## 14 Abstract

15 The scarcity of continuous, terrestrial, palaeoenvironmental records in eastern South Africa  
16 leaves the evolution of late Quaternary climate and its driving mechanisms uncertain. Here we use a  
17 ~7-m long core from Mfabeni peatland (KwaZulu-Natal, South Africa) to reconstruct climate  
18 variability for the last 32 thousand years (cal ka BP). We infer past vegetation and hydrological  
19 variability using stable carbon ( $\delta^{13}\text{C}_{\text{wax}}$ ) and hydrogen isotopes ( $\delta\text{D}_{\text{wax}}$ ) of plant-wax *n*-alkanes and use  
20  $P_{\text{aq}}$  to reconstruct water table changes. Our results indicate that late Quaternary climate in eastern  
21 South Africa did not respond directly to orbital forcing nor to changes in sea surface temperatures  
22 (SSTs) in the western Indian Ocean. We attribute the arid conditions evidenced at Mfabeni during the  
23 Last Glacial Maximum (LGM) to low SSTs and an equatorward displacement of: i) the southern  
24 hemisphere westerlies, ii) the subtropical high-pressure cell and iii) the South Indian Ocean  
25 Convergence Zone (SIOCZ), which we infer was linked to increased Antarctic sea-ice extent. The  
26 northerly location of the high-pressure cell and the SIOCZ inhibited moisture advection inland and  
27 pushed the rain-bearing cloud band north of Mfabeni, respectively. The increased humidity at  
28 Mfabeni between 19–14 cal kyr BP likely resulted from a southward retreat of the westerlies, the  
29 high-pressure cell and the SIOCZ, consistent with a decrease in Antarctic sea ice extent. Between 14–  
30 5 cal kyr BP, when the westerlies, the high-pressure cell and the SIOCZ were in their southernmost  
31 position, local insolation became the dominant control, leading to stronger atmospheric convection  
32 and an enhanced tropical easterly monsoon. Generally drier conditions persisted during the past c. 5  
33 cal ka BP, probably resulting from an equatorward return of the westerlies, the high-pressure cell and  
34 the SIOCZ. Higher SSTs and heightened ENSO activity may have played a role in enhancing climatic  
35 variability during the past c. 5 cal ka BP. Our findings highlight the influence of the latitudinal position

36 of the westerlies, the high-pressure cell and SIOCZ in driving climatological and environmental  
37 changes in eastern South Africa.

40 hemisphere westerlies; tropical easterlies

41

## 42 **1. Introduction**

43 Eastern South Africa is an important region for scientific focus, specifically for furthering our  
44 understanding of regional and global climate dynamics. The region is particularly dynamic and  
45 sensitive to long-term climate change as it lies within a climatic transition zone, where it is strongly  
46 influenced by both temperate (southern westerlies) and tropical (tropical easterlies) climate systems.  
47 In eastern South Africa, modelled precipitation reductions and projected regional warming (3–6°C by  
48 2099), threaten the stability of current ecosystems in a region populated by communities already  
49 economically vulnerable to the effects of climate change (IPCC, 2013). Past climate and  
50 environmental reconstruction and the determination of climate driving mechanisms will provide  
51 valuable information for assessing future climate and environmental trends in the region.

52 Changes in vegetation, precipitation and temperature from the beginning of the Last Glacial  
53 Maximum (LGM; *c.* 26.5 ka; Clark et al., 2009) to the present-day are poorly constrained in eastern  
54 South Africa. Whether this region was characterized by aridity or increased humidity during the last  
55 glacial period remains unclear. Proxy data show spatial complexity (e.g., Baker et al., 2016; Chase et  
56 al., 2017; Chevalier and Chase, 2015 & 2016, Dupont et al., 2011; Schefuß et al., 2011; Scott et al.,  
57 2012; Scott, 2016; Schmidt et al., 2014; Simon et al., 2015), and modelled LGM (26.5–19 ka; Clark et  
58 al., 2009) precipitation patterns for the region are highly variable and often do not even agree on the  
59 sign of precipitation change. For example, the PMIP3 model ensemble mean suggests increased LGM  
60 precipitation in the east of South Africa with dry conditions towards the north (compared to the  
61 present day; Braconnot et al., 2007; Chevalier et al., 2017). Conversely, the NCAR CCSM3 model  
62 indicates drier than present conditions in the centre of South Africa and along the eastern coast  
63 (Otto-Bliesner et al., 2006). These contrasting simulations for the last glacial period highlight the  
64 difficulty in simulating past precipitation in South Africa, with a lack of a comprehensive  
65 understanding regarding the relevant climate processes involved (Stone, 2014).

66 The mechanisms driving Quaternary climate variability in South Africa are complex and  
67 spatially heterogeneous. For example, hydroclimate may be paced by austral summer insolation  
68 fluctuations, resulting from changes in the Earth's orbital precession on 23–19 ka timescales. Strong  
69 summer insolation (during precession maxima) causes stronger atmospheric convection and an  
70 increase in the land/ocean temperature contrast, which results in higher moisture transport by the

71 tropical easterlies and higher precipitation in eastern South Africa (e.g., Simon et al., 2015; Chevalier  
72 and Chase, 2015). Climate may also be influenced by high-latitude forcing related to changes in the  
73 Earth's orbital obliquity and eccentricity on longer, i.e., glacial-interglacial timescales, which may  
74 result in the latitudinal contraction and expansion of the climatic belts (e.g., Dupont, 2011). The  
75 model of Nicholson and Flohn (1980) suggests an equatorward displacement of the tropical rainbelt  
76 (Nicholson, 2008) during the last glacial period, although proxy data from South Africa provide no  
77 conclusive support for this scenario. In addition, during glacial periods, the Walker Circulation may  
78 have been weaker with its ascending limb further to the east, over the Indian Ocean (e.g., DiNezio et  
79 al., 2018). This possibly resulted in an eastward displacement of the cloud band (SIOCZ) and thus a  
80 drier summer rainfall zone (SRZ; Tyson, 1999). Furthermore, changes in the latitudinal position of the  
81 southern hemisphere westerlies (as a response to fluctuations in Antarctic sea ice extent) have been  
82 invoked to influence climate in South Africa (Chase and Meadows, 2007; Chevalier and Chase, 2015;  
83 Chase et al., 2017). The western South African region has received most focus regarding the southern  
84 hemisphere westerly influence in controlling climate variability (e.g., Stuut et al., 2004; van Zinderen  
85 Bakker, 1976). Some studies also suggest possible mechanistic links between SSTs in the Agulhas  
86 Current and the Indian Ocean and rainfall variability in South Africa, with high SSTs linked to  
87 increasing South African summer precipitation (e.g., Baker et al., 2017; Chevalier and Chase, 2015;  
88 Dupont, 2011; Dupont et al., 2011; Reason and Mulenga, 1999). Climate forcing experiments also  
89 indicate that changes in greenhouse gas concentrations may have driven eastern South African  
90 rainfall changes, increasing precipitation between 17–11 kyr (Otto-Bliesner et al., 2014).

91 The spatially heterogeneous nature of climate variability in South Africa from the last glacial  
92 period to the present-day, and the multiple possible climate drivers render the region an important  
93 focus for palaeoclimate research. Two important questions remain: i) what was the climate like in  
94 eastern South Africa during the last glacial period? and, ii) what were the causes for the climate  
95 variability? These questions are difficult to answer with the majority of long, continuous, terrestrial  
96 records situated further north, within the range of the modern tropical rainbelt (e.g., Barker et al.,  
97 2007; Tierney et al., 2008), making it hard to assess the long-term climate drivers in the south, in  
98 particular in eastern South Africa. In this area, terrestrial sediment archives suitable for  
99 palaeoenvironmental reconstruction are scarce, in particular those extending to the LGM. Marine  
100 and speleothem archives have hitherto mostly formed the basis of Quaternary climate research in  
101 this region (e.g., Dupont et al., 2011; Holmgren et al., 2003). Here we provide stable carbon ( $\delta^{13}\text{C}$ )  
102 and hydrogen ( $\delta\text{D}$ ) isotope records of terrestrial plant-waxes (long-chained *n*-alkanes) from Mfabeni  
103 peatland, one of the longest continuous terrestrial archives from South Africa. Our vegetation and  
104 hydroclimate reconstructions are compared with a previous biomarker-palaeoclimate study from  
105 Mfabeni (Baker et al., 2014, 2016 & 2017). We more than double the temporal resolution of the

106 previous plant-wax  $\delta^{13}\text{C}$  record from Baker et al. (2017), from c. 1200 to c. 500 years, revealing  
107 important and previously undocumented environmental variability.

108

## 109 **2. Regional setting**

110 The mid-latitude westerlies, in association with the subtropical high (and low) pressure cells  
111 and the SIOCZ, play critical roles in determining climatic conditions across the whole South African  
112 continent (Fig. 1; Dyson and van Heerden, 2002; Macron et al., 2014; Munday and Washington,  
113 2017). During austral winter, an anti-clockwise rotating subtropical high-pressure cell is located over  
114 southern Africa, which drives large-scale subsidence and suppresses rainfall (Fig. 1b). This high-  
115 pressure cell creates a blocking effect over the continent, which stops moisture advection inland over  
116 the majority of South Africa during winter (Dedekind et al., 2016), except for in the winter rainfall  
117 zone (WRZ), where the westerlies bring rainfall. During summer, the high-pressure cell shifts to the  
118 south, and the Angola and Kalahari low pressure cells dominate the continent, enabling monsoonal  
119 systems (tropical easterlies) to penetrate southern Africa, bringing rainfall to the summer rainfall  
120 zone (SRZ; Fig. 1a; Tyson and Preston-Whyte, 2000; Munday and Washington, 2017). The dominant  
121 rain-producing mechanism in the SRZ during the summer are tropical temperature troughs (TTTs),  
122 which are embedded within the SIOCZ and form a northwest-southeast orientated cloud band,  
123 extending over the continent into the southwest Indian Ocean (Fig. 1a; Todd and Washington 1999;  
124 Tyson and Preston-Whyte, 2000). TTTs form from interactions between tropical convection and mid-  
125 latitude perturbations, which result in heavy precipitation events (Tyson, 1986; Macron et al., 2014;  
126 Chase et al., 2017). A combination of strong easterly flux from the Indian Ocean and low pressure  
127 over the continent during the summer results in the development of TTTs (Fig. 1a; Cook, 2000;  
128 Macron et al., 2014; Rácz and Smith, 1999; Todd and Washington 1999).

129 South Africa can be divided into several climate zones: the SRZ lies in the north and east where  
130 66 % of the mean annual precipitation falls between October and March (Fig. 1a; Chase and  
131 Meadows, 2007). Based on late Quaternary precipitation reconstructions, further subdivisions of the  
132 SRZ (northern SRZ, central/eastern SRZ) have been suggested by Chevalier and Chase (2015). In the  
133 extreme south and west of South Africa lies the WRZ (Fig. 1a), where 66 % of the mean annual  
134 precipitation falls between April and September (Chase and Meadows, 2007). This rainfall is  
135 associated with temperate frontal systems related to the southern hemisphere westerlies (Fig. 1b;  
136 Mason and Jury, 1997; Tyson, 1986; Tyson and Preston-Whyte, 2000). In between the SRZ and WRZ  
137 lies the year-round rainfall zone (YRZ) which receives precipitation both in summer and winter  
138 seasons (Fig. 1a; Chase and Meadows, 2007). This zone comprises much of the southern Cape of  
139 South Africa and is highly heterogeneous in terms of precipitation seasonality and amount, spanning

140 some of the wettest (e.g., along the south coast), and driest (e.g., Namib Desert) regions in South  
141 Africa.

142 Mfabeni peatland is located within the SRZ, on the coastal plain of northern KwaZulu-Natal  
143 (28°09'8.1"S; 32°31'9.4"E; 9 m above sea level; Fig. 1; Fig. 2). The dominating subtropical high-  
144 pressure cell across the majority of South Africa during the austral winter months leads to mild and  
145 dry winter conditions at Mfabeni. Occasional rainfall during the winter months at Mfabeni is  
146 associated with the passage of cold fronts, which develop in the western Atlantic and move across  
147 southern Africa (Fig. 1b; Grab and Simpson, 2000). These cold fronts trigger rainout of atmospheric  
148 moisture, which is sourced from the Indian Ocean and Agulhas region (Gimeno et al., 2010). When  
149 the subtropical high-pressure cell has moved south during the austral summer, the tropical easterlies  
150 dominate, TTTs form and conditions at Mfabeni are hot and humid. The average annual rainfall  
151 amount between 2010 and 2018 at Mfabeni in the winter months (June–August) was measured at  
152 134 mm compared to 426 mm during the summer months (December–February), meaning the  
153 majority of rainfall (76 %) falls during the summer months (data from World Weather Online). A  
154 northeast–southwest precipitation gradient is present across the peatbog, with 1200 mm year<sup>-1</sup> of  
155 precipitation in the east decreasing to 900 mm year<sup>-1</sup> westwards towards Lake St. Lucia (Fig. 1; Fig. 2;  
156 Taylor et al., 2006). The main source of water to Mfabeni is precipitation, predominantly provided by  
157 the tropical easterlies and TTTs, sourced from the Indian Ocean and Agulhas Current region (Fig. 1;  
158 Tyson, 1999; Gimeno et al., 2010). Mean summer temperatures (November to March) surpass 21 °C.  
159 The wind regime is characterised by moderate northeasterly winds during the summer and more  
160 intense southwesterly winds during winter.

161 Mfabeni is one of the oldest, continuously growing peatlands in South Africa (Grundling et al.,  
162 2013). It lies within a topographical inter-dunal depression between the Indian Ocean to the east and  
163 Lake St. Lucia to the west (Fig. 2; Grundling et al., 2013). Towards the ocean, it is bordered by an 80–  
164 100 m high vegetated dune barrier and to the west by the 15–70 m high Embomveni sand dune ridge  
165 (Fig. 2). Over the last 44 ka, the mire accumulated c. 11 m of peat, deposited on top of a basal clay  
166 layer (Grundling et al., 2015). This clay layer was crucial in the formation and development of the  
167 mire, limiting water loss during low sea level stands (Grundling et al., 2013). Mfabeni is bound to the  
168 north and south by beach ridges isolating it from Lake Bhangazi and Lake St. Lucia, respectively (Fig.  
169 2; Grundling et al., 2013). When lake levels in Lake Bhangazi are high, minor water exchange  
170 between Mfabeni and Bhangazi occurs, but there are no fluvial inputs to either system. Surface  
171 drainage occurs southwards towards Lake St Lucia (Fig. 2). The peatland receives groundwater via the  
172 swamp forest and the western dunes. This groundwater, which is important in keeping the mire wet  
173 during the dry season, discharges towards the center of the peatland and then flows within a sub-  
174 surface layer towards the east (Grundling et al., 2015). In the northern and eastern part of the

175 peatland, the vegetation is sedge and reed fen (comprising of sedges and grasses). In the western  
176 and southern parts of Mfabeni is swamp forest (Venter, 2003).

177 The modern water balance at Mfabeni is dominated by the interplay between  
178 evapotranspiration (ET; 1035 mm) and precipitation (1053 mm). Groundwater inflow (14 mm) and  
179 stream outflow (9 mm) have a minor contribution to the modern water balance (all measured  
180 between May 2008 and April 2009; Grundling et al., 2015). Changes in regional climate have much  
181 potential to influence the fine balance between ET and precipitation. For example, ET is suppressed  
182 when cloud cover is increased during the summer months and increased during times of higher wind  
183 speed (Grundling et al., 2015). ET is higher in the swamp forest than in the sedge and reed fen,  
184 therefore a change in vegetation composition also has the potential to impact ET rates. The  
185 depositional setting of the Mfabeni peatland provides a unique opportunity to reconstruct past  
186 eastern South African climate variability at centennial-scale resolution from the Late Pleistocene to  
187 the present day.

188

### 189 **3. Methodological background**

190 To reconstruct past vegetation and hydroclimate we use the distribution, and the carbon and  
191 hydrogen isotopic composition, of long chain *n*-alkanes derived from plant-waxes.

192

#### 193 *3.1 Distributions of plant-waxes*

194 To obtain information on water table variations, we quantify the relative contribution of plant-waxes  
195 derived from submerged and floating macrophytes relative to that of emergent and terrestrial plants  
196 ( $P_{aq}$ ). Odd-numbered *n*-alkanes ( $C_{25}$ – $C_{35}$ ) are derived from the epicuticular wax coating of terrestrial  
197 higher plants (Eglinton and Hamilton, 1967). Conversely, aquatic plant-waxes (of submerged  
198 macrophyte origin) are dominated by mid-chain *n*-alkanes (typically  $C_{23}$  and  $C_{25}$ ; e.g., Baker et al.,  
199 2016; Ficken et al., 2002). Thus we quantify  $P_{aq}$  using Equation 1 (Ficken et al., 2000).

200

---

---

Eq. 1

201 with  $C_x$  the amount of each homologue.

202

203 To assess *n*-alkane degradation we used the carbon preference index (CPI; Bray and Evans, 1961).  
204 The CPI reflects the molecular distribution of odd-to-even *n*-alkanes, within a certain carbon number  
205 range (here,  $n$ - $C_{26}$  to  $n$ - $C_{34}$ ; Equation 2). High CPI values indicate a higher contribution of odd-  
206 numbered *n*-alkanes (relative to even), indicating the *n*-alkanes are derived from higher terrestrial  
207 plants. Low CPI values indicate either low contribution from terrestrial higher plants or high organic  
208 matter degradation (Eglinton and Hamilton, 1967).

209

$$\text{CPI}_{27-33} = 0.5 * (\Sigma C_{\text{odd}27-33} / \Sigma C_{\text{even}26-32} + \Sigma C_{\text{odd}27-33} / \Sigma C_{\text{even}28-34})$$

211

Eq. 2

212 with  $C_x$  the amount of each homologue.

213

### 214 3.2 Carbon and hydrogen isotopes of terrestrial plant-waxes

215 To reconstruct vegetation changes, we use the carbon isotopic composition of terrestrial plant-  
216 waxes ( $\delta^{13}\text{C}_{\text{wax}}$ ). On late Quaternary timescales, the primary factor determining the amplitude of  
217 fractionation between the  $\delta^{13}\text{C}$  of atmospheric  $\text{CO}_2$  ( $\delta^{13}\text{C}_{\text{atm}}$ ) and the carbon isotopic composition of  
218 the plant ( $\delta^{13}\text{C}_{\text{plant}}$ ) is the plant carbon fixation pathway ( $\text{C}_3/\text{C}_4/\text{CAM}$ ; e.g., Diefendorf and Freimuth,  
219 2017). On these timescales, changes in the  $\delta^{13}\text{C}_{\text{atm}}$  are too small to significantly influence  $\delta^{13}\text{C}_{\text{wax}}$   
220 (Tippie et al., 2010). Shrubs and trees use the  $\text{C}_3$  photosynthetic pathway and show the largest  
221 fractionation. Grasses utilize either the  $\text{C}_3$  or the  $\text{C}_4$  pathway, with  $\text{C}_4$  plants having the smallest net  
222 fractionation (Collister et al., 1994). The differences in carbon isotope fractionation during carbon  
223 uptake leads to different  $\delta^{13}\text{C}_{\text{wax}}$  signatures, and allows the determination of past vegetation types: *n*-  
224 alkane  $\delta^{13}\text{C}$  values of  $\text{C}_3$  plants are c. -36‰ VPDB (Vienna Pee Dee Belemnite) and c. -20‰ VPDB for  
225  $\text{C}_4$  plants (e.g., Diefendorf and Freimuth, 2017).

226 The hydrogen isotope composition of plant-waxes ( $\delta\text{D}_{\text{wax}}$ ) reflects the isotopic composition of  
227 the water used during lipid biosynthesis (Sachse et al., 2012), rendering it a valuable tool for  
228 reconstructing past hydrological conditions (e.g., Collins et al., 2013; Schefuß et al., 2005).  $\delta\text{D}_{\text{wax}}$  is  
229 influenced by three main factors: i) the isotopic composition of precipitation; ii) enrichment of soil  
230 and leaf water due to ET; and iii) differences in the apparent isotopic fractionation between source  
231 water and plant-waxes due to differences in vegetation type. The importance of each factor varies by  
232 study site and with time. The detailed interpretation of the Mfabeni  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  is discussed in  
233 section 6.1.

234

## 235 4. Methods: compound specific C and H isotope analyses

236 Core MF4-12 (6.96 m recovery, 8.77 m penetration) was recovered from the centre of  
237 Mfabeni peatland during January 2012 using a vibrocoring device (Fig. 2). The chronology of the core  
238 is established by 24  $^{14}\text{C}$  AMS (accelerator mass spectrometry) dates from bulk peat (Fig. 3, S1). The  
239 chronology is extended from that published in Humphries et al. (2017) and the age model is made  
240 using Bacon 2.2 program (Blaauw and Christen, 2011). Radiocarbon ages were calibrated using the  
241 southern hemisphere calibration curve, ShCal13 (Hogg et al., 2016) and the post-bomb southern  
242 hemisphere curve, zone 1–2, for the uppermost modern dates (Hua et al., 2016).

243 Freeze-dried, bulk peat samples were ground and homogenized using a pestle and mortar  
244 and lipids were extracted from c. 2 g of peat using a DIONEX Accelerated Solvent Extractor (ASE 200)  
245 at 100 °C and at 1000 psi for 5 minutes (repeated 3 times) using a dichloromethane (DCM):methanol  
246 (MeOH) (9:1, v/v) mixture. Prior to extraction, squalane was added as an internal standard. Copper  
247 turnings were used to remove elemental sulfur from the total lipid extract (TLE). To remove water,  
248 the TLE was passed over a Na<sub>2</sub>SO<sub>4</sub> column (eluting with hexane). Subsequent to saponification (by  
249 adding 6 % KOH in MeOH) and extraction (with hexane), the neutral fractions were split into a further  
250 three fractions: hydrocarbon, ketone, and polar, by silica gel column chromatography (mesh size 60  
251 μm) and elution with hexane, DCM and DCM:MeOH (1:1), respectively. By eluting the hydrocarbon  
252 fractions with hexane over AgNO<sub>3</sub>-impregnated silica columns we obtained the saturated  
253 hydrocarbon fractions. The saturated hydrocarbon fractions were measured using a Thermo Fischer  
254 Scientific Focus gas-chromatograph (GC) with flame-ionization-detection (FID) equipped with a  
255 Restek Rxi 5ms column (30 m x 0.25 mm x 0.25 μm), in order to determine the concentrations of  
256 long-chain *n*-alkanes. The GC oven temperature was set at 60 °C, held for 2 minutes, increased at 20  
257 °C/minute to 150 °C and then at 4 °C/minute to 320 °C and held for 11 minutes. The split/splitless  
258 inlet temperature was 260 °C. To estimate the sample concentrations needed for isotope analyses,  
259 samples were compared with an external standard that was run every 5 samples, which contained *n*-  
260 alkanes (C<sub>19</sub>–C<sub>34</sub>) at a concentration of 10 ng/μl. A quantification uncertainty of <5% was yielded  
261 through replicate analyses of the external standard.

262 The δ<sup>13</sup>C values of the long-chain *n*-alkanes were measured using a Thermo Trace GC Ultra  
263 equipped with an Agilent DB-5 column (30m x 0.25mm x 0.25μm) coupled to a Finnigan MAT 252  
264 isotope ratio mass spectrometer (IR-MS) via a combustion interface operated at 1000 °C. The GC  
265 temperature was programmed from 120 °C (hold time 3 min), followed by heating at 5 °C/minute to  
266 320 °C (hold time 15 minutes). The external CO<sub>2</sub> reference gas was used to calibrate the δ<sup>13</sup>C values  
267 and they are reported in ‰ VPDB. Samples were analysed in duplicate when *n*-alkane concentrations  
268 were adequate for multiple runs. The internal standard (squalane, δ<sup>13</sup>C= -19.9‰), yielded an  
269 accuracy of 0.6‰ and a precision of 0.2‰ (n=37). The external standard mixture was analysed every  
270 6 runs. The long-term precision and accuracy of the external *n*-alkane standard was 0.2 and 0.15‰,  
271 respectively. For δ<sup>13</sup>C the average precision of the *n*-C<sub>29</sub> and *n*-C<sub>31</sub> alkane in replicates was 0.2‰ and  
272 0.1‰ (n=22), respectively.

273 The δD compositions of long-chain *n*-alkanes were measured using a Thermo Trace GC  
274 coupled via a pyrolysis reactor (operated at 1420 °C) to a Thermo Fisher MAT 253 IR-MS. The GC  
275 column and temperature program was similar to that used for the δ<sup>13</sup>C analysis. The external H<sub>2</sub>  
276 reference gas was used to calibrate the δD values and they are reported in ‰ VSMOW. The H<sup>3+</sup>  
277 factor was monitored daily and fluctuated around 5.2 ppm nA<sup>-1</sup> during analyses. After every sixth

278 measurement, an *n*-alkane standard of 16 externally calibrated alkanes was measured. The long-term  
279 precision and accuracy of the external *n*-alkane standard was 2.7 and 2‰, respectively. Samples  
280 were analysed in duplicate when *n*-alkane concentrations were adequate for multiple runs. The  
281 internal standard (squalane,  $\delta D = -180\text{‰} \pm 2$ ), yielded an accuracy of 0.9‰ and a precision of 1.9‰  
282 ( $n=36$ ). For  $\delta D$  the average precision in replicates was 1‰ for both *n*-C<sub>29</sub> and *n*-C<sub>31</sub> alkanes ( $n=52$ ).

283 The last glacial period Mfabani  $\delta D_{\text{wax}}$  values were corrected to account for the effect of  
284 changes in global ice volume (Collins et al., 2013; Schefuß et al., 2005). For this, the benthic  
285 foraminifera-based oxygen isotope curve (Waelbroeck et al., 2002) was interpolated to each sample  
286 age and then converted to  $\delta D$  values using the global meteoric water line (Craig, 1961).

287

## 288 5. Results

289 This study focusses on the last 32 cal ka BP (c. 590 cm). The average temporal resolution  
290 between the 62 samples analysed for  $\delta^{13}\text{C}$  and  $\delta D$  is c. 500 years. From 590 to 70 cm (c. 32–2 cal kyr  
291 BP) the core is very dark brown in colour containing peat with humus, fine detritus and silt. From 70  
292 cm to core top, the sediments are similar in colour to the peat below and contain fibrous peat with  
293 humus and herbaceous fine detritus (Humphries et al., 2017). Between 457 and 358 cm (c. 23–14 cal  
294 kyr BP; comprising the LGM) mean grain sizes average at 110  $\mu\text{m}$ , with smaller diameters averaging  
295 at 50  $\mu\text{m}$  between 298 and core top (c. 11 cal kyr BP–present, Holocene; Fig. 4g). The lithology of  
296 core MF4-12 does not exactly match with that observed from core SL6 (Baker et al., 2014; 2016;  
297 2017), although sandy peat is observed during the LGM at both locations. This result is not surprising  
298 as multiple cores taken in transects across the bog indicate peat heterogeneity (Grundling et al.,  
299 2013).

300 Long chain *n*-alkane CPI values are generally around 6 (ranging from 2–13), indicating good *n*-  
301 alkane preservation. The two samples with CPI values of 2, potentially containing more degraded *n*-  
302 alkanes, are highlighted in red (Fig. 4b & c; Fig. 5b & c; Fig. 6f & g). However, the in- or exclusion of  
303 these samples does not affect the observed pattern of changes and we thus consider the record to  
304 be suitable for palaeoclimate reconstruction. The samples contain *n*-alkanes with carbon chain  
305 lengths ranging from C<sub>17</sub>–C<sub>35</sub>, with C<sub>29</sub> and C<sub>31</sub> generally having the highest abundance. The high  
306 abundances of C<sub>29</sub> and C<sub>31</sub> enabled reliable isotopic analyses. The relationship between the  $\delta D$  and  
307  $\delta^{13}\text{C}$  of the C<sub>29</sub> and C<sub>31</sub> *n*-alkanes is strong, with  $R^2$  values of 0.8 and 0.9, respectively. Consequently,  
308 for the  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta D_{\text{wax}}$ , we use the amount-weighted mean of the C<sub>29</sub> and C<sub>31</sub> *n*-alkanes.

309 The  $\delta^{13}\text{C}_{\text{wax}}$  values range from -29‰ to -21‰ (Fig. 4b). The ice volume  $\delta D$  correction  
310 decreases the glacial Mfabeni  $\delta D_{\text{wax}}$  values by <8 ‰ (Fig. 4c). The ice-corrected  $\delta D_{\text{wax}}$  values of the *n*-  
311 C<sub>29</sub> and *n*-C<sub>31</sub> alkanes range from -181‰ to -128‰ (Fig. 4c).  $P_{\text{aq}}$  values range from 0.02–0.7, averaging  
312 at 0.2 (Fig. 4f).

313 During the LGM,  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  values are relatively high averaging at -23‰ and c. -136‰,  
314 respectively (Fig. 4b & c) and  $P_{\text{aq}}$  values are low (c. 0.24; Fig. 4f). At c. 19 cal ka BP a 4‰ negative shift  
315 in  $\delta^{13}\text{C}_{\text{wax}}$  values occurs (Fig. 4b). This negative shift in  $\delta^{13}\text{C}_{\text{wax}}$  is concurrent with a gradual shift to  
316 lower  $\delta\text{D}_{\text{wax}}$  values (Fig. 4c) and an increase in  $P_{\text{aq}}$  values (Fig. 4f). Between 14 and 5 cal kyr BP,  $\delta^{13}\text{C}_{\text{wax}}$   
317 values are relatively stable and average at -28‰ (Fig. 4b).  $\delta\text{D}_{\text{wax}}$  values become gradually lower  
318 during this period reaching -173‰ at 7.5 cal ka BP. At 5 cal ka BP,  $\delta\text{D}_{\text{wax}}$  values shift towards more  
319 positive values by 16‰ (Fig. 4c). Relatively high  $P_{\text{aq}}$  values occur between 14–5 cal kyr BP (Fig. 4f).  
320 After c. 5 cal ka BP several high amplitude millennial-scale fluctuations in both  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$   
321 values are evident. These fluctuations interrupt a trend where the isotope values of both  $\delta^{13}\text{C}_{\text{wax}}$  and  
322  $\delta\text{D}_{\text{wax}}$  gradually increase towards present day. A pronounced shift to higher  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  values  
323 occurs at 2.8 cal ka BP. From c. 900 cal yr BP,  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  values become higher reaching core  
324 top values of -21 and -128‰, respectively (Fig. 4b & c). Generally high, but variable and rapidly  
325 fluctuating  $P_{\text{aq}}$  values are evident between c. 5–0 cal kyr BP.  $P_{\text{aq}}$  values decrease substantially after  
326 1.3 cal ka BP from 0.6 to a core top value of c. 0 (Fig. 4f).

327

## 328 6. Discussion

### 329 6.1 Interpretation of the proxy signals

330 The relatively high  $\text{CPI}_{27-33}$  values indicate that the long-chain *n*-alkanes within the peat are  
331 derived from terrestrial higher plants and are relatively non-degraded. The long-chain *n*-alkanes are  
332 likely sourced directly from the local vegetation surrounding the coring location. It is possible that  
333 during times of stronger wind strength (i.e., during the LGM; Humphries et al., 2017) increased  
334 aeolian transport resulted in a higher biomarker contribution from more distal sources (i.e., the  
335 surrounding dune vegetation). Good preservation of *n*-alkanes in Mfabeni peat was also observed in  
336 nearby core SL6, but this was based on a CPI calculated using *n*- $\text{C}_{21-31}$  (Baker et al., 2016). No  
337 relationship exists between the CPI and  $P_{\text{aq}}$  ( $R^2 = 0.11$ ), which suggests that CPI variations at the  
338 location of core MF4-12 are not related to changes in organic matter preservation due to water table  
339 level variations.

340 The main source of carbon for terrestrial higher plants (the source of the  $\text{C}_{29}$  and  $\text{C}_{31}$  *n*-alkanes) is  
341 atmospheric  $\text{CO}_2$ , whereas aquatics also assimilate dissolved carbon, complicating the interpretation  
342 of their carbon isotope signal. We thus focus solely on  $\text{C}_{29}$  and  $\text{C}_{31}$  *n*-alkanes that are predominantly  
343 derived from terrestrial plants (Eglinton and Hamilton, 1967). The majority of the samples (67 %)   
344 have dominant *n*-alkane chain lengths of  $\text{C}_{29}$  and  $\text{C}_{31}$ . For the remaining 33 % of the samples,  
345 concentrated between 6 and 1.1 cal kyr BP, the dominant chain length switched to *n*- $\text{C}_{25}$ , indicating a  
346 higher *n*-alkane input from submerged macrophytes (Ficken et al., 2000). The *n*- $\text{C}_{25}$  are unlikely to be  
347 sourced from mosses, as mosses are rare in subtropical peatland environments (Baker et al., 2016).

348 Instead, the C<sub>25</sub> is likely mainly derived from aquatic plants, which produce mid-chain *n*-alkanes as  
349 dominant homologues (C<sub>20</sub>–C<sub>25</sub>; Ficken et al., 2000). This increase of *n*-alkanes sourced from aquatic  
350 plants *c.* 6–1.1 cal kyr BP is unlikely to have had any impact on the isotopic composition of the long-  
351 chain *n*-alkanes (C<sub>29</sub> and C<sub>31</sub>) as these are minor components in aquatic plants (e.g., Aichner et al.,  
352 2010). Therefore, we interpret the  $\delta^{13}\text{C}_{\text{wax}}$  as changes in the C<sub>3</sub>/C<sub>4</sub> ratio of terrestrial higher plants.

353 Grasses exhibiting the C<sub>4</sub> or C<sub>3</sub> photosynthetic pathway in South Africa are largely  
354 geographically separated, with C<sub>4</sub> grasses dominant within the SRZ and C<sub>3</sub> grasses more prevalent in  
355 the YRZ, WRZ and at higher altitudes (Vogel et al., 1978). As C<sub>4</sub> grasses require less water to fix CO<sub>2</sub>,  
356 thus having greater water-use efficiency than C<sub>3</sub> grasses, C<sub>4</sub> photosynthesis is favored in arid regions  
357 (e.g. Downes, 1969; Osborne and Sack, 2012). C<sub>4</sub> grasses also have the potential to achieve higher  
358 rates of photosynthesis than C<sub>3</sub> particularly at high irradiance and temperature levels (Black et al.,  
359 1969; Monteith, 1978), as their more efficient carbon fixation has a higher energy demand (Sage,  
360 2004). Today growing season temperatures are a controlling factor for the distribution of C<sub>4</sub> and C<sub>3</sub>  
361 grasses (with C<sub>4</sub> grasses having an advantage over C<sub>3</sub> grasses at higher temperatures; Sage et al.,  
362 1999). Consequently C<sub>4</sub> grasses are mainly found in warm and dry environments such as the African  
363 savannas (Beerling and Osborne, 2006). Furthermore, under reduced atmospheric (i.e., glacial) CO<sub>2</sub>,  
364 the higher carbon fixation efficiency of C<sub>4</sub> grasses provides an important advantage over C<sub>3</sub> grasses  
365 (Sage, 2004; Pinto et al., 2014). Previous palynological studies indicate that the dominant  
366 components of the pollen assemblage at Mfabeni are Poaceae and Cyperaceae (Finch and Hill, 2008).  
367 Although Cyperaceae species can be either C<sub>3</sub> or C<sub>4</sub>, most Cyperaceae in eastern South Africa (67 %)  
368 are of the C<sub>4</sub>-type (Stock et al., 2004). The C<sub>4</sub> vegetation at Mfabeni is thus mostly Poaceae or  
369 Cyperaceae from the sedge and reed fen. The C<sub>3</sub> vegetation at Mfabeni is comprised of arboreal taxa  
370 from the swamp forest (e.g., Myrtaceae and *Ficus*) and locally distributed *Podocarpus* (Finch and Hill,  
371 2008; Venter, 2003). Shifts to higher  $\delta^{13}\text{C}_{\text{wax}}$  values (more C<sub>4</sub>-type vegetation) at Mfabeni could  
372 indicate an expansion of grassland (at the expense of arboreal taxa), or a shift from C<sub>3</sub> to C<sub>4</sub> grasses,  
373 resulting from: i) less precipitation, ii) a longer/more intense dry season, iii) heightened ET, iv)  
374 reduced water table height, v) higher temperatures, vi) reduced atmospheric CO<sub>2</sub>, or vii) increased  
375 insolation levels (or any combination of the above).

376 The  $\delta\text{D}_{\text{wax}}$  reflects the  $\delta\text{D}_{\text{precip}}$ , ET and vegetation type. The  $\delta\text{D}_{\text{precip}}$  can be influenced by  
377 changes in air temperature, with an estimated temperature effect of *c.* 0.5‰ per 1°C for  $\delta^{18}\text{O}_{\text{precip}}$   
378 (Dansgaard, 1964). The maximum estimated temperature change of *c.* 6 °C in the SRZ of South Africa  
379 from the LGM to Holocene (Gasse et al., 2008), would thus correspond to a change in  $\delta^{18}\text{O}_{\text{precip}}$  of  
380 3‰. Conversion to changes in  $\delta\text{D}_{\text{precip}}$  using the global meteoric water line would thus lead to a  
381 potential LGM to Holocene  $\delta\text{D}_{\text{precip}}$  enrichment of 24‰ (Craig, 1961). However, the Mfabeni  $\delta\text{D}_{\text{wax}}$   
382 record shows a depletion in  $\delta\text{D}_{\text{wax}}$  from the LGM to the Holocene, rather than an enrichment. The

383 observed glacial  $\delta D$  depletion is therefore a conservative estimate. Consequently, changes in air  
384 temperature from the LGM to the Holocene did not exert a dominant control on Mfabeni  $\delta D_{wax}$ .

385 Changes in vegetation type ( $C_3/C_4$ ) have the potential to reduce or exaggerate shifts in  $\delta D_{wax}$ .  
386 There are differences in the apparent fractionation (the integrated isotopic fractionation between  
387 precipitation and plant-wax lipids) between plant types using different photosynthetic pathways.  $C_3$ -  
388 type shrubs and trees fractionate the least,  $C_4$ -type grasses slightly more, while  $C_3$ -type grasses show  
389 the highest apparent fractionation (Sachse et al., 2012). The difference in  $\delta D_{wax}$  between dicots ( $C_3$ ,  
390 shrubs, trees and forbs) and monocots ( $C_4$ , grasses) is likely the result of leaf architecture and the  
391 nature of water movement in the leaf. Monocots display progressive evaporative enrichment along  
392 parallel veins along the leaf, which does not occur in dicots. This grass-blade enrichment results in  
393 higher  $\delta D_{wax}$  values in  $C_4$  grasses (Helliker and Ehleringer, 2000). However, recent data suggest that  
394 the effect of  $C_3$ -tree to  $C_4$ -grass vegetation type changes on  $\delta D_{wax}$  is likely relatively small (Collins et  
395 al., 2013; Vogts et al., 2016).

396 The  $\delta D_{precip}$  is strongly controlled by the 'amount effect', where there is a negative correlation  
397 between monthly precipitation amount and  $\delta D_{precip}$  (Dansgaard, 1964). Close to the equator, passage  
398 of the tropical rainbelt can result in precipitation that is extremely depleted in D. Conversely, in arid  
399 regions, rainfall tends to be enriched in D, because of enhanced evaporation of the raindrops as they  
400 fall (Risi et al., 2008). Studies investigating the present-day relationship between precipitation  
401 amount and the isotopic variations in rainfall indicate shifts in  $\delta^{18}O$  of up to 15‰ (c. 120‰ in  $\delta D$ )  
402 with the passage of the tropical rainbelt and shifts in  $\delta^{18}O$  of 7‰ (c. 56‰ in  $\delta D$ ) with the passage of  
403 convective storms (Gat et al., 2001). During times of heightened ET and/or lower precipitation  
404 amount, soil waters become enriched in D (Sprenger et al., 2017). In addition, under conditions of  
405 low ambient relative humidity, leaf water becomes enriched in D through increased transpiration  
406 (Kahmen et al., 2013). Large values of isotopic enrichment (c. 40‰ in  $\delta^{18}O$ , 180‰ in  $\delta D$ ) are  
407 associated with the effects of evaporation (e.g., Cappa et al., 2003). The control of precipitation  
408 amount and ET on D operates in the same direction, and thus the mechanisms are not easily  
409 disentangled.

410 Mfabeni has high rates of ET, which can equal, or even exceed precipitation during dry  
411 periods (Grundling et al., 2015). Consequently, both precipitation amount and ET are likely to control  
412 the isotopic composition of soil and leaf waters, and subsequently of the leaf waxes at Mfabeni. High  
413  $\delta D_{wax}$  values at Mfabeni likely result from decreased summer precipitation amount and/or  
414 heightened ET. The similarity between the  $\delta D_{wax}$  pattern and the regional precipitation/aridity stacks  
415 (Fig. 4d & e; Chevalier and Chase, 2015; 2016) supports the inference that precipitation amount and  
416 ET drive Mfabeni  $\delta D_{wax}$ . Furthermore, this similarity indicates that the hydrological fluctuations in the

417 Mfabeni record represent hydrological change at a broader spatial scale (Fig. 4c–e), but also suggest  
418 that the pollen-based precipitation stacks may also include an element of ET variability.

419

## 420 6.2 Climatic and environmental conditions at Mfabeni over the last 32 cal ka BP

421 The  $\delta^{13}\text{C}_{\text{wax}}$ ,  $\delta\text{D}_{\text{wax}}$  and  $\text{P}_{\text{aq}}$  data from Mfabeni indicate that the vegetation, hydrology and the  
422 water table varied considerably over the last 32 cal ka BP (Fig. 4 & 5). The high  $\delta^{13}\text{C}_{\text{wax}}$  values during  
423 the LGM indicate that the vegetation was likely dominated by more drought-tolerant  $\text{C}_4$  plant types  
424 (Fig. 4b). Similar LGM  $\delta^{13}\text{C}_{\text{wax}}$  depletion was observed previously at Mfabeni (Fig. 4h; Baker et al.,  
425 2017). Drier conditions during the LGM correspond with low  $\text{P}_{\text{aq}}$  values that indicate a higher relative  
426 contribution of terrestrial-over-aquatic  $n$ -alkanes, likely a consequence of a lower water table (Fig.  
427 4f). The high  $\delta\text{D}_{\text{wax}}$  values during the LGM suggest decreased precipitation amount and/or higher ET,  
428 which are both consistent with a drier environment (Fig. 4c). We cannot completely rule out the  
429 possible impact of increased drainage of the peatbog during the LGM due to low eustatic sea level  
430 (Grundling et al., 2013). A lower water table during the LGM would likely serve to further soil water D  
431 enrichment. Nevertheless, the fact that the peat continued to grow during the LGM suggests that the  
432 sea level effect was minor. The organic geochemical proxies agree with palynological data indicating  
433 regional grassland dominance (high Poaceae, Cyperaceae and Asteraceae) with low amounts of  
434 arboreal taxa (Fig. 6; Finch and Hill, 2008). Regional aridity and increased wind strength during the  
435 LGM at Mfabeni are also indicated by increased mean grain size of the lithogenic sediment fraction  
436 (Fig. 4g), and the modal grain size of the distal aeolian component (Humphries et al., 2017). Evidence  
437 for reduced precipitation (from the regional precipitation stack; Fig. 4d) and high aridity (from the  
438 regional aridity stack; Fig. 4e) during the LGM, provide evidence that the dry conditions at Mfabeni  
439 appear to be part of a wider eastern South African pattern (Fig. 4d & e).

440 The shift to more negative  $\delta^{13}\text{C}_{\text{wax}}$  values following the LGM, at c. 19 cal ka BP, indicating that  
441 the vegetation at Mfabeni changed to more  $\text{C}_3$ -type (Fig. 4b), is also evident in Mfabeni core SL6 (Fig.  
442 4h; Baker et al., 2017). This change is thus likely representative of a  $\text{C}_4$ – $\text{C}_3$  change across the peat bog.  
443 The palynological record indicates no shift towards arboreal taxa at this time but instead a  
444 continuation of grasslands (Fig. 6a & b; Finch and Hill, 2008). A decrease in Cyperaceae percentages  
445 (as most Cyperaceae is of  $\text{C}_4$  type), may be responsible for the  $\text{C}_4$  to  $\text{C}_3$  shift observed in the  $\delta^{13}\text{C}_{\text{wax}}$   
446 record, but the gradual nature of the Cyperaceae decrease points to an additional driver (Fig. 6c). The  
447 shift is more likely the result of a switch from  $\text{C}_4$  to  $\text{C}_3$  grasses. If temperature was driving the  
448 vegetation shifts at Mfabeni, we would expect a shift from  $\text{C}_3$  to  $\text{C}_4$  grasses from the LGM to the  
449 Holocene (with a c. 6°C increase in temperature). Nevertheless, the LGM to Holocene shift from  $\text{C}_4$  to  
450  $\text{C}_3$  grasses suggests that temperature did not drive the vegetation change at Mfabeni. We suggest  
451 that the shift from  $\text{C}_4$  to  $\text{C}_3$  grasses may have been caused instead by i) more precipitation, ii) a

452 shorter/less intense dry season, iii) lower ET, and/or iv) increased water table height. Furthermore,  
453 with C<sub>3</sub> vegetation favored under lower insolation conditions, a decrease in local summer insolation  
454 from the LGM to Holocene (Fig. 4a) could have played a role in driving the vegetation shifts.

455 After c. 19 cal ka BP, the  $\delta^{13}\text{C}_{\text{wax}}$  values continue to decrease to -29‰ until they stabilize at c.  
456 14 cal ka BP. This trend in  $\delta^{13}\text{C}_{\text{wax}}$  values between c. 19 and 14 cal kyr BP, indicating an expansion of  
457 C<sub>3</sub> vegetation, corresponds well with the  $\delta^{13}\text{C}_{\text{wax}}$  record from Mfabeni core SL6 (Baker et al., 2017;  
458 Fig. 4b & 4h). There are, however, some minor differences between the two  $\delta^{13}\text{C}_{\text{wax}}$  records. We  
459 attribute these to small-scale variations in vegetation across the peatbog, the lower sampling  
460 resolution of core SL6 and to dating uncertainties in both records. The shift to lower  $\delta^{13}\text{C}_{\text{wax}}$  values at  
461 c. 19 cal ka BP occurs at the same time as a rise in the water table as documented by an increase in  
462  $P_{\text{aq}}$  values (Fig. 4f). An abrupt increase in precipitation amount and a decrease in aridity is evident in  
463 the precipitation and aridity stacks at c. 19 cal ka BP. All proxy records for precipitation (the regional  
464 stacks and the Mfabeni  $\delta D_{\text{wax}}$  data; Fig. 4) strongly suggest a switch to wetter conditions after c. 19  
465 cal ka BP.

466 The  $\delta^{13}\text{C}_{\text{wax}}$  values between 14–5 cal kyr BP reflect a stable period of C<sub>3</sub>-type vegetation (Fig.  
467 4b). At the same time, gradually decreasing  $\delta D_{\text{wax}}$  values indicate increasing humidity. The gradual  
468 increase in precipitation is also evident in the precipitation stack, but this trend is interrupted by an  
469 abrupt return to aridity at c. 14.2 cal ka BP, coinciding with the Antarctic Cold Reversal (Chase et al.,  
470 2017). This abrupt arid event is only evident in one sample at Mfabeni and thus higher resolution  
471 sampling is needed across this interval. The aridity stack indicates low aridity during this interval, but  
472 high variability suggests a complex interplay between high ET (from increased temperatures,  
473 resulting in less effective precipitation) and generally more precipitation (Fig. 4e). Pollen data from  
474 Mfabeni provide evidence for an expansion of arboreal type vegetation at c. 12 cal ka BP (Fig. 6a;  
475 Finch and Hill, 2008). The pollen data thus suggest the establishment of swamp forest vegetation  
476 during the early Holocene, indicative of a moist climate (Fig. 6a). Mfabeni aeolian sediment flux is  
477 low and stable throughout this period, also suggesting a moist climate (Humphries et al., 2017). The  
478 moist climate likely resulted in vegetated dunes, reducing the amount of material available for  
479 aeolian transport. The relatively high  $P_{\text{aq}}$  values between 14–5 cal kyr BP indicate a high and stable  
480 water table at this time (Fig. 4f). Elevated total organic carbon percentages within Mfabeni core SL6  
481 during the Holocene, also suggest increased water levels (Baker et al., 2017).

482 Between c. 5–0 cal kyr BP several high-amplitude millennial-scale C<sub>3</sub>/C<sub>4</sub> vegetation changes  
483 are evident superimposed on an overall shift from predominantly C<sub>3</sub> to more C<sub>4</sub>-type vegetation  
484 towards the present-day (Fig. 5b). This variability contrasts with the more gradual C<sub>4</sub>/C<sub>3</sub> vegetation  
485 transition from the glacial period to Holocene. The  $\delta^{13}\text{C}_{\text{wax}}$  values from Mfabeni core SL6 between c.  
486 6–1 cal kyr BP also indicate a period of predominantly C<sub>4</sub>-type vegetation, implying arid conditions

487 during this time (Baker et al., 2017; Fig. 4h). A similar pattern of a long-term trend with  
488 superimposed short-term variability is visible in the in  $\delta D_{\text{wax}}$  record. The general enrichment in D  
489 reflects gradual drying, punctuated by millennial-scale pulses of aridity, with the most pronounced  
490 arid event at c. 2.8 cal ka BP (Fig. 5c). Counterintuitively, the high abundance of  $n\text{-C}_{25}$  alkanes and  
491 high but variable  $P_{\text{aq}}$  values between c. 5–0 cal kyr BP indicate a generally high water table,  
492 interrupted by brief periods of a lower water table (Fig. 5d). After 2.3 cal ka BP, both  $\delta^{13}\text{C}_{\text{wax}}$  and  
493  $\delta D_{\text{wax}}$  values become higher and  $P_{\text{aq}}$  values lower (Fig. 5b–d). This suggests increased  $\text{C}_4$ -type  
494 vegetation cover, decreased summer precipitation amount and/or higher ET and low water table  
495 levels. A slight increase in precipitation followed by gradually decreasing precipitation over the last c.  
496 5 ka is evidenced in the precipitation stack (Fig. 4d). This initial increase in precipitation at c. 5 cal ka  
497 BP corresponds to an abrupt decrease in aridity (Fig. 4d & e). The increased variability observed in  
498 our records between 5–0 cal kyr BP could be an artefact of the high temporal resolution of our  
499 record during this interval ( $\sim 220$  vs  $\sim 700$  years per sample for the remainder of the record).  
500 Nevertheless, (Fig. 4d) other data from the region (e.g., Baker et al., 2017, Humphries et al., 2017;  
501 2016, Finch and Hill, 2008, Neumann et al., 2010) also indicate climatic instability and arid climatic  
502 conditions during the last c. 5 cal ka BP, suggesting that the observed variability is likely real (Fig. 5e).

503 It is interesting that modern  $\delta D_{\text{wax}}$  values and those during the LGM appear similar (Fig. 4c),  
504 implying similarly arid conditions during both periods. The southern aridity stack also indicates  
505 extremely arid conditions during the last few thousand years and the authors stress the importance  
506 of temperature in controlling aridity (Fig. 4e; Chevalier and Chase, 2016). It is possible that modern  
507 high mean annual temperatures drove these modern-day  $\delta D_{\text{wax}}$  values to appear similar to those  
508 from the LGM. High modern day temperatures, increase ET and result in less ‘effective precipitation’  
509 and arid conditions, even when rainfall is high (Chevalier and Chase, 2016). During the LGM, lower  
510 temperatures would have reduced ET, leading to apparent humid conditions, despite reduced rainfall  
511 amount.

512

### 513 *6.3 Climate driving mechanisms*

514 Modern observations suggest that high SSTs within the Mozambique Channel and Agulhas  
515 Current induce increased evaporation (e.g., Walker, 1990), resulting in higher rainfall in the SRZ  
516 (Tyson, 1999). Variations in local SSTs are thus thought to be an important driver of hydroclimate in  
517 eastern South Africa. This mechanism may also play a role on longer timescales. Indeed, Chevalier  
518 and Chase (2015) invoke SSTs as the dominant driver of precipitation variability during the LGM.  
519 Mfabeni vegetation and hydrology reconstructions over the last 32 cal ka BP do not show a clear  
520 relationship with changes in southwest Indian Ocean SSTs (Fig. 4j, Sonzogni et al., 1998). For example  
521 if SSTs drove the climate at Mfabeni then the abrupt shift to more  $\text{C}_3$  type vegetation and the gradual

522 shift to a wetter climate at c. 19 cal ka BP would be expected to correspond with an increase in SSTs.  
523 This is not the case, and SSTs do not increase until c. 15.7 ka (Sonzogni et al., 1998; Fig. 4). The lowest  
524 temperatures within the Mozambique Channel correspond to Heinrich Event 1 (SSTs c. 3°C colder  
525 than present day), an event which is not evident as a particularly arid period in the Mfabeni dataset.  
526 Mozambique Channel SSTs thus do not fully explain the variability observed in the records  
527 comprising the precipitation stack. These differences, as proposed previously by Chevalier and Chase  
528 (2015), suggest that SST variability is unlikely to be the sole driver of the changes in hydroclimate  
529 within this part of the SRZ. Chevalier and Chase (2015) proposed that the differences observed  
530 between SSTs and the records comprising the precipitation stack is due to the modulation of  
531 precipitation by the position of the westerlies.

532 We attribute the arid climate and the associated expansion of drought tolerant C<sub>4</sub> plants and  
533 a low water table at Mfabeni during the LGM, in part, to a northward displacement of the westerlies,  
534 the SIOCZ and the subtropical high-pressure cell, shifting the hydroclimate to a more evaporative  
535 regime, where ET exceeds precipitation. In addition, lower SSTs (Fig. 4j) in the Mozambique Channel  
536 at this time likely reduced moisture availability. It is possible that the combination of a northward  
537 displacement of these three systems (the westerlies, SIOCZ and subtropical high-pressure cell) and  
538 lower SSTs shifted the fine balance between precipitation and ET at Mfabeni towards higher ET rates  
539 during the LGM.

540 Palaeoenvironmental studies (e.g., Lamy et al., 2001; Lamy et al., 2010; Stuut and Lamy,  
541 2004), climate model simulations (e.g., Rojas et al., 2009; Toggweiler et al., 2006) and theoretical  
542 models (e.g., Cockcroft et al., 1987) provide evidence for an equatorward migration and  
543 strengthening of the southern hemisphere westerlies in response to the increased extent of Antarctic  
544 sea ice during the LGM. Records from the present WRZ such as Elands Bay Cave (Baxter, 1996),  
545 Pakhuis Pass (Scott, 1994) and Driehoek Vlei (Meadows and Sugden, 1993) indicate increased winter  
546 rainfall, interpreted as a northward shift and strengthening of the westerlies during the LGM (Chase  
547 and Meadows, 2007). An equatorward migration of the westerlies may have expanded the limit of  
548 the WRZ in South Africa northward, to around 25°S in the west and 30°S in the east (Cockcroft et al.,  
549 1987). This would have put Mfabeni (at 28°S) within the range of the southern westerlies. Although  
550 during the LGM the westerlies were in a more northerly position, and had the potential to provide  
551 rainfall (via the passage of more cold fronts; Nkoana et al., 2015), we do not see any evidence for  
552 increased precipitation at Mfabeni. Today mid-latitude cyclones (frontal systems; Fig. 1b) associated  
553 with the westerlies trigger rainout of atmospheric moisture, sourced from the Indian Ocean and  
554 Agulhas Current, during the winter months (Gimeno et al., 2010). However, the co-occurring  
555 subtropical high-pressure cell over the South African interior may have limited the amount of  
556 moisture advection towards Mfabeni, thus even with increased cyclone occurrence, arid conditions

557 persisted. Furthermore, with a northerly displaced subtropical high-pressure cell inhibiting  
558 monsoonal penetration, the duration of the dry season at Mfabeni may have been extended,  
559 shortening the rain season and heightened ET rates.

560 A northward migration and strengthening of the westerlies is also associated with a northerly  
561 displaced and weaker South Indian Anticyclone (Fig. 1; Cohen and Tyson, 1995). A weakening of the  
562 western portion of the South Indian Anticyclone results in a northeastward shift of the SIOCZ (and  
563 the rain-bearing cloud band associated with TTTs; Cook, 2000). This northeastward shift results in  
564 higher precipitation over coastal Africa (around 15°N) and Madagascar and lower than normal  
565 precipitation to the south, in eastern South Africa (Cook, 2000). We propose that a northeastward  
566 shift of the SIOCZ during the LGM may have also played a key role in driving aridity at Mfabeni.

567 The latitudinal position of the subtropical high-pressure cell is highly correlated to rainfall  
568 variability along the eastern coast of South Africa (Dyson and van Heerden, 2002). Multivariate  
569 analysis of zonal moisture fluxes in South Africa indicates that the latitudinal position of the  
570 subtropical high-pressure cell directly controls the amount of moisture advection (monsoonal  
571 penetration) towards the southern African interior during the summer months (Vigaud et al., 2009).  
572 When the cell is shifted southward, during the summer, the tropical easterlies are able to penetrate  
573 further inland, resulting in higher continental moisture availability (Vigaud et al., 2009). Conversely,  
574 when the cell is shifted northward, during the winter, monsoonal circulation south of 25°S is  
575 impeded, creating a deficit in moisture advection from the ocean to the continent (Tyson and  
576 Preston-Whyte, 2000; Vigaud et al., 2009). A more northerly location of the subtropical high-pressure  
577 cell, during the LGM, would have lengthened the dry season, resulting in aridity at Mfabeni.

578 We suggest that the shift to more humid conditions at c. 19 cal ka BP was related to the  
579 retreat of the westerlies, the subtropical high-pressure cell and the SIOCZ, as Antarctic sea ice began  
580 to retreat poleward (Fig. 4k), allowing an increased influence of the moist tropical easterlies. With  
581 the subtropical high-pressure cell further south, stronger easterly flux from the Indian Ocean likely  
582 enhanced the development of TTTs in the region leading to increased precipitation. This shift at c. 19  
583 cal ka BP was unlikely driven by a change in local summer insolation because insolation was  
584 decreasing at this time. We suggest that the abrupt shift to more C<sub>3</sub> vegetation was a non-linear  
585 response to increasing moisture availability in the region (Fig. 4c). Precipitation amount may have  
586 reached a critical threshold at c. 19 cal ka BP for the establishment of C<sub>3</sub> type vegetation, resulting in  
587 the observed abrupt vegetation shift (Fig. 4b).

588 Between 14–5 kyr BP, a reduced extent of Antarctic sea ice (Fig. 4k & 5g), resulted in a more  
589 poleward position of the westerlies and the subtropical high-pressure cell. The diminished effect of  
590 the westerlies and the subtropical high-pressure cell in eastern South Africa at this time permitted  
591 the tropical systems (easterlies), to dominate the climatic regime at Mfabeni. With a strengthened

592 (but poleward displaced) South Indian Anticyclone the SIOCZ was likely situated over Mfabeni  
593 resulting in increased rainfall. Strong easterly flux would have increased the development of TTTs in  
594 the region, resulting in higher humidity at Mfabeni. Increasing humidity at Mfabeni during the  
595 Holocene, corresponds with increasing southern hemisphere summer insolation (Fig. 4a). The  
596 importance of insolation for South African climate variability during the late Quaternary has been  
597 suggested before (e.g., Partridge et al., 1997; Simon et al., 2015). Our results support the hypothesis  
598 that insolation control on precipitation variability was only significant during the Holocene (e.g.,  
599 Schefuß et al., 2011; Chevalier and Chase, 2015). We suggest that direct local insolation forcing is  
600 only dominant in this region when the westerlies and subtropical high-pressure cell are located far  
601 south, which allows monsoonal precipitation to penetrate into the continent during the summer  
602 months.

603 To explain the millennial-scale climatic variability over the glacial-interglacial transition  
604 within their central and eastern African sites (which also includes Mfabeni), Chevalier and Chase  
605 (2015) and Chase et al. (2017) suggest that this region may be influenced by the position and the  
606 intensity of the westerlies, and the interactions between the westerlies and the tropical easterlies  
607 (resulting in TTT development). We highlight the importance of the location of TTT development (i.e.,  
608 the SIOCZ) and stress the interconnections between TTT development, the latitudinal position of the  
609 westerlies and the subtropical high-pressure cell on glacial-interglacial timescales.

610 After c. 5 cal ka BP, palaeoenvironmental records from both the WRZ and YRZ, such as from  
611 Verlorenvlei (Fig. 1; Fig. 5f; Carr et al., 2015), Seweweekspoort (Fig. 1; Fig. 4i; Chase et al., 2017),  
612 Klaarfontein (Fig. 1; Meadows and Baxter, 2001), Cecilia Cave (Fig. 1; Baxter, 1989) and Eilandvlei  
613 (Wündsche et al., 2018), document increased moisture availability, implying a recurring more  
614 northerly location of the westerlies. Chevalier and Chase et al. (2015) propose that increased  
615 precipitation in the WRZ during the late Holocene was due to both the warmer interglacial climate  
616 and the northward expansion of the westerly storm tracks. Although no indication for an increase in  
617 sea ice is evident from EPICA salt concentration data (Fig. 4k), diatom data (*Fragilariopsis curta* and *F.*  
618 *cylindrus*) from PS2090/ODP1094 in the southern South Atlantic document an increase in sea ice  
619 during the late Holocene (Fig. 5g), which may have pushed the southern westerlies equatorward. In  
620 addition, climate modelling results imply a northward shift of the southern westerlies at this time  
621 (Hudson and Hewitson, 2001). Consequently, in a comparable way to the LGM, the increased sea ice  
622 during the late Holocene (Fig. 5g), may have displaced (and strengthened) the westerlies, the South  
623 African high-pressure system and the SIOCZ equatorward, resulting in higher aridity at Mfabeni. A  
624 slight decrease in Mozambique Channel SSTs may have also played a role in the generally arid climate  
625 at Mfabeni during the last c. 5 cal ka BP (Fig. 4j; Sonzogni et al., 1998). Interestingly, the hydrological  
626 variability at Mfabeni (Fig. 5c) during the last c. 5 cal ka BP, is not present in the central and eastern

627 South African precipitation stack (Fig. 4d). We attribute this to the highly sensitive balance between  
628 ET and precipitation at Mfabeni (Grundling et al., 2015), and the fact that the precipitation stack  
629 smooths local hydrological variability.

630 It is possible that anthropogenic influences also played a role in shaping the environment at  
631 Mfabeni, at least, during the late Holocene. However, unequivocal agricultural and exotic pollen  
632 indicators are absent from the pollen record and although pollen data indicate that forest decline  
633 occurred during the late Holocene, it is unclear whether this was related to human influence or  
634 regional climate change (Fig. 6; Finch and Hill, 2008). The forest decline could have affected the  
635 water table and increased the relative amount of C<sub>4</sub>-type vegetation. The appearance of *Morella* and  
636 *Acacia* in the late Holocene may indicate the development of open vegetation or secondary forest  
637 due to fire disturbance (Fig. 6e; Finch and Hill, 2008). Human activities or climate change may be  
638 responsible for changes in fire regime. With no palaeo-charcoal data available for Mfabeni yet, no  
639 direct evidence for increased fire activity during the late Holocene exists. In addition, the  
640 palaeoenvironmental evidence available suggests that the arid conditions during the late Holocene  
641 were regional in nature (Scott, 1999; 2003; Humphries et al., 2016, Neumann et al., 2010). Thus, any  
642 human activity was unlikely the primary cause of the late Holocene regional aridity and the large  
643 magnitude of environmental changes observed at Mfabeni.

644 Today ENSO activity is one of the most important driving mechanisms for inter-annual  
645 climatic variability in South Africa. Southern Africa's seasonal rainfall is linked to ENSO, with dry (wet)  
646 conditions associated with El Niño (La Niña) events (Archer et al., 2017; Mason and Jury, 1997).  
647 Interannual variability in the strength and position of the SIOCZ is linked to ENSO variability (Cook,  
648 2000). During La Niña years, the SIOCZ is located over the continent, resulting in wet conditions in  
649 eastern South Africa. During El Niño, the SIOCZ shifts northeastward over the Indian Ocean and as a  
650 consequence, dry conditions prevail in eastern South Africa (Lindesay, 1988; Cook, 2001; Hart et al.,  
651 2018). Furthermore, during El Niño events, a northward shift of the westerlies may occur, which  
652 could increase rainfall over western South Africa but lead to aridity in the east (i.e., at Mfabeni;  
653 Lindesay, 1988). Palaeoenvironmental studies in the Pacific Basin and South America indicate that  
654 during the early Holocene El Niño events were smaller and occurred less frequently, with a shift to  
655 stronger ENSO activity after c. 5 cal ka BP (Fig. 5h, Moy et al., 2002; Huffman, 2010; Rodbell et al.,  
656 1999; Sandweiss et al., 1996). It is difficult to disentangle the possible potential drivers of climate  
657 variability during the last c. 5 cal ka BP at Mfabeni. We therefore invoke a possible combination of  
658 northerly-displaced westerlies, lower SSTs and the impact of ENSO variability as potential climatic  
659 drivers during this time.

660

## 661 **7. Conclusions**

662 Compound specific carbon and hydrogen isotope data and *n*-alkane distributions ( $P_{aq}$ ) from  
663 Mfabeni peatbog are used to reconstruct climatic conditions, over the last 32 cal ka BP in eastern  
664 South Africa. The LGM at Mfabeni was characterized by a high contribution of  $C_4$  grasses, low  
665 precipitation amount/high ET and a low water table. We attribute the arid LGM conditions to an  
666 equatorward displacement (and strengthening) of the southern hemisphere westerlies, the SIOCZ  
667 and the subtropical high-pressure cell, which may have extended the length and increased the  
668 intensity of the dry season, as well as shifted the location of TTT formation northeast of Mfabeni.  
669 These mechanisms for driving LGM climate in South Africa are consistent with an increase in  
670 Antarctic sea ice extent. Between *c.* 19–5 cal kyr BP an expansion of  $C_3$ -type vegetation occurred,  
671 with more rainfall and a higher water table at Mfabeni. At *c.* 19 cal ka BP, a southward retreat of the  
672 westerlies, the SIOCZ and the subtropical high-pressure cell occurred, coincident with a retreat in  
673 Antarctic sea ice. This ice retreat combined with an increase in local summer insolation, after *c.* 12 cal  
674 ka BP, may have resulted in more precipitation and an increased wet season length at Mfabeni.  
675 When the westerlies, the SIOCZ and the subtropical high-pressure cell were in their southernmost  
676 position (*c.* 14–5 cal kyr BP), local insolation became the dominant control on Mfabeni climate,  
677 leading to stronger convection and enhanced monsoonal precipitation from the tropical easterlies.  
678 The late Holocene (*c.* <5 cal ka BP) was characterized by increased environmental instability and  
679 increasingly arid conditions. We attribute these trends to concurring low SSTs, and the recurring  
680 influence of the southern westerlies and/or heightened ENSO activity.

681 The Mfabeni record indicates that climate and environmental variability in eastern South  
682 Africa over the last 32 cal ka BP were driven by a combination of i) enhanced/reduced moisture  
683 transport by the tropical easterlies, driven by variations in southern hemisphere summer insolation,  
684 and ii) latitudinal displacements (and the strengthening/weakening) of the westerlies, the SIOCZ and  
685 the subtropical high-pressure cell. With the expansion and retreat of Antarctic sea ice ultimately  
686 responsible for the displacement of these systems, we invoke high-latitude climate forcing as an  
687 important driver of climate in eastern South Africa.

688

689 **Data availability:** Supplementary data for the depth-age model (**S1**) is available with this manuscript.  
690 A new depth-age model of core MF1 (Finch and Hill, 2008), produced by Bacon, can be found within  
691 the supplementary information (**S2**). Other data is available on PANGAEA.

692

693 **Author contributions:** CM and ES conducted  $\delta^{13}C_{wax}$  and  $\delta D_{wax}$  analyses. Interpretation was carried  
694 out by CM, JF, TH, FP, MH, MZ and ES.

695

696 **Competing interests:** The authors declare no competing financial interests.

697

698 **Acknowledgements:** This research was funded by the Bundesministerium für Bildung und Forschung  
699 (BMBF; RAiN project 03G0840A/B) and NRF Grant 84431 (JF). We thank R. Kreutz for assistance with  
700  $\delta^{13}\text{C}_{\text{wax}}$  and  $\delta\text{D}_{\text{wax}}$  data acquisition.

747 isotope data from Verlorenvlei (Carr et al., 2015). **g)** An estimation of the extent of Antarctic sea ice  
748 based on the abundance of *Fragilariopsis curta* and *Fragilariopsis cylindrus* at site PS2090/ODP1094  
749 (SW of Cape Town; Bianchi and Gersonde, 2004). **h)** Red colour intensity time-series from Laguna  
750 Pallcacocha. High values are light coloured inorganic clastic laminae, which were deposited during  
751 ENSO-driven episodes (Moy et al., 2002). The Mfabeni sample with a CPI value of *c.* 2 is highlighted in  
752 red (5b & c).

753

754 **Figure 6.** Summary figure highlighting the main climate phases and driving mechanisms at Mfabeni.  
755 All pollen data is from Finch and Hill (2008). Note, the new age model for pollen % data is in the  
756 supplementary material (S2). **a)** *Podocarpus* % data from Mfabeni. **b)** Poaceae % data from Mfabeni.  
757 **c)** Cyperaceae % data from Mfabeni. **d)** Asteraceae % data from Mfabeni. **e)** *Morella serrata* % data  
758 from Mfabeni. Poaceae and Cyperaceae were excluded from the regional pollen sum so their  
759 percentages are based on total pollen frequencies. *Podocarpus*, Asteraceae and *M. serrata*  
760 percentages are based on regional frequencies. See Finch and Hill (2008) for more details. **f)** Stable  
761 carbon isotopic composition (weighted mean) of  $C_{29}$ – $C_{31}$  *n*-alkanes from Mfabeni. **g)** Hydrogen  
762 isotope composition (weighted mean) of  $C_{29}$ – $C_{31}$  *n*-alkanes from Mfabeni. Red is the  $\delta D_{wax}$  corrected  
763 for ice volume changes. The two Mfabeni samples with CPI values of *c.* 2 are highlighted in red. Blue  
764 shading = Mfabeni wet, orange = Mfabeni arid.
