20  
21 **Abstract.** Currently, the rate of global warming has led to persistent drought patterns. It is  
22 considered to be the preliminary reason affecting socio-economic development under the  
23 background of dynamic forecasting of water supply and forest ecosystems in West Asia.

24 However, long-term climate records in the semi-arid Chitral Mountains of northern Pakistan are  
25 seriously lacking. Therefore, we developed a new tree-ring width chronology of *Cedrus deodara*  
26 spanning the period of 1537-2017. We reconstructed the March-August Palmer Drought  
27 Sensitivity Index (PDSI) for the past 424 years back to A.D. 1593. Our reconstruction was  
28 featured with nine dry and eight wet periods 1593-1598, 1602-1608, 1631-1645, 1647-1660,  
29 1756-1765, 1785-1800, 1870-1878, 1917-1923, 1981-1995, and 1663-1675, 1687-1708, 1771-  
30 1773, 1806-1814, 1844-1852, 1932-1935, 1965-1969 and 1996-2003, respectively. This  
31 reconstruction is consistent with other dendroclimatic reconstructions in west Asia, confirming  
32 its reliability. The analysis of multi-taper method and wavelet analysis revealed drought  
33 variability at periodicities of 2.1-2.4, 3.3, 6, 16.8, and 34-38 years. The drought patterns could be  
34 linked to the broad-scale atmospheric-oceanic variability such as El Niño-Southern Oscillation  
35 (ENSO), Atlantic Multi-decadal Oscillation (AMO) and solar activity. In terms of current  
36 climate conditions, our findings have important implications for developing drought-resistant  
37 policies in communities on the fringes of Hindu Kush mountain Ranges in northern Pakistan.  
38 Keywords: Tree rings, Growth-climate response, Drought variability, ENSO, dendroclimatology,  
39 the broad-scale atmospheric-oceanic variability

40

## 41 **1. Introduction**

42 Numerous studies have shown that the intensity and frequency of drought events have  
43 increased due to rapid climate warming (IPCC, 2013; Trenberth et al., 2014). The apparent  
44 drought has had serious adverse effects on social, natural, and economic systems (Ficklin et al.,  
45 2015; Yao and Chen, 2015; Tejedor et al., 2017; Yu et al., 2018). Global drought is considered to

46 be the most destructive climate disaster that has caused billions of dollars in worldwide loss (van  
47 der Schrier et al., 2013; Lesk et al., 2016).

48 Pakistan has a semi-arid climate, and its agriculture economy is most vulnerable to drought  
49 (Kazmi et al., 2015; Miyan, 2015). The long-term drought from 1998 to 2002 reduced  
50 agricultural production, with the largest reduction in wheat, barley and sorghum (from 60% to  
51 80%) (Ahmad et al., 2004). The northern Pakistan is considered to be the world's largest area of  
52 irrigation network (Treydte et al., 2006). The production and life of local residents are strongly  
53 dependent on monsoon precipitation brought by the mighty ocean and atmospheric circulation  
54 system, including El Niño Southern Oscillation (ENSO), Atlantic Multi-decadal Oscillation  
55 (AMO), Pacific Decadal Oscillation (PDO) and others (Treydte et al., 2006; Cook et al., 2010;  
56 Miyan, 2015; Zhu et al., 2017). However, the current warming rate has changed the regional  
57 hydrological conditions, leading to an unsustainable water supply (Hellmann et al., 2016; Wang  
58 et al., 2017). It is not only critical for agricultural production but also leads to forest mortality,  
59 vegetation loss (Martínez-Vilalta and Lloret, 2016) and increases the risk of wildfires (Turner et  
60 al. 2015; Abatzoglou and Williams 2016). The degradation of grassland and loss of livestock  
61 caused by drought eventually affect the lifestyle of nomadic peoples, especially in high-altitude  
62 forested areas (Pepin et al., 2015; Shi et al., 2019).

63 The Hindu Kush Himalayan region (HKH) is the source of ten major rivers in Asia, which  
64 provides water resources for one fifth of the world's population (Rasul, 2014; Bajracharya et al.,  
65 2018). The region is particularly prone to drought, floods, avalanches and landslides, with more  
66 than 1 billion people exposed to increasing frequency and serious risks of natural disasters  
67 (Immerzeel et al., 2010; Immerzeel et al., 2013). The extent of climate change in this area is  
68 significantly higher than the world average, which has seriously threatened the safety of life and

69 property, traffic and other infrastructure in the downstream and surrounding areas (Lutz et al.,  
70 2014). Dry conditions are exacerbated by an increase in the frequency of heatwaves in recent  
71 decades (Immerzeel et al., 2010; IPCC, 2013). The intensity and frequency of drought trend are  
72 very complex in HKH, and there is no manifest measuring tool to compute how long the drought  
73 period might persist. Climate uncertainty complicates the situation, for example, whether the  
74 drought trend is increasing or decreasing (Chen et al., 2019). Most studies believe that the  
75 wetting trend in HKH is going to increase in current decades (Treydte et al., 2006). However,  
76 some extreme drought events in the region are very serious and persistent (Gaire et al., 2017).  
77 Little has been done to examine the linkage between drought trend and large-scale ocean climate  
78 drivers (Cook et al., 2003; Gaire et al., 2017). Besides in northern Pakistan, there is little research  
79 on the dendroclimatology and instrumental climate records are inadequate in terms of quality and  
80 longevity (Treydte et al., 2006; Khan et al., 2019). In high altitude, arid and semi-arid areas,  
81 forest growth more sensitive to climate change, so dare need to understand more about the long-  
82 term drought regimes of the past (Wang et al., 2008). Climate reconstruction is the best way to  
83 understand long-term climate change and expand climate record to develop forest management  
84 strategies. Researchers used multiple proxies, including ice cores, speleothems, lake sediments,  
85 and historical documents and tree rings to reconstruct past short-term or long-term climate  
86 change. In addition, tree rings were widely used in long-term paleoclimatic reconstructions and  
87 forecasting future climate because of their accurate dating, high resolution, wide distribution,  
88 easy access, long time series, and abundant environmental information recorded (Esper et al.,  
89 2016; Zhang et al., 2015; Klippel et al., 2017; Shi et al., 2018; Chen et al., 2019)

90 In this study, we collected drought-sensitive tree-ring cores of *Cedrus deodar* from the upper  
91 and lower HKH region of Pakistan. These tree rings have a good potential for dendroclimatic study

92 (Yadav, 2013). Then, the March-August **Palmer Drought Sensitivity Index (PDSI)** was  
93 reconstructed for the past 424 years to examine the climatic variability and driving forces. To  
94 verify its reliability, we compared our reconstructed PDSI with other available paleoclimatic  
95 records (Treydte et al., 2006) near our research area. The intensity and drought mechanism in this  
96 area were also discussed. This will be the first time that the drought index has been reconstructed  
97 in northern Pakistan and is considered to be a baseline for more tree-ring reconstruction in  
98 Pakistan.

99

## 100 **2 Material and Methods**

### 101 **2.1 Study area**

102 We conducted our research in the Chitral, Hindu-Kush (HK) Mountains of northern  
103 Pakistan (35.36° N, 71.48° E, Fig. 1). Northern Pakistan is a subtropical monsoon climate.  
104 Summer is dry and hot, spring is wet and warm, and in some high altitudes, it snows all the year-  
105 round. March is the wettest month (with an average precipitation of 107 mm), while July or  
106 August is the driest (with an average precipitation of 6.3 mm). July is the hottest month (mean  
107 monthly temperature 36 °C), and January is the coldest (mean monthly temperature -0.8 °C) (Fig.  
108 2). The soil at our sampling sites is acidic, with little variation among a stand of forest. Similarly,  
109 the soil water holding capacity ranged from 47%±2.4% to 62%±4.6%, while the soil moisture  
110 ranged from 28%±0.57% to 57%±0.49% (Khan et al., 2010). Chitral forest is mainly composed  
111 of *Cedrus deodara*, *Juglans regia*, *Juniperus excelsa*, *Quercus incana*, *Q. diltata*, *Q. baloot* and  
112 *Pinus wallichiana*. *C. deodara* was selected for sampling because of the high dendroclimatic  
113 value (Khan et al., 2013).

114 Climate data such as monthly precipitation and temperature (1965-2016) were obtained  
115 from the meteorological station of Chitral in northern Pakistan. PDSI downloaded from the  
116 datasets of the nearest grid point (35.36° N, 71.48° E) through Climatic Research Unit (CRU  
117 TS.3.22, 0.5° latitude × 0.5° longitude). The most common reliable period spanning from 1965 to  
118 2016 was used (<http://climexp.knmi.nl/>) for dendroclimatic studies (Harris et al., 2014; Shekhar,  
119 2015).

120 The Atlantic Multi-decadal Oscillation (AMO) index was downloaded from KNMI Climate  
121 Explorer [https://climexp.knmi.nl/data/iamo\\_hadsst.dat](https://climexp.knmi.nl/data/iamo_hadsst.dat) over the period 1890-2016. The  
122 reconstructed June-August South Asia Summer Monsoon (JJA-SASM) data was downloaded  
123 from Monsoon Asia Drought Atlas (MADA)  
124 <http://drought.memphis.edu/MADA/TimeSeriesDisplay.aspx> over the period 1300-2005.

125

## 126 **2.2 Tree rings collection and chronology development**

127 Tree-ring cores collected in Chitral forest from *C. deodara* trees, located in the northern  
128 area of Pakistan. To maintain the maximum climatic signals contained in tree rings, undisturbed  
129 open canopy trees were selected. One core per tree at breast height (~1.3 m above ground) was  
130 sampled using a 5.15 mm diameter increment borer (Haglöf Sweden, Langsele, Sweden). In  
131 addition, several ring-width series were also downloaded from the International Tree-Ring Data  
132 Bank from the Bumburet forest and Zairat forest (<https://www.ncdc.noaa.gov/paleo-search/>)  
133 collected in 2006 (Fig. 1).

134 All tree-ring samples were first glued than progressively mounted, dried, and polished  
135 according to a set procedure (Fritts, 1976; Cook and Kairiukstis, 1990). The preceding calendar

136 year was assigned and properly cross-dated. False rings were identified by Skeleton-plot and  
137 cross dated as mentioned in Stokes and Smiley (1968).

138 The cores were measured using the semi-automatic Velmex measuring system (Velmex,  
139 Inc., Bloomfield, NY, USA) with an accuracy of 0.001 mm. The COFECHA program was then  
140 used to check the accuracy of cross-dating and measurement (Holmes, 1983). All false one has  
141 been modified and the cores that didn't match the master chronology were not used to develop  
142 tree-ring chronology. For quality checks, the COFECHA 2002 program was used. (Holmes,  
143 1998). The synthesized tree-ring width chronology (Fig. 3) was built by the program R (Zang  
144 and Biondi, 2015). To preserve climate signals and avoid noise, appropriate detrending was  
145 introduced. Biological trends of tree growth associated with tree age were conservatively  
146 detrended by fitting negative exponential curves or linear lines (Fritts, 1976). The tree-ring  
147 chronology was truncated where the expressed population signal (EPS) was large than 0.85,  
148 which is a generally accepted standard for more reliable and potential climate signal results  
149 (Wigley et al., 1984; Cook and Kairiukstis, 1990). The mean correlation between trees ( $R_{bar}$ ),  
150 means sensitivity (MS) and EPS was calculated to evaluate the quality of chronology (Fritts,  
151 1976). Higher mean sensitivity and EPS were considered to be a strong response to climate  
152 change (Cook and Kairiukstis, 1990).

153

### 154 **2.3 Statistical analysis**

155 Correlation analysis was conducted between tree-ring indexes (TRI) and monthly  
156 temperature, precipitation, and PDSI (from previous June to current September, collected from  
157 the nearby stations or downloaded from KNMI). **Then, the PDSI was reconstructed according to**  
158 **the relationship between TRI and climate variables.** To test the validity and reliability of our

159 model, reconstruction was checked by the split-period calibration/verification methods subjected  
160 to different statistical parameters, including reduction of error (RE), coefficient of efficiency  
161 (CE), Pearson correlation coefficient ( $r$ ), R-square ( $R^2$ ), product mean test (PMT), sign test (ST)  
162 and Durban-Watson test (DWT) (Fritts, 1976). PMT is used to test the level of consistency  
163 between the actual and estimated values, taking into account the signs and magnitudes of  
164 departures from the calibration average (Fritts, 1976). ST expresses the coherence between  
165 reconstructed and instrumental climate data by calculating the number of coherence and  
166 incoherence, which is often used in previous studies (Fritts, 1976; Cook et al., 2010). DWT is  
167 used to calculate first-order autocorrelation or linear trend in regression residuals (Cook and  
168 Pederson, 2011; Wiles et al., 2015). The RE and CE larger than zero were considered skills  
169 (Fritts, 1976; Cook et al., 1999).

170 **According to the reference of Chen et al. (2019),** we defined the wet or dry years of our  
171 reconstruction with the PDSI value greater than or less than the mean  $\pm 1$  standard deviation. **The**  
172 **mean  $\pm 1$  standard deviation is easy to calculate the dry and wet years, which has been observed**  
173 **in different tree-ring PDSI reconstructions (Wang et al., 2008; Chen et al., 2019).** We assessed  
174 the dry and wet periods for many years based on strength and intensity.

175 Although there were few reconstructions in our study area, we compared our reconstruction  
176 with other available drought reconstructions near the study area (Treydte et al., 2006). The multi-  
177 taper method (MTM) was used for spectral analysis, and the Wavelet analysis was used to  
178 determine the statistical significance of band-limited signals embedded in red noise by providing  
179 very high-resolution spectral estimates that eventually give best possible option against leakage.  
180 To identify the local climate change cycle, the background spectrum was used (Mann and Lees,  
181 1996).

182

### 183 **3 Results**

#### 184 **3.1 Main climate limiting factors for *Cedrus deodar***

185 The statistical parameters of the tree-ring chronologies, including MS (0.16), Rbar (0.59),  
186 and EPS (0.94) indicated that there were enough common signals in our sampled cores, and our  
187 chronology is suitable for dendroclimatic study. According to the threshold of EPS (EPS > 0.85),  
188 1593-2016 was selected as the reconstruction period to truncate the period 1537-1593 of the  
189 chronology (Fig. 3).

190 The TRI was significantly positively correlated with monthly PDSI ( $p < 0.01$ ) (Fig. 4a).  
191 However, the TRI was positively correlated with the precipitation in October of the previous  
192 year and February-May of the current year, and negatively correlated with the precipitation in  
193 September of the previous year ( $p < 0.001$ ). The TRI was significantly positively ( $p < 0.001$ ) with  
194 the minimum temperature in September and December of the previous year and January and  
195 February of the current year (Fig. 4b). Similarly, the TRI was significantly negatively ( $p < 0.001$ )  
196 correlated the maximum temperature in January, October and December of the previous year and  
197 February-June of the current year. The TRI was only significantly positively correlated the  
198 maximum temperature in September (Fig. 4b).

199

#### 200 **3.2 Reconstruction of the past drought variation in northern Pakistan**

201 The correlation between and TRI was the highest from March to August, indicating that the  
202 growth of *C. deodara* was most strongly affected by the drought before and during the growing  
203 season. Based on the above correlation analysis results, the March-August PDSI was the most  
204 suitable for seasonal reconstruction. The linear regression model between TRI and mean March-

205 August PDSI for the calibration period from 1960 to 2016 was significant ( $F=52.4$ ,  $p < 0.001$ ,  
206 adjusted  $R^2 = 0.49$ ,  $r = 0.70$ ). The regression model was:

$$207 \quad Y = 5.1879x - 5.676$$

208 Where  $Y$  is the mean March-August PDSI and  $x$  is the tree-ring index.

209 The split calibration-verification test showed that the variance explained was higher during  
210 the two calibration periods (1960-1988 and 1989-2016). For the calibration period (1960-2016),  
211 the reconstruction accounted for 39.2% of the scPDSI variation (37.6 after accounting for the  
212 loss of degrees of freedom). Statistics of  $R$ ,  $R^2$ , ST, and PMT are all significant at  $p < 0.05$ ,  
213 indicating that the model was reliable (Table 1). **The RE and CE has a theoretical range of  $-\infty$  to**  
214 **+1, but the benchmark for determining skill is the calibration and verification period mean.**  
215 **Therefore, a RE  $> 0$  and CE  $> 0$  indicates reconstruction skill in excess of climatology (Cook et**  
216 **al., 1999).** Here, the most rigorous RE and CE tests in the verification period were all positive.  
217 Hence, these results made the model more obvious and robust in PDSI reconstruction.

218 The instrumental and reconstructed scPDSIs of the Hindu Kush Mountains had similar  
219 trends and parallel calibrations during short- and long-time scales in the 20th century (Fig. 5).  
220 However, the reconstructed scPDSI did not fully capture the magnitude of extremely dry or wet  
221 conditions.

222

### 223 **3.3 The drought regime in the Chitral Mountain, northern Pakistan for the past 424 years**

224 Fig. 5 showed the dry and wet years of the past 424 years (1593-2016) in the Chitral  
225 Mountain in northern Pakistan. The dry periods were recorded in 1593-1598, 1602-1608, 1631-  
226 1645, 1647-1660, 1756-1765, 1785-1800, 1870-1878, 1917-1923, and 1981-1995. Similarly, the

227 wet periods were recorded in 1663-1675, 1687-1708, 1771-1173, 1806-1814, 1844-1852, 1932-  
228 1935, 1965-1969, and 1996-2003.

229 To verify the accuracy and reliability of our reconstruction, we compared our results with  
230 the nearby precipitation reconstruction of Treydte et al. (2006) (Fig. 6). In the reconstruction of  
231 Treydte et al. (2006), the high and low raw  $\delta^{18}\text{O}$  value represents dry and wet conditions,  
232 respectively, just opposite to the PDSI index. In most periods, our PDSI reconstruction and the  
233 precipitation reconstruction of Treydte et al. (2006) showed good consistency (Fig. 6). However,  
234 in some periods, they also showed inconsistent or even opposite changes in drought  
235 reconstruction. For example, in 1865-1900, the reconstruction of Treydte et al. (2006) was very  
236 wet, while our reconstruction was normal. In periods 1800-1810 and 1694-1702, the  
237 reconstruction of Treydte et al. (2006) was very dry, but our reconstruction was wet (Fig. 6).

238 Spectral analysis showed that the historical PDSI changes in the Hindukush Mountains  
239 showing several significant (95% or 99% confidence level) with periods at 33-38 (99%), 16.8  
240 (99%), 2-3 (99%) years, corresponding to significant periodic peaks (Fig. 7).

241 The spatial correlation analysis between our reconstructed and actual PDSI from May to  
242 August shows that our drought reconstruction is a good regional representative (Fig. 8). This  
243 shows that our reconstruction is reliable and can reflect the drought situation in the region. In  
244 addition, the PDSI of low-frequency (the 31-year moving average) reconstruction had good  
245 consistency with AMO ( $r = 0.53$ ,  $p < 0.001$ , 1890-2001) and SASM ( $r = 0.35$ ,  $p < 0.001$ , 1608-  
246 1990), which indicated that these are the potential factors affecting the drought pattern in the  
247 region.

248

## 249 **4 Discussion**

#### 250 **4.1 Drought variation in Chitral HinduKush Range of Pakistan**

251 The growth-climate relationship revealed the positive and negative influence of  
252 precipitation and summer temperature on growth. It means that water availability (PDSI) is the  
253 main limiting factor affecting the growth of *C. deodara*. Singh et al. (2006) reported that the  
254 previous October precipitation limited the growth of *C. deodara*, while Ahmed et al. (2011)  
255 found no such effect. Except for last August, November, and current September, maximum  
256 temperature has a negative impact on the growth of *C. deodara*, while the minimum temperature  
257 does not. These results suggest that moisture conditions in April-July are critical to the growth of  
258 *C. deodar* in the study area (Borgaonkar et al., 1996; Hussain et al., 2007; Khan et al., 2013).  
259 Remarkably, Chitral does not receive monsoon rains. That's why it is hard to understand how  
260 trees respond to different moisture trends.

261 Here we developed a 467-year (1550-2017) of tree ring chronology of *C. deodara*, and  
262 reconstructed the 424-year (1593-2016) drought variability of the Chitral Hindukush Range in  
263 northern Pakistan. **The point years (narrow rings)**, 2002, 2001, 2000, 1999, 1985, 1971, 1962,  
264 1952, 1945, 1921, 1917, 1902 and 1892, were recorded in our tree-ring record. **The narrow ring**  
265 **formation occurs when extreme drought stress reduces cell division (Fritts et al., 1976; Shi et al.,**  
266 **2014). Therefore, the narrow rings are also consistent with the extreme drought years.** Among  
267 them, 2001, 1999, 1952, and 1921 were identified by previous studies (Esper et al., 2003; Ahmed  
268 et al. 2010; Zafar et al., 2010; Khan et al., 2013; He et al., 2018). Sigdel and Ikeda (2010)  
269 reported that droughts occurred in 1974, 1977, 1985, 1993, and the winter of 2001 and the  
270 summers of 1977, 1982, 1991, and 1992. Our PDSI reconstruction fully captured the widespread  
271 drought in Pakistan, Afghanistan, and Tajikistan in 1970-1971 (Yu et al., 2014). The above  
272 drought has disrupted the people's daily life, leading to food and water shortages and livestock

273 losses in high altitude areas (Yadav, 2011; Yadav and Bhutiyani, 2013; Yadav et al., 2017). This  
274 drought may also be due to the failure of Western disturbance precipitation (Hoerling et al.,  
275 2003).

276 In Fig. 5, the mean of our reconstructed PDSI is below zero. There are two possible reasons  
277 for this phenomenon. First, tree growth is more sensitive to drying than to wetting. As a result,  
278 more drought information is recorded in ring widths. This leads to a drier (less than zero) PDSI  
279 reconstructed with tree rings. This phenomenon exists in many tree-ring PDSI reconstructions  
280 (Hartl-Meier et al., 2017; Wang et al., 2008). Second, the period (1960-2016) used to reconstruct  
281 the equation is relatively dry. This cause the mean of the reconstruction equation to be lower  
282 than zero (dry), resulting in lower values for the whole reconstructions. Therefore, when  
283 applying the PDSI data reconstructed by tree rings, its relative value is relatively reliable, and the  
284 absolute value data can only be used after adjustment. The adjustment method of the absolute  
285 value needs to be further studied.

286 Our reconstruction also captured a range of climate changes mentioned in other studies  
287 (Ahmad et al., 2004; Yu et al., 2014; Chen et al. 2019; Gaire et al., 2019). Our dry periods  
288 (1981-1987, 1870-1875 to 1761-1764) were consistent with the results of Chen et al. (2019). The  
289 dry period 1645-1631 also reported in tree-ring based drought variability of Silk Road (Yu et al.,  
290 2014). Most notably, three mega drought events in Asian history (Yadav, 2013; Panthi et al.,  
291 2017; Gaire et al., 2019), namely, the Strange Parallels drought (1756-1768), the East India  
292 drought (1790-1796) and late Victorian Great Drought (1876 to 1878) was clearly recorded in  
293 our reconstructed PDSI. Based on the above results, drought changes in Northern Pakistan and  
294 the central Himalayas are closely related to large-scale ocean-atmospheric circulation and  
295 synchronous in western Asia (Gaire et al., 2019). The driest period of 1917-1921 of our

296 reconstruction, followed by another dry period 1784-1802, coincided with the eruption of Laki  
297 volcano (Iceland) in 1783. This could mean that widespread drought on the continent could be  
298 linked to volcanic eruptions (Chen et al., 2019). Interestingly, the wet period of 1995-2016 was  
299 very consistent with those of Yadav et al. (2017). These results suggested that the long-term  
300 continuous wets in 31 years of the past 576 years (1984-2014) may have increased the mass of  
301 glaciers in the northwest Himalaya and Karakoram (Cannon et al., 2014). The devastating floods  
302 of July 2010 were also captured by our reconstruction, affecting about a fifth of Pakistan (20  
303 million peoples) (Yaqub et al., 2015). Therefore, we speculate that the size of the Hindukush  
304 glacier and the mass of glaciers near our study areas will continue to increase if it continues to  
305 get wet.

306 Our PDSI reconstruction and the precipitation reconstruction of Treydte et al. (2006)  
307 showed a strong consistency (Fig. 6), which proves that our reconstruction is reliable. The  
308 inconsistency between them in some periods may be because the PDSI is affected by temperature  
309 and may not be completely consistent with precipitation (Li et al., 2015). The inconsistency  
310 between the reconstruction of ring width and oxygen isotope in some periods may also be due to  
311 the different response of radial growth and isotope to disturbance (McDowell et al., 2002). In  
312 addition, the lack of consistency between different data sets or regions may be due to the  
313 dominance of internal climate variability over the impact of natural exogenous forcing conditions  
314 on multi-decadal timescales (Bothe et al., 2019).

315

#### 316 **4.2 The linkage of drought variation with the ocean oscillations**

317 The results of wavelet and MTM analysis indicated that the low and high-frequency periods  
318 of drought in northern Pakistan may teleconnection with both large-small scale climate

319 oscillation (Fig. 7). The spatial correlation exhibited the significant similarity of El Niño-  
320 Southern Oscillation (ENSO) in the region (Fig. 8). The intensity of India monsoon in this area  
321 was modulated by ENSO patterns. The high frequency of drought cycle (2.1-3.3 years) may be  
322 related to the ENSO (van Oldenborgh and Burgers, 2005). Khan et al. (2014) showed that most  
323 of our study area is covered by monsoon shadow, but the Asian monsoon showed an overall  
324 weak trend in recent decades (Wang and Ding, 2006; Ding et al., 2008). Therefore, the increase  
325 of regional precipitation may be linked to the ENSO. Previous studies (Wang et al., 2006; Palmer  
326 et al., 2015; Shi et al., 2018; Chen et al., 2019) have confirmed that ENSO is an important factor  
327 in regulating the hydrological conditions related to the AMO. In the past, severe famine and  
328 drought occurred simultaneously with the warm phase of ENSO, and these events were related to  
329 the failure of Indian Summer Monsoon (Shi et al., 2014).

330 The middle-frequency cycle (16 years) may be related to the solar cycle, which is similar to  
331 other studies in South Asia (Panthi et al., 2017; Shekhar et al., 2018; Chen et al., 2019). Solar  
332 activity may affect climate fluctuations in the Chitral, Hindukush ranges, northern Pakistan  
333 (Gaire et al., 2017). The low-frequency (36-38 years) may be caused by the Atlantic Multi-  
334 decadal Oscillation (AMO), which is the anomalies of sea surface temperatures (SST) in the  
335 North Atlantic basin. Previous studies have shown that the AMO may alter drought or  
336 precipitation patterns in North America (McCabe et al., 2004; Nigam et al., 2011) and Europe  
337 (Vicente-Serrano and López-Moreno, 2008). Although our study area is far from the Atlantic  
338 Ocean, it may also be affected by AMO (Lu et al., 2006; Wang et al., 2011; Yadav, 2013). Lu et  
339 al. (2006) found that the SST anomalies in the North Atlantic (such as AMO) can affect the  
340 Asian summer monsoon. Goswami et al. (2006) reported the mechanism for the AMO influence  
341 on the Indian monsoon precipitation. The warm AMO appears to cause a late withdrawal of the

342 Indian monsoon through strengthening the meridional gradient of tropospheric temperature in  
343 autumn (Goswami et al., 2006; Lu et al., 2006). Yadav (2013) suggested that the role of AMO in  
344 modulating winter droughts over the western Himalaya through the tropical Pacific Ocean. Wang  
345 et al. (2009) pointed out that the AMO heat the Eurasian middle and upper troposphere in all four  
346 seasons, resulting in weakened Asian winter monsoons but enhanced summer monsoons. This is  
347 consistent with the findings that the AMO affecting climate in China, which is made possible by  
348 the Atlantic-Eurasia wave train from the North Atlantic and increased due to global warming  
349 (Qian et al., 2014). Further work is still needed to unravel the links between the Pacific and  
350 Atlantic Oceans and how the two are coupled through the atmosphere and oceans to affect  
351 drought in Asia.

352 Dimri (2006) found that the precipitation surplus in winter from 1958 to 1997 was related to  
353 the significant heat loss in the northern Arabian Sea, mainly due to intensification of water vapor  
354 flow in the west and the enhancement of evaporation. As a result, large-scale changes in Atlantic  
355 temperature could also regulate western Asia climate. Our result was supported by other  
356 dendroclimatic studies (Sano et al., 2005; Chen et al., 2019). Precipitation in Mediterranean,  
357 Black sea (Hatwar et al., 2005; Giesche et al., 2019), and parts of northern Pakistan showed an  
358 upward trend from 1980 to 2010, but the precipitation in the Chitral Mountains received from  
359 Winter Indian Monsoon (WID) (December-March) and the rain shadows in summer (Khan et al.,  
360 2013). Predicting different climate cycle patterns is not easy. Besides, the flow of the Upper  
361 Indus Basin (UIB) depends on changes in the Ablation air mass (Rashid et al., 2018; Rao et al.,  
362 2018), so small changes in the Ablation mass may eventually lead to changes in water quality  
363 and quantity. The UIB is considered as a water tower in the plain (Immerzeel et al., 2010), so the

364 Hindukush Mountains are particularly important for extending the proxy network to improve  
365 understanding of different climatic behaviors.

366 Due to reconstruction indices, species, geographical differences and other reasons, it does  
367 not remain the same with the whole period. The drought regimes in Hindukush ranges in  
368 northern Pakistan may be linked to regional, local, and global climate change. We only studied  
369 the response of *C. deodara* to different climate change in the Chitral region, northern Pakistan.  
370 Therefore, we suggest further high-resolution and well-dated record are needed to augment  
371 dendroclimatic network in the region.

372

## 373 **5 Conclusion**

374 Based on the significance of the tree-ring width of *C. deodara*, we developed a 467-years  
375 chronology (1550-2017). Considering that EPS threshold is greater than 0.85 (> 5 trees), we  
376 reconstructed the current March-August PDSI from 1593 to 2016. Our reconstruction captured  
377 different drought changes in different time scale in the Chitral, Hindukush Mountain, Pakistan,  
378 which falls in the Indus civilization. Several studies have shown that the Indus civilization  
379 changed dramatically in history because of its unpleasant climate. Three historic mega drought  
380 events, the Strange Parallel Droughts (1756-1768) the East Indian Drought (1790-1796) and late  
381 Victorian Great Drought (1876-1878) were captured by our reconstructed PDSI. These large  
382 scales and small droughts may be caused by cold or hot climate. Our results are consistent with  
383 other dendroclimatic records, which further support the feasibility of our reconstruction. Besides,  
384 due to a different climate change patterns in the region, we suggested extending the different  
385 proxy networks to understand the remote teleconnection across the continent on the multi-  
386 decadal to centennial timescales to meet future climate challenges.

387

## 388 **Acknowledgments**

389 This research was supported by the Key Project of the China National Key Research and  
390 Development Program (2016YFA0600800), the Fundamental Research Funds for the Central  
391 Universities (2572019CP15 and 2572017DG02), the Open Grant for Eco-meteorological  
392 Innovation Laboratory in northeast China, China Meteorological Administration (stqx2018zd02),  
393 and the Chinese Scholarship Council. We appreciate the staff of the International Office,  
394 Northeast Forestry University for their excellent services. **We thank Dr. Muhammad Usman, Mr.**

671 **Figure captions**

672 **Fig. 1** Map of the weather stations (Drosh station) and sampling sites in the Chitral, HinduKush  
673 Mountains, Pakistan. Different colors represent the elevation changes of the study area.

674 **Fig. 2** Monthly maximum, mean, minimum temperature (°C) and total precipitation (mm) in the  
675 Drosh Weather Station (35.07° N, 71.78° E, 1465 m), Pakistan (1965-2013).

676 **Fig. 3** The regional tree-ring width chronology from 1550 to 2017 in the Chitral, HinduKush  
677 Mountains, Pakistan. The gray area represents the sample depth.

678 **Fig. 4** Pearson correlation coefficients between the tree-ring index of *C. deodara* and monthly  
679 total precipitation (1965-2013) and scPDSI (1960-2013) (a) and monthly maximum and

680 minimum temperature (1965-2013) (b) from June of the previous year to September of the  
681 current year. Significant correlations ( $p < 0.05$ ) are denoted by asterisks. The “previous” and  
682 “current” represents the previous and current year, respectively.

683 **Fig. 5** The scPDSI reconstruction in the Chitral HinduKush Mountain, Pakistan. (a) Comparison  
684 between the reconstructed (black line) and actual (red line) scPDSI; (b) The variation of  
685 annual (black solid line) and 11-year moving average (red bold line) Mar-Aug scPDSI from  
686 1593 to 2016 with mean value  $\pm$  one standard deviation (black dash lines).

687 **Fig. 6** Comparison of our PDSI reconstruction (a) with the precipitation reconstruction (tree-ring  
688  $\delta^{18}\text{O}$ ) of Treydte et al. (2006) (b) in northern Pakistan. Purple and brown shaded areas  
689 represent the consistent wet and dry periods in the two reconstructions, respectively. Two  
690 correlation coefficients ( $r = -0.24$  and  $r = -0.11$ ) are the correlation of two original annual  
691 resolution reconstruction series and two 11-year moving average series, respectively.

692 **Fig. 7** The Multi-taper method spectrums of the reconstructed scPDSI from 1593 to 2016. Red  
693 and green line represents the 95% and 99% confidence level, respectively. The figures  
694 above the significant line represents the significant periods of drought at 95% confidence  
695 level.

696 **Fig. 8** (a) Spatial correlation between the actual May-August PDSI and the reconstructed May-  
697 August scPDSI (1901-2017). (b) The wavelet analysis of the reconstructed scPDSI in the  
698 Chitral HinduKush Ranges, Pakistan. The 95% significance level against red noise was  
699 shown as a black contour.
