivity of 6.6°C for a doubling of CO_2 from 3 to 6 PAL.

494 We have shown that $p\text{CO}_2$ is the main controlling factor for atmospheric global warming
495 whereas the effects of the paleogeography (warming) and reduced solar constant (cooling) nearly
496 cancel each other out at the global scale (see also Lunt et al., 2016). These results agree with previous
497 studies suggesting that $p\text{CO}_2$ is the main factor controlling climate (Barron et al., 1995; Crowley and
498 Berner, 2001; Royer et al., 2007; Foster et al., 2017). However, we also demonstrate that
499 paleogeography plays a major role in the latitudinal distribution of temperatures and impacts oceanic
500 temperatures (with a similar magnitude than a doubling of $p\text{CO}_2$), thus confirming that it is also a
501 critical driver of the Earth's climate (Poulsen et al., 2003; Donnadieu et al., 2006; Fluteau et al., 2007;
502 Lunt et al., 2016). The large climatic influence of the continental configuration has not been reported
503 for paleogeographic configurations closer to each other, e.g., the Maastrichtian and Cenomanian
504 (Tabor et al., 2016). The main features influencing climate in our study (i.e. the configuration of

505 equatorial and polar zonal connections and the land/sea distribution) are indeed not fundamentally
506 different in the two geological periods investigated by Tabor et al. (2016). Paleogeography is thus a
507 first-order control on climate over long timescales.

508 Early work has suggested that high latitude warming can be amplified in deep time simulations
509 by rising CO₂ via cloud and vegetation feedbacks (Otto-bliesner and Upchurch, 1997; Deconto et al.,
510 2000) or by increasing ocean heat transport (Barron et al., 1995; Schmidt and Mysak, 1996; Brady et
511 al., 1998), in particular when changing the paleogeography (Hotinski and Toggweiler, 2003). Our study
512 confirms that the paleogeography is a primary control on the steepness of the oceanic meridional
513 temperature gradient. Furthermore, paleogeography is the only process, among those investigated,
514 that controls both the atmosphere and ocean temperature gradients in the tropics and it has a greater
515 impact than atmospheric CO₂ on the reduction of the atmospheric temperature gradient at high
516 latitudes in the Southern Hemisphere between the CT and the preindustrial. The increase in $p\text{CO}_2$
517 appears as the second most important parameter controlling the SST gradient at high latitudes and is
518 the main control of the reduced atmospheric gradient in the Northern Hemisphere due to low cloud
519 albedo feedback. The effect of paleovegetation on the reduced temperature gradient is marginal at
520 high latitudes in our simulations, in contrast to the significant warming reported in early studies (Otto-
521 bliesner and Upchurch, 1997; Upchurch, 1998; Deconto et al., 2000) but in agreement with more
522 recent model simulations suggesting a limited influence of vegetation in the Cretaceous high-latitudes
523 warmth (Zhou et al., 2012). However, our modeling setup prescribes boreal vegetation at latitudes
524 higher than 50° whereas evidence exist to support the development of evergreen forests poleward of
525 60° of latitude (Sewall et al., 2007; Hay et al., 2019) and of temperate forests up to 60° of latitude
526 (Otto-bliesner and Upchurch, 1997). The presence of such vegetation types could change the albedo
527 of continental regions but also heat and water vapor transfer by altered evapo-transpiration
528 processes, thus leading to warming amplification at high-latitudes and reduced temperature gradients
529 (Otto-bliesner and Upchurch, 1997; Hay et al., 2019). Based on these studies and on our results, we
530 cannot exclude that different types of high-latitude could promote a greater impact of
531 paleovegetation in reducing the temperature gradient.

532

533 5. CONCLUSIONS

534 To quantify the impact of major climate forcings on the Cenomanian-Turonian climate, we
535 perform a series of 6 simulations using the IPSL-CM5A2 earth system model in which we incrementally
536 implement changes in boundary conditions on a preindustrial simulation to obtain ultimately a
537 simulation of the Cenomanian-Turonian stage of the Cretaceous. This study confirms the primary
538 control exerted by atmospheric $p\text{CO}_2$ on atmospheric and sea-surface temperatures, followed by

539 paleogeography. In contrast, the flattening of meridional SST gradients between the preindustrial and
540 the CT is mainly due to paleogeographic changes and to a lesser extent to the increase in $p\text{CO}_2$. The
541 atmospheric gradient response is more complex because the flattening is controlled by several factors
542 including paleogeography, $p\text{CO}_2$ and polar ice sheet retreat. While predicted oceanic and atmospheric
543 temperatures show reasonable agreement with data in the low and mid latitudes, predicted
544 temperatures in the high latitudes are colder than paleotemperatures reconstructed from proxies,
545 which leads to steeper equator-to-pole gradients in the model than those inferred from proxies.
546 However, this mismatch, often observed in data-model comparison studies, has been reduced in the
547 last decades and could be further resolved by considering possible sampling/seasonal biases in the
548 proxies and by continuously improving model physics and parameterizations.

565 The login/password combination requested at first use to download the ORCHIDEE component is
566 anonymous/anonymous. We recommend to refer to the project website:

567 `http://forge.ipsl.jussieu.fr/igcmg_doc/wiki/Doc/Config/IPSLCM5A2` for a proper installation and
568 compilation of the environment.

569

570 Data availability: Data that support the results of this study, as well as boundary condition files are

571 available on request to the authors.

572 AUTHOR CONTRIBUTION

573 M.L performed and analyzed the numerical simulations, in close cooperation with Y.D and J.B.L, and
574 led the writing. M.G run the OTIS model to provide the Cenomanian-Turonian tidal dissipation. All
575 authors discussed the results and analyses presented in the final version of the manuscript.

576 COMPETING INTERESTS

577 The authors declare that they do not have competing interests.

578 ACKNOWLEDGMENTS

579 We express our thanks to Total E&P for funding the project and granting permission to publish. We
580 thank the CEA/CCRT for providing access to the HPC resources of TGCC under the allocation 2018-
581 GEN2212 made by GENCI. J.A.M.G receives funding from the Natural Environmental Research Council
582 (grant NE/S009566/1, MATCH). We acknowledge use of the Ferret (ferret.pmel.noaa.gov/Ferret/)
583 program for analysis and graphics in this paper.

584 FIGURES

585

Figure 1: Time series for mean annual oceanic temperatures. (a) Sea-surface temperature and (b) deep-ocean (2500 m) temperature. The piControl and 1X-NOICE simulations are perfectly equilibrated. The 4X simulations still have a small linear drift, around 0.1°C/century or less : 0.07, 0.08, 0.05 and 0.01°C/century during the last 500 years for SST of 4X-NOICE, 4X-NOICE-PFT-SOIL, 4X-NOICE-PFT-SOIL-SOLAR and 4X-CRETACEOUS respectively; 0.11, 0.08, 0.07 and 0.06°C/century during the last 500 years, for deep-ocean of 4X-NOICE, 4X-NOICE-PFT-SOIL, 4X-NOICE-PFT-SOIL-SOLAR and 4X-CRETACEOUS respectively.

Figure 2: Modern and Cenomanian-Turonian geographic configurations used for the piControl and 4X-CRETACEOUS simulations respectively, and meridional oceanic area anomaly between Cretaceous paleogeography and Modern. geography.

Figure 3: Evolution of Albedo (surface and planetary) and emissivity, in percentages and of T2M (°C) from piControl to 4X-CRETACEOUS simulations. The major change is always recorded with the change of pCO₂ between 1X-NOICE and 4X-NOICE simulations.

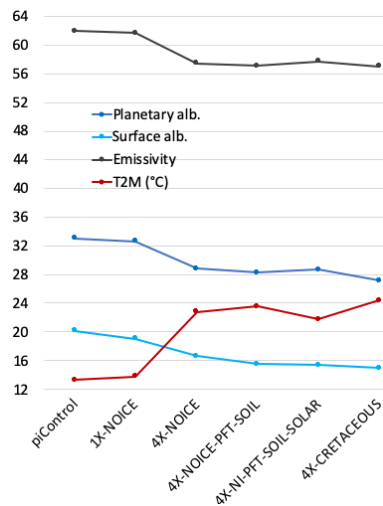

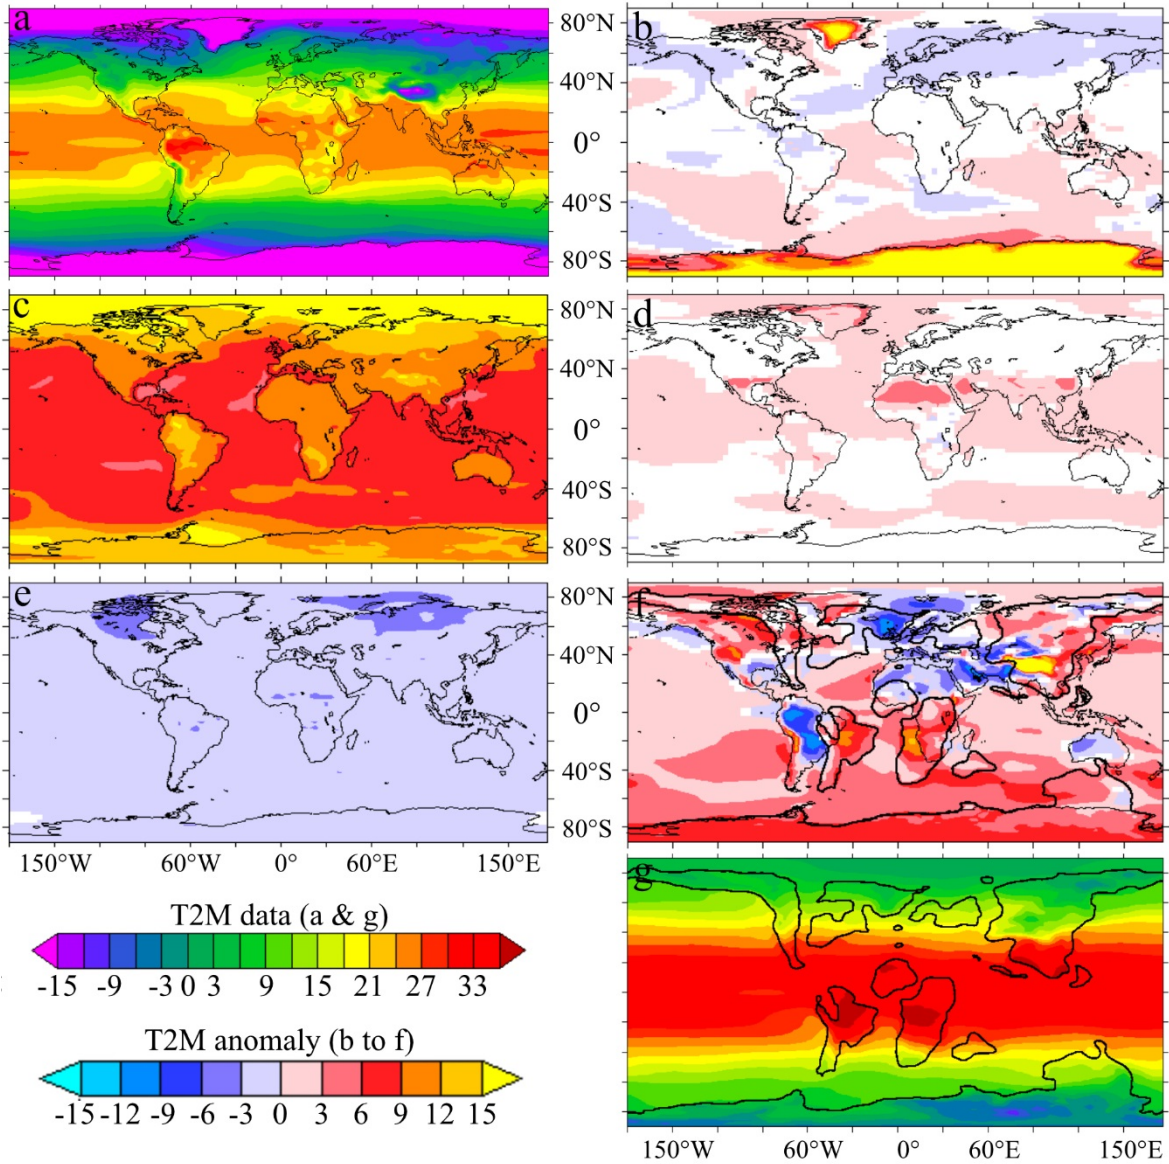

Figure 4: T2M (°C) for (a) piControl initial simulation and (g) Cretaceous final simulation, and anomalies (°C) for intermediate simulations: (b) 1X-NOICE-piControl, (c) 4X-NOICE-1X-NOICE, (d) 4X-NOICE-PFT-SOIL – 4X-NOICE, (e) 4X-NOICE-PFT-SOIL-SOLAR – 4X-NOICE-PFT-SOIL, (f) 4X-CRETACEOUS - 4X-NOICE-PFT-SOIL. White color (not represented in the colourbar) correspond to areas where the anomaly is not statistically significant according to the student test.

Figure 5: Mean annual cloudiness for 1X-NOICE and 4X-NOICE simulations. (a) Anomaly of total cloudiness (4X-NOICE – 1X-NOICE). (b) Low-altitude cloudiness (Below 680 hPa of atmospheric pressure - solid curves) and high-altitude cloudiness (Above 440 hPa of atmospheric pressure - dashed curves) for 1X-NOICE (black) and 4X-NOICE (red) simulations.

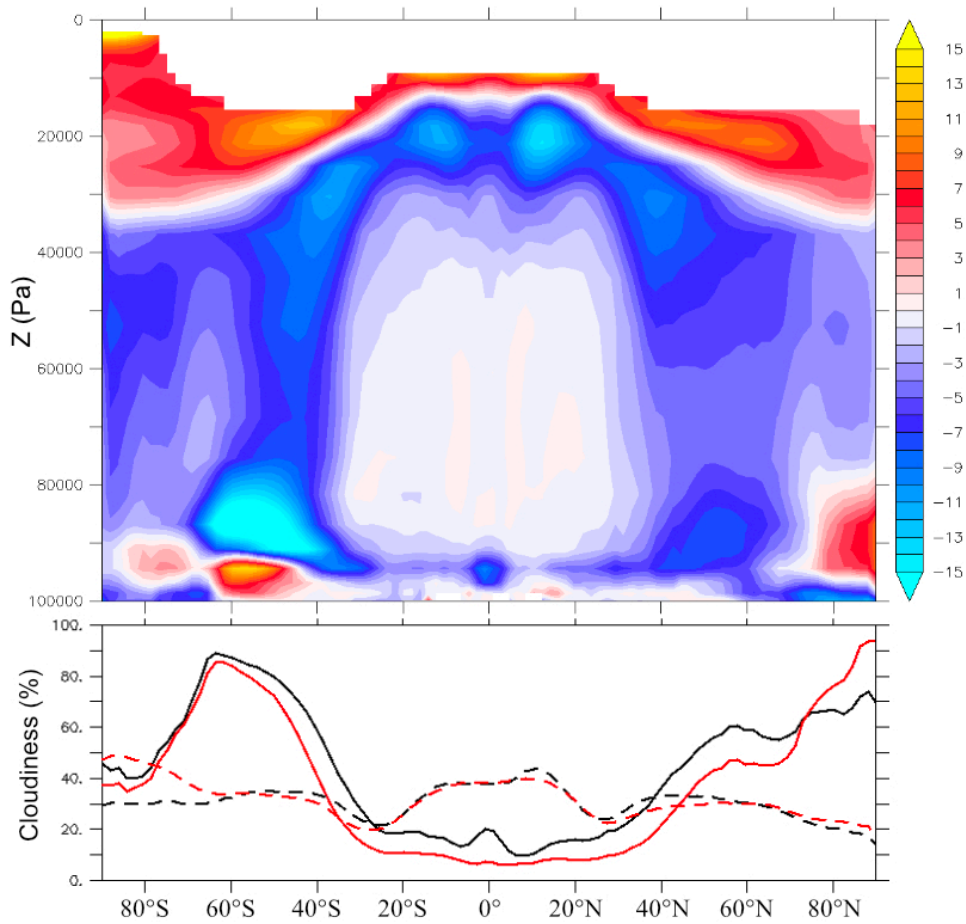

Figure 6: T2M ($^{\circ}\text{C}$) mean annual meridional gradients for 4X-NI-PFT-SOIL-SOLAR (black) and 4X-CRETACEOUS (red) simulations. Solid curve corresponds to annual average, dashed curves correspond to winter and summer values. The 4X-CRETACEOUS simulation is generally warmer than the 4X-NI-PFT-SOIL-SOLAR-SOLAR simulation, with the exception of the boreal summer.

Figure 7: Surface currents for 4X-NOICE-PFT-SOIL-SOLAR (left) and 4X-CRETACEOUS (right) simulations. (a), (b) Intensity of surface circulation (Sv – Annual Mean for 0-80 meters of water depth). Strong equatorial winds lead to the formation of an equatorial circumglobal current. (c), (d) Intensity of surface circulation (Sv – Annual Mean for 0-80 meters of water depth). The closure of the Drake passage (DP-300 meters of water depth) leads to the suppression of the ACC.

610 Figure 8 - (a), (b) Global mean annual meridional stream-function (S_v) for the first 300 meters of water depth. Red and blue
 611 colors indicate clockwise and anti-clockwise circulation respectively. (a): 4X-NI-PFT-SOIL-SOLAR and (b) 4X-
 612 CRETACEOUS. (c) Oceanic heat transport for 4X-NI-PFT-SOIL-SOLAR and 4X-CRETACEOUS simulations. Positive and
 613 negative values indicate northward and southward transport direction, respectively.

614 Figure 9: (a) Mean annual meridional Sea-Surface Temperature gradients for all simulations. (b) Same SST curves than (a)
 615 but superimposed such as equator temperatures are equal, allowing to compare the steepness of the curves. (c) Meridional
 616 atmospheric surface temperature gradients for all simulations. (d) Same curves than (c) but superimposed such as equator
 617 temperatures are equal. (e) Same curves than (c) but superimposed such as equator
 618 temperatures are equal. (f) Same curves than (c) but superimposed such as equator
 619 temperatures are equal.

630 *Figure 10: Meridional surface temperature gradients for the 4X-CRETACEOUS simulation. (a) Oceanic temperatures: the*
 631 *solid line corresponds to the mean annual temperature obtained from the modeling. Dashed lines correspond to winter and*
 632 *summer seasonal averages. The grey shaded areas correspond to local monthly temperatures. Data points are obtained with*
 633 *several proxies for the Cenomano-Turonian period. The green data point is obtained from TEX 86 for the Maastrichtian (70*
 634 *Ma) and extrapolated for 90 Ma. The Huber et al. (2018) point is obtained from δ^{80} on foraminifera and the Vandenmark et*
 635 *al., 2007 point is interpreted from the presence of crocodilian fossils. MAT=Mean Annual Temperature, CM=Coldest Month.*
 636 *(b) Atmospheric temperatures: same legend as (a) for modeled temperatures. Data points are obtained from several proxies*
 637 *including CLAMP analysis on paleofloras, leaf analyses, paleosol-derived climofunction or bioclimatic analysis. Symbols*
 638 *represent mean annual temperatures and solid lines associated ranges/errors. Dashed lines represent monthly mean*
 639 *temperatures. Orange data points are for Cenomano-Turonian ages (100-90 Ma), blue data points for Albian and green data*
 640 *points for Coniacian-Santonian (88-85 Ma).*

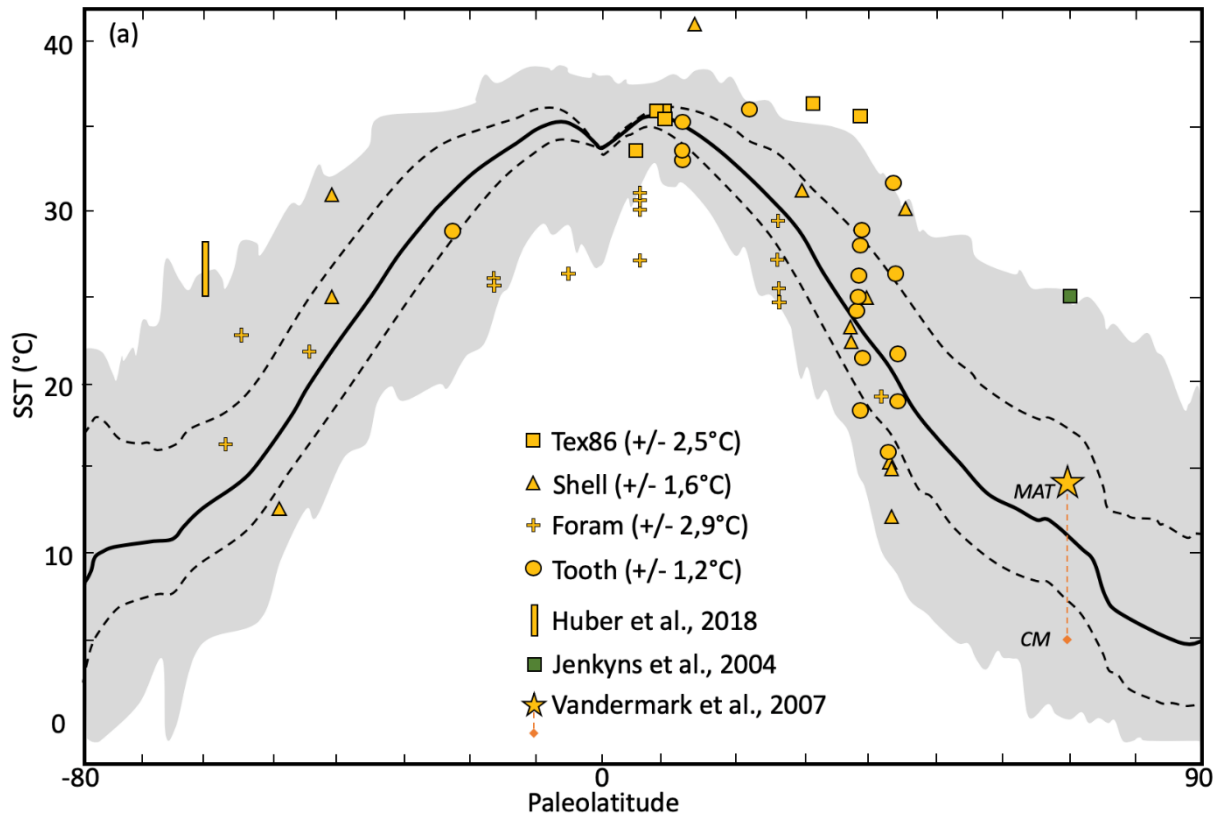

Figure 11: Plot of atmospheric and sea surface mean annual temperature gradients vs pCO₂ for different modelling studies and data compilation. Data gradients are plotted for a default pCO₂ value of 4 P.A.L. Gradients are expressed in °C per °latitude and are calculated from 30 to 80 degrees of latitude. Gradients linked by a line correspond to studies realized with the same model & paleogeography. Solid lines or gradients marked with a (E) correspond to an Eocene paleogeography. Dashed lines or gradients marked with a C correspond to a Cretaceous paleogeography.
