Comments to the Author:

Dear Jianjun Zou,

I have now received feedback from the two reviewers on your revised manuscript “Millennial-scale variations of sedimentary oxygenation in the western subtropical North Pacific and its links to the North Atlantic climate” submitted to Climate of the past. Both reviewers are very pleased with the way you addressed and responded to their comments given in the first round of reviews, and recommend to accept the paper after technical corrections. I will therefore ask you to respond to the minor comments raised in the new reviewer reports before final acceptance of the paper.

Best regards,

Bjørg Risebrobakken

Editor, Climate of the Past

Reply#1: We thank both reviewers for commenting positively on the revised version of our original manuscript. We particularly appreciate that each reviewer found that our manuscript is worth for publication after minor technical corrections.

Referee #1

Zou et al have made substantial revision to their manuscript 'Millennial-scale variations of sedimentary oxygenation in the western subtropical North Pacific and its links to North Atlantic climate'.

I only have a few (small) comments, and I am happy to see the manuscript published once these have been considered:

Abstract:

Lines 36-38: the way I read this is that an increase in deep ocean respired CO₂
concentrations leads to deoxygenation of the upper water column (e.g. top 1000 m represents subsurface layer). Subsurface is not necessarily the same as mid-depth, which I think it what you actually mean? Perhaps remnant of (copied and pasted from response reviewers comments):

‘Lines 848-846 (484-486?): does not make sense. How does subsurface water oxygen consumption lead to lower oxygen concentrations in deeper waters?

Reply#30: Thanks for your suggestion. We have removed the sentence in the revised manuscript. The replenishment of oxygen in deep water is controlled by both lateral advection and vertical supply. The oxygen consumption in subsurface water would reduce the oxygen content in the ocean interior, thus lead to a lower oxygen concentration in deeper waters.’

Reply#2: Thanks for this comment. Here we would like to highlight the deoxygenation in the ocean interior at that time. In order to make a clear statement, the subsurface was replaced by ocean interior in Line 38 of the revised manuscript.

As stated in Reply#30 of the first-round of response letter, we suggested the oxygen consumption because of organic matter degradation in the ocean interior would reduce the vertical supply of oxygen to deeper waters, despite the replenishment of oxygen due to lateral advection.

Lines 45 to 48: perhaps rephrase; e.g. cold spells enhanced oxygenation linked to NPIW, while interglacial increase after 8.5 ka linked to intensification of Kuroshio Current.

Add a line about why the Kuroshio Current intensified?

Reply#3: Thanks. We rephrased this sentence as follows. Please refer to Lines 45-48 in the revised MS.

“The enhanced oxygenation during cold spells is linked to the North Pacific Intermediate Water (NPIW), while interglacial increase after 8.5 ka is linked to an intensification of the Kuroshio Current due to strengthened northeast trade winds over the tropics.”

Line 62: add 'is' between pump and widely.

Reply#4: Added in Line 62 of the revised manuscript.

Introduction:

Lines 88-89: do you mean a small subpolar input or a minimum input, or reducing the input (as it read now)?

Reply#5: Thanks. The word lower was replaced by small in Line 88 of the revised manuscript.
Material and methods: could you add the response to this query to the section? Gives strength to your interpretation.

Reply#6: Thanks. We agree with this suggestion. In the revised manuscript (Lines 281-285), the following sentence (including references) has been added to give more information on sedimentation rate.

“Variation in sedimentation rate has been attributed to changes in eustatic sea level, summer EAM intensity, path and/or intensity of Kuroshio Current. Generally, sea level is thought to be the first-order factor for controlling linear sedimentation rate changes (Beny et al., 2018; Li et al., 2015; Zhao et al., 2017).”

Anonymous Referee #2

The authors have substantially revised their manuscript, which I feel now has the attributes to be accepted for publication in Climate of the Past. I appreciate the thoroughness of their rebuttal letter, well done!

I have two last very minor comments, which I would like to see addressed before the manuscript can be formally accepted -

1. 311 and throughout – I’m not sure I understand why Mn is plotted as total Mn and not, like U and Mo, as Mnexcess or Mn/Al for example?

Reply#7: In this study, the Mo/Mn ratio is a ratio of total Mo concentration to total Mn concentration. The main reasons that the Mo/Mn ratio was used are ascribed to (1) the contrasting geochemical behaviors between these two elements and (2) a strong positive correlation between Mo/Mn and excess U.

The sedimentary Mn concentration in core CSH1 ranges between 0.04% and 0.06% with an average of 0.05% over the last 50ka, which is less than the Mn concentrations in Upper Crust (0.06%) (Taylor and McLennan, 2009), the suspended particulate matter of Yangtze River (0.116%) (Gaillardet et al., 1999) and the average shale (0.085%) (Li and Schoonmaker, 2014). Therefore, there is no excess Mn in sediments of core CSH1. The reason can be ascribed to dilution by biogenic materials and dissolution of Mn oxides and oxyhydroxides.

We also calculated the ratio of Mn/Al and it shows a similar downcore trend to that of total Mn concentration (Figure S1) and therefore we preferred the total Mn rather than Mn/Al ratio in the manuscript.
Figure S1 Downcore records of Mn concentration and Mn/Al ratio in core CSH1 over the last 50 ka.

Fig. 7, panel d, the Pa/Th record has superposed measurements, which I think must be a small mistake.

Reply#8: In Fig.7d, the data of Pa/Th are taken from two references (Böhm et al., 2015; McManus et al., 2004). In order to make distinction of these two sources, different colored lines are used in revised Figure 7d.

Figure 7. Proxy records favoring the existence of out-of-phase connections between
the subtropical North Pacific and North Atlantic during the last deglaciation and enhanced carbon storage at mid-depth waters. (a) $U_{\text{excess}}$ concentration in core CSH1; (b) Mo/Mn ratio in core CSH1; (c) benthic $\delta^{13}C$ record in core PC-23A in the Bering Sea (Rella et al., 2012); (d) Indicator of strength of Atlantic Meridional Ocean Circulation ($^{231}P_{\text{a}}/^{230}\text{Th}$) (Böhm et al., 2015; McManus et al., 2004); (e) Atmospheric CO$_2$ concentration (Marcott et al., 2014). Light gray and dark gray vertical bars are the same as those in Figure 4.

Key Points
1. This study reconstructs the history of sedimentary oxygenation processes at mid-depths in the western subtropical North Pacific since the last glacial period.
2. Sediment-bound redox-sensitive proxies reveal millennial-scale variations in sedimentary oxygenation that correlated closely to changes in the North Pacific Intermediate Water.
3. A millennial-scale out-of-phase relationship between deglacial ventilation in the western subtropical North Pacific and the formation of North Atlantic Deep Water is suggested.
4. A larger CO2 storage at mid-depths of the North Pacific corresponds to the termination of atmospheric CO2 rise during the Bölling-Alleröd interval.
Abstract

The deep ocean carbon cycle, especially carbon sequestration and outgassing, is one of the mechanisms to explain variations in atmospheric CO₂ concentrations on millennial and orbital timescales. However, the potential role of subtropical North Pacific subsurface waters in modulating atmospheric CO₂ levels on millennial timescales is poorly constrained. An increase in respired CO₂ concentration in the glacial deep ocean due to biological pump generally corresponds to deoxygenation in the subsurface layer of the ocean interior. This link thus offers a chance to study oceanic ventilation and coeval export productivity based on redox-controlled, sedimentary geochemical parameters. Here, we investigate a suite of geochemical proxies in a sediment core from the Okinawa Trough to understand sedimentary oxygenation variations in the subtropical North Pacific over the last 50,000 years (50 ka). Our results suggest that enhanced mid-depth western subtropical North Pacific (WSTNP) sedimentary oxygenation occurred during cold intervals and after 8.5 ka, while oxygenation decreased during the Bölling-Allerød (B/A) and Preboreal. The enhanced sedimentary oxygenation during cold spells is linked to the North Pacific Intermediate Water (NPIW), while interglacial increase after 8.5 ka is linked to an intensification of the Kuroshio Current due to strengthened northeast trade winds over the tropics. The enhanced sedimentary oxygenation in the WSTNP is aligned with intensified formation of North Pacific Intermediate Water (NPIW) during cold spells, while better sedimentary oxygenation seems to be linked to an intensified Kuroshio Current after 8.5 ka. The enhanced formation of NPIW during Heinrich Stadial 1 (HS1) was likely driven by the perturbation of sea ice formation and sea surface salinity oscillations in high-latitude North Pacific. The diminished sedimentary oxygenation during the B/A due to decreased NPIW formation and enhanced export production, indicates an expansion of oxygen minimum zone in the North Pacific and enhanced CO₂ sequestration at mid-depth waters, along with termination of atmospheric CO₂ concentration increase. We attribute the millennial-scale changes to intensified NPIW and enhanced abyss flushing during deglacial cold and warm intervals, respectively, closely related to variations in North Atlantic Deep Water formation.
Keywords: sedimentary oxygenation; millennial timescale; North Pacific Intermediate Water; North Atlantic Deep Water; subtropical North Pacific
1. Introduction

A more sluggish deep ocean ventilation combined with a more efficient biological pump is widely thought to facilitate enhanced carbon sequestration in the ocean interior, leading to atmospheric CO$_2$ drawdown during glacial cold periods (Sigman and Boyle, 2000). These changes are tightly coupled to bottom water oxygenation and sedimentary redox changes on both millennial and orbital timescales (Hoogakker et al., 2015; Jaccard and Galbraith, 2012; Sigman and Boyle, 2000). Reconstruction of past sedimentary oxygenation is therefore crucial for understanding changes in export productivity and renewal of deep ocean circulation (Nameroff et al., 2004). Previous studies from North Pacific margins as well as open subarctic Pacific have identified drastic variations in export productivity and ocean oxygen levels at millennial and orbital timescales using diverse proxies such as trace elements (Cartapanis et al., 2011; Chang et al., 2014; Jaccard et al., 2009; Zou et al., 2012), benthic foraminiferal assemblages (Ohkushi et al., 2016; Ohkushi et al., 2013; Shibahara et al., 2007) and nitrogen isotopic composition ($\delta^{15}$N) of organic matter (Addison et al., 2012; Chang et al., 2014; Galbraith et al., 2004; Riethdorf et al., 2016) in marine sediment cores. These studies suggested that both North Pacific Intermediate Water (NPIW) and export of organic matter regulate the sedimentary oxygenation variation during the last glaciation and Holocene in the subarctic Pacific. By contrast, little information exists on millennial-scale oxygenation changes to date in the western subtropical North Pacific (WSTNP).

The modern NPIW precursor waters are mainly sourced from the NW Pacific marginal seas (Shcherbina et al., 2003; Talley, 1993; You et al., 2000), spreading into the subtropical North Pacific at intermediate depths of 300 to 800 m (Talley, 1993). The pathway and circulation of NPIW have been identified by You (2003), who suggested that cabbeling, a mixing process to form a new water mass with increased density than that of parent water masses, is the principle mechanism responsible for transforming subpolar source waters into subtropical NPIW along the subarctic-tropical frontal zone. More specifically, a lower small subpolar input of about 2 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3/\text{s}$) is sufficient for subtropical ventilation (You et al., 2003).
Benthic foraminiferal $\delta^{13}C$, a quasi-conservative tracer for water mass, from the North Pacific indicates an enhanced ventilation (higher $\delta^{13}C$) at water depths of < 2000 m during the last glacial period (Keigwin, 1998; Matsumoto et al., 2002). Furthermore, on the basis of both radiocarbon data and modeling results, Okazaki et al. (2010) suggested the formation of deep water in the North Pacific during the early deglaciation in Heinrich Stadial 1 (HS1). Enhanced NPIW penetration was further explored using numerical model simulations (Chikamoto et al., 2012; Gong et al., 2019; Okazaki et al., 2010). In contrast, substantial effects of intensified NPIW formation during Marine Isotope Stage (MIS) 2 and 6 on the ventilation and nutrient characteristics of lower latitude mid-depth Eastern Equatorial Pacific have been suggested by recent studies (Max et al., 2017; Rippert et al., 2017). The downstream effects of intensified NPIW are also reflected in the record of $\delta^{13}C$ of *Cibicides wuellerstorfi* in core PN-3 from the middle Okinawa Trough (OT), where lower deglacial $\delta^{13}C$ values were attributed to enhanced OC accumulation rates due to higher surface productivity by (Wahyudi and Minagawa, 1997).

The Okinawa Trough is separated from the Philippine Sea by the Ryukyu Islands and is an important channel of the northern extension of the Kuroshio in the WSTNP (Figure 1). Initially the OT opened at the middle Miocene (Sibuet et al., 1987) and since then, it has been a depositional center in the East China Sea (ECS), receiving large sediment supplies from nearby rivers (Chang et al., 2009). Surface oceanographic characteristics of the OT over glacial-interglacial cycles are largely influenced by the Kuroshio and ECS Coastal Water (Shi et al., 2014); the latter is related to the strength of summer East Asian monsoon (EAM) sourced from the western tropical Pacific. Modern physical oceanographic investigations showed that intermediate waters in the OT are mainly derived from horizontal advection and mixing of NPIW and South China Sea Intermediate Water (Nakamura et al., 2013). These waters intrude into the OT through two ways: (i) deeper part of the Kuroshio enters the OT through the channel east of Taiwan (sill depth 775 m) and (ii) through the Kerama Gap (sill depth 1100 m). In the northern OT, the subsurface water mainly flows through horizontal advection through the Kerama Gap from the Philippine Sea.
(Nakamura et al., 2013). Recently, Nishina et al. (2016) found that an overflow through the Kerama Gap controls the modern deep-water ventilation in the southern OT.

Both surface characteristics and deep ventilation in the OT varied significantly since the last glaciation. During the last glacial period, the mainstream of the Kuroshio likely migrated to the east of the Ryukyu Islands or also became weaker due to lower sea levels (Shi et al., 2014; Ujiié and Ujiié, 1999; Ujiié et al., 2003) and the hypothetical emergence of a Ryukyu-Taiwan land bridge (Ujiié and Ujiié, 1999). In a recent study, based on the Mg/Ca-derived temperatures in surface and thermocline waters, and planktic foraminiferal indicators of water masses from two sediment cores located in the northern and southern OT, Ujiié et al. (2016) argued that the hydrological conditions of the North Pacific Subtropical Gyres since MIS 7 is modulated by the interaction between the Kuroshio and the NPIW. Besides the Kuroshio, the flux of East Asian rivers to the ECS, which is related to the summer EAM and the sea level oscillations coupled with topography have also been regulating the surface hydrography in the OT (Chang et al., 2009; Kubota et al., 2010; Sun et al., 2005; Yu et al., 2009).

Based on benthic foraminiferal assemblages, previous studies have implied a reduced oxygenation in deep waters of the middle and southern OT during the last deglacial period (Jian et al., 1996; Li et al., 2005), but a strong ventilation during the Last Glacial Maximum (LGM) and the Holocene (Jian et al., 1996; Kao et al., 2005). High sedimentary δ^{15}N values, an indicator of increased denitrification in the subsurface water column, also occurred during the late deglaciation in the middle OT (Kao et al., 2008). Inconsistent with these results, Dou et al. (2015) suggested an oxic depositional environment during the last deglaciation in the southern OT based on weak positive cerium anomalies. Furthermore, Kao et al. (2006) hypothesized a reduced ventilation of deepwater in the OT during the LGM due to the reduction of KC inflow using a 3-D ocean model. Thus, the patterns and reasons that caused sedimentary oxygenation in the OT remain controversial.

2. Paleo-redox proxies
The sedimentary redox conditions are governed by the rate of oxygen supply from the overlying bottom water and the rate of oxygen removal from pore water (Jaccard et al., 2016), processes that are related to the supply of oxygen by ocean circulation and organic matter respiration, respectively. Contrasting geochemical behaviors of redox-sensitive trace metals (Mn, Mo, U, etc.) have been used to reconstruct bottom water and sedimentary oxygen changes (Algeo, 2004; Algeo and Lyons, 2006; Crusius et al., 1996; Dean et al., 1997; Tribovillard et al., 2006; Zou et al., 2012), as their concentrations readily respond to redox condition of the depositional environment (Morford and Emerson, 1999).

In general, enrichment of Mn with higher speciation states (Mn (III) and Mn (IV)) in the form of Mn-oxide coatings is observed in marine sediments, when oxic conditions prevail into greater sediment depths as a result of low organic matter degradation rates and well-ventilated bottom water (Burdige, 1993). Under reducing conditions, the authigenic fraction of Mn (as opposed to its detrital background) is released as dissolved Mn (II) species into the pore water and thus its concentration is usually low in suboxic (O₂ and HS⁻ absent) and anoxic (HS⁻ present) sediments. In addition, when Mn enrichment occurs in oxic sediments as solid phase Mn oxyhydroxides, it may lead to co-precipitation of other elements, such as Mo (Nameroff et al., 2002).

The elements Mo and U behave conservatively in oxygenated seawater, but are preferentially enriched in oxygen-depleted water (Morford and Emerson, 1999). However, these two trace metals behave differently in several ways. Molybdenum can be enriched in both oxic sediments, such as the near surface manganese-rich horizons in continental margin environments (Shimmield and Price, 1986) and in anoxic sediments (Nameroff et al., 2002). Under anoxic conditions, Mo can be reduced either from the +6 oxidation state to insoluble MoS₂, though this process is known to occur only under extremely reducing conditions, such as hydrothermal and/or diagenesis (Dahl et al., 2010; Helz et al., 1996) or be converted to particle-reactive thiomolybdates (Vorlicek and Helz, 2002). Zheng et al. (2000) suggested two critical thresholds for Mo scavenging from seawater: 0.1 µM hydrogen sulfide (H₂S) for
Fe-S-Mo co-precipitation and 100 µM H₂S for Mo scavenging as Mo-S or as particle-bound Mo without Fe. Although Crusius et al. (1996) noted insignificant enrichment of sedimentary Mo under suboxic conditions, Scott et al. (2008) argued that burial flux of Mo is not so low in suboxic environments. Excess concentration of Mo (Mo_{excess}) in sediments thus suggests the accumulation of sediments either in anoxic (H₂S occurrence) or well oxygenated conditions (if Mo_{excess} is in association with Mn-oxides).

In general, U is enriched in anoxic sediments (>1 µM H₂S), but not in oxic sediments (>10 µM O₂) (Nameroff et al., 2002). Accumulation of U depends on the content of reactive organic matter (Sundby et al., 2004) and U precipitates as uraninite (UO₂) during the conversion of Fe (III) to Fe (II) in suboxic conditions (Morford and Emerson, 1999; Zheng et al., 2002). One of the primary removal mechanisms for U from the ocean is via diffusion across the sediment-water interface of reducing sediments (Klinkhammer and Palmer, 1991). Under suboxic conditions, soluble U (VI) is reduced to insoluble U (IV), but free sulfide is not required for U precipitation (McManus et al., 2005). Jaccard et al. (2009) suggested that the presence of excess concentration of U (U_{excess}) in the absence of Mo enrichment is indicative of a suboxic, but not sulfidic condition, within the diffusional range of the sediment-water interface.

The felsic volcanism is also a primary source of uranium (Maithani and Srinivasan, 2011). Therefore, the potential input of uranium from active volcanic sources around the northwestern Pacific to the adjacent sediments should not be neglected.

In this study, we investigate a suite of redox-sensitive elements and the ratio of Mo/Mn along with productivity proxies from a sediment core retrieved from the northern OT to reconstruct the sedimentary oxygenation in the WSTNP over the last 50ka. Based on that, we propose that multiple factors, such as NPIW ventilation, the strength of the Kuroshio Current and export productivity, control the bottom sedimentary oxygenation in the OT on millennial timescales since the last glacial.

3. Oceanographic setting

Surface hydrographic characteristics of the OT are mainly controlled by the warmer, more saline, oligotrophic Kuroshio water and cooler, less saline, nutrient-rich
Changjiang Diluted Water, and the modern flow-path of the former is influenced by the bathymetry of the OT (Figure 1a). The Kuroshio Current originates from the North Equatorial Current and flows into the ECS from the Philippine Sea through the Suao-Yonaguni Depression. In the northern OT, Tsushima Warm Current (TWC), a branch of the Kuroshio, flows into the Japan Sea through the shallow Tsushima Strait. Volume transport of the Kuroshio varies seasonally due to the influence of the EAM with a maximum of 24 Sv in summer and a minimum of 20 Sv in autumn across the east of Taiwan (Qu and Lukas, 2003).

A lower sea surface salinity (SSS) zone in summer relative to the one in winter in the ECS migrates toward the east of OT, indicating enhanced impact of the Changjiang discharge associated with summer EAM (Figures 2a and 2b). An estimated ~80% of the mean annual discharge of the river Changjiang is supplied to the ECS (Ichikawa and Beardsley, 2002) and in situ observational data show a pronounced negative correlation between the Changjiang discharge and SSS in July (Delcroix and Murtugudde, 2002). Consistently, previous studies from the OT reported such close relationship between summer EAM and SSS back to the late Pleistocene (Chang et al., 2009; Clemens et al., 2018; Kubota et al., 2010; Sun et al., 2005).

Despite the effects of EAM and the Kuroshio, evidence of geochemical tracers (temperature, salinity, oxygen, nutrients and radiocarbon) collected during the World Ocean Circulation Experiment (WOCE) in the Pacific (transects P24 and P03) favors the presence of low salinity, nutrient-enriched intermediate and deep waters (Talley, 2007). Dissolved oxygen content is <100 μmol/kg at water depths below 600 m in the OT, along WOCE transects PC03 and PC24 (Talley, 2007). Modern oceanographic observations at the Kerama Gap reveal that upwelling in the OT is associated with the inflow of NPIW and studies using a box model predicted that overflow through the Kerama Gap is responsible for upwelling (3.8–7.6 × 10⁻⁶ m s⁻¹) (Nakamura et al., 2013; Nishina et al., 2016).

4. Materials and methods

4.1. Chronostratigraphy of core CSH1
A 17.3 m long sediment core CSH1 (31° 13.7’ N, 128° 43.4’ E; water depth: 703 m) was collected from the northern OT, close to the main stream of Tsushima Warm Current (TWC) (Figure 1b) and within the depth of NPIW (Figure 1c) using a piston corer during Xiangyanghong09 Cruise in 1998, carried out by the First Institute of Oceanography, Ministry of Natural Resources of China. This location is enabling us to reconstruct millennial-scale changes in the properties of TWC and NPIW. Core CSH1 mainly consists of clayey silt and silt with occurrence of plant debris at some depth intervals (Ge et al., 2007) (Figure 3a). In addition, three layers of volcanic ash were observed at depths of 74–106 cm, 782–794 cm, 1570–1602 cm. These three intervals can be correlated with well-known ash layers, Kikai-Akahoya (K-Ah; 7.3 ka), Aira-Tanzawa (AT; 29.24 ka) and Aso-4 (roughly around MIS 5a) (Machida, 1999), respectively. The core was split and sub-sampled at 4 cm interval and then stored in the China Ocean Sample Repository at 4 °C until analysis.

Previously, paleoceanographic studies have been conducted and a set of data has been investigated for core CSH1, including the contents of planktic foraminifers as well as their carbon (δ¹³C) and oxygen isotope (δ¹⁸O) compositions (Shi et al., 2014), pollen (Chen et al., 2006), paleomagnetism (Ge et al., 2007) and CaCO₃ (Wu et al., 2004). An age model for this core has been constructed by using ten Accelerator Mass Spectrometry (AMS) ¹⁴C dates and six oxygen isotope (δ¹⁸O) age control points. The whole 17.3 m core contains ca. 88 ka-long record of continuous sedimentation (Shi et al., 2014).

Notably, the original age model, which used constant radiocarbon reservoir ages throughout core CSH1 are suitable to reveal orbital-scale Kuroshio variations (Shi et al., 2014), but insufficient to investigate millennial-scale climatic events. A higher abundance of *Neogloboquadrina pachyderma* (*dextral*), e. g. that occurred during warmer intervals, such as the Bölling-Alleröd (B/A), has been challenging to explain. On the other hand, paired measurements of ¹⁴C/¹²C and ²³⁰Th ages from Hulu Cave stalagmites suggest magnetic field changes have greatly contributed to high atmospheric ¹⁴C/¹²C values at HS4 and the Younger Dryas (YD) (Cheng et al., 2018). Thus a constant reservoir age (ΔR=0) assumed when calibrating foraminiferal
radiocarbon dates using CALIB 6 software and the Marine 13 calibration dataset (Reimer et al., 2013) for core CSH1 may cause large chronological uncertainties.

Here, we recalibrated the radiocarbon dates using updated CALIB 7.04 software with Marine 13 calibration dataset (Reimer et al., 2013). Moreover, on the basis of significant correlation between planktic foraminifera species *Globigerinoides ruber* δ¹⁸O and Chinese stalagmite δ¹⁸O (Cheng et al., 2016), a proxy of summer EAM related to SSS of the ECS, we improve the age model for core CSH1 (Figures 3b-3d).

Overall, the new chronological framework is similar to the one previously reported by Shi et al. (2014), but with more dates. In order to compare with published results associated with ventilation changes in the North Pacific, here we mainly report the history of sedimentary oxygenation in the northern OT since the last glacial period.

Linear sedimentation rate varied between ~10 and 40 cm/ka with higher sedimentation rates (around 30-40 cm/ka) between ~24 ka and 32.5 ka. Variation in sedimentation rate has been attributed to changes in eustatic sea level, summer EAM intensity, path and/or intensity of Kuroshio Current. Generally, sea level is thought to be the first-order factor for controlling linear sedimentation rate changes (Beny et al., 2018; Li et al., 2015; Zhao et al., 2017). The new age control points are shown in Table 2.

### 4.2. Chemical analyses

Sediment subsamples for geochemical analyses were freeze-dried and ground to a fine powder with an agate mortar and pestle. Based on the age model, 85 subsamples from core CSH1, representing a temporal resolution of about 600 years (every 4 cm interval) were selected for detailed geochemical analyses of major and minor elements, and total carbon (TC), organic carbon (TOC) and nitrogen (TN) contents. The pretreatment of sediment and other analytical methods have been reported elsewhere (Zou et al., 2012).

TC and TN were determined with an elemental analyzer (EA; Vario EL III, Elementar Analysen system GmbH) in the Key Laboratory of Marine Sediment and Environment Geology, First Institute of Oceanography, Ministry of Natural Resources of China, Qingdao. Carbonate was removed from sediments by adding 1M HCl to the
homogenized sediments for total organic carbon (TOC) analysis using the same equipment. The content of calcium carbonate (CaCO₃) was calculated using the equation:

\[ \text{CaCO}_3 = (\text{TC} - \text{TOC}) \times 8.33 \]

where 8.33 is the ratio between the molecular weight of carbonate and the atomic weight of carbon. National reference material (GSD-9), blank sample and replicated samples were used to control the analytical process. The relative standard deviation of the GSD-9 for TC, TN and TOC is \( \leq 3.4\% \).

About 0.5 g of sediment powder was digested in double distilled HF:HNO₃ (3:1), followed by concentrated HClO₄, and then re-dissolved in 5% HNO₃. Selected major and minor elements such as aluminum (Al) and manganese (Mn) were determined by inductively coupled plasma optical emission spectroscopy (ICP-OES; Thermo Scientific iCAP 6000, Thermo Fisher Scientific), as detailed elsewhere (Zou et al., 2012). In addition, Mo and U were analyzed with inductively coupled plasma mass spectrometry (ICP-MS; Thermo Scientific XSERIES 2, Thermo Fisher Scientific), as described in Zou et al. (2012). Precision for most elements in the reference material GSD-9 is \( \leq 5\% \) relative standard deviation. The excess fractions of U and Mo were estimated by normalization to Al:

\[ \text{Excess fraction} = \text{total element} - (\text{element/Al}_{\text{average shale}} \times \text{Al})_{\text{average shale}} \]

with U/Al average shale = \( 3.07 \times 10^{-6} \) and Mo/Al average shale = \( 0.295 \times 10^{-6} \) (Li and Schoonmaker, 2014).

In addition, given the different geochemical behaviors of Mn and Mo and co-precipitation and adsorption processes associated with the redox cycling of Mn, we calculated the ratio of Mo to Mn, assuming that higher Mo/Mn ratio indicates lower oxygen content in the depositional environment and vice versa. In combination with the concentration of excess uranium, we infer the history of sedimentary oxygenation in the subtropical North Pacific since the last glaciation.

5. Results

5.1. TOC, TN, and CaCO₃

The content of CaCO₃ varies from 8.8 to 35% (Figure 4a) and it mostly shows higher values with increasing trends during the last deglaciation. In contrast, the
content of CaCO$_3$ is low and exhibits decreasing trends during the late MIS 3 and the LGM (Figure 4a). TN content shows a larger variation compared to TOC (Figure 4b), but it still strongly correlates with TOC ($r = 0.74$, $p<0.01$) throughout the entire core. Concentration of TOC ranges from 0.5 to 2.1% and it shows higher values with stable trends during the last glacial phase (MIS 3) (Figure 4c). Molar ratios of TOC/TN vary around 10, with higher ratios at the transition into the LGM (Figure 4d), corresponding to higher linear sedimentation rate (Figure 4e).

Both TOC and CaCO$_3$ have been used as proxies for the reconstruction of past export productivity (Cartapanis et al., 2011; Lembke-Jene et al., 2017; Rühlemann et al., 1999). Molar C/N ratios of $>10$ (Figure 4c) suggest that terrigenous organic sources significantly contribute to the TOC concentration in core CSH1. The TOC content therefore may be not a reliable proxy for the reconstruction of surface water export productivity during times of the LGM and late deglaciation, when maxima in C/N ratios co-occur with decoupled trends between CaCO$_3$ and TOC concentrations.

Several lines of evidence support CaCO$_3$ as a reliable productivity proxy, particularly during the last deglaciation. The strong negative correlation coefficient ($r = -0.85$, $p<0.01$) between Al and CaCO$_3$ in sediments throughout core CSH1 confirms the biogenic origin of CaCO$_3$ against terrigenous Al (Figure 4f). Generally, terrigenous dilution decreases the concentrations of CaCO$_3$. An inconsistent relationship between CaCO$_3$ contents and sedimentation rates indicates a minor effect of dilution on CaCO$_3$. Furthermore, the increasing trend in CaCO$_3$ associated with high sedimentation rate during the last deglacial interval indicates a substantial increase in export productivity (Figures 4a and 4d). The high coherence between CaCO$_3$ content and alkenone-derived sea surface water (SST) (Shi et al., 2014) indicates a direct control on CaCO$_3$ by SST. Moreover, a detailed comparison between CaCO$_3$ concentrations and the previously published foraminiferal fragmentation ratio (Wu et al., 2004) shows, apart from a small portion within the LGM, no clear co-variation between them. These pieces of evidence suggest that CaCO$_3$ changes are driven primarily by variations in carbonate primary production, and not overprinted by secondary processes, such as carbonate dissolution through changes in the
lysocline depth and dilution by terrigenous materials. Likewise, a similar deglacial trend in CaCO₃ is also observed in core MD01-2404 (Chang et al., 2009), indicating a ubiquitous, not local picture in the OT. All these lines of evidence thus support CaCO₃ of core CSH1 as a reliable productivity proxy to a first order approximation.

5.2. Redox-sensitive Elements

Figure 4 shows time series of selected redox-sensitive elements (RSEs) and proxies derived from them. Mn shows higher concentrations during the LGM and HS1 (16 ka–22 ka) and middle-late Holocene, but lower concentrations during the last deglacial and Preboreal periods (15.8 ka–9.5 ka, Figure 4g). Generally, concentrations of excess Mo and excess U (Figures 4j and 4l) show coherent patterns with those of Mo and U (Figures 4i and 4k), but both are out-of-phase with Mn over the last glacial period (Figure 4h). Pronounced variations in U concentration after 8.5 ka are related to the occurrence of discrete volcanic materials. A significant positive Eu anomaly (Zhu et al., 2015) confirms the occurrence of discrete volcanic materials and its dilution effects on terrigenous components since 7 ka. Occurrence of discrete volcanic material is likely related to intensified Kuroshio Current during the mid-late Holocene, as supported by higher hydrothermal Hg concentrations in sediments from the middle OT (Lim et al., 2017). A negative correlation between Mn and Moexcess during the last glaciation and the Holocene, and the strong positive correlation between them during the LGM and HS1 (Figures 5a and 5b) further corroborate the complex geochemical behaviors of Mn and Mo. A strong positive correlation between Moexcess and Mn (Figure 5b) may be attributed to co-precipitation of Mo by Mn-oxyhydroxide under oxygenated conditions. Here, we thus use the Mo/Mn ratio, instead of excess Mo concentration to reconstruct variations in sedimentary redox conditions in our study area. Overall, the Mo/Mn ratio shows similar downcore pattern to that of Moexcess with higher ratios during the last deglaciation, but lower ratios during the LGM and HS1. A strong correlation (r = 0.69) between Mo/Mn ratio and excess U concentration (excluding the data of Holocene, due to the contamination with volcanic material, Figure 5c) further corroborates the integrity of Mo/Mn as an indicator of sedimentary oxygenation changes.
Rapidly decreasing Mo/Mn ratios indicate a well oxygenated sedimentary environment after ~8 ka (Figure 4h). Both higher Mo/Mn ratios and excess U concentrations, together with lower Mn concentrations suggest suboxic depositional conditions during the late deglacial period (15.8 ka–9.5 ka), whereas lower ratios during the LGM, HS1 and HS2 indicate relatively better oxygenated sedimentary conditions. A decreasing trend in Mo/Mn ratio and excess U concentration from 50 ka to 25 ka also suggest higher sedimentary oxygen levels.

6. Discussion

6.1. Constraining paleoredox conditions in the Okinawa Trough

In general, three different terms, hypoxia, suboxia and anoxia, are widely used to describe the degree of oxygen depletion in the marine environment (Hofmann et al., 2011). Here, we adopt the definition of oxygen thresholds by Bianchi et al. (2012) for oxic (>120 µmol/kg O₂), hypoxic (<60–120 µmol/kg O₂) and suboxic (<2–10 µmol/kg O₂) conditions, whereas anoxia is the absence of measurable oxygen.

Proxies associated with RSEs, such as sedimentary Mo concentration (Lyons et al., 2009; Scott et al., 2008) have been used to constrain the degree of oxygenation in seawater. Algeo and Tribovillard (2009) proposed that open-ocean systems with suboxic waters tend to yield U_excess enrichment relative to Mo_excess, resulting in sediment (Mo/U)_excess ratio less than that of seawater (7.5-7.9). Under increasingly reducing and occasionally sulfidic conditions, the accumulation of Mo_excess increase relative to that of U_excess leading the (Mo/U)_excess ratio either is equal to or exceeds with that of seawater. Furthermore, Scott and Lyons (2012) suggested a non-euxinic condition with the presence of sulfide in pore waters, when Mo concentrations range from > 2 µg/g, the crustal average to < 25 µg/g, a threshold concentration for euxinic condition. Given that the northern OT is located in an open oceanic setting, we use these two proxies to evaluate the degree of oxygenation in sediments.

Both bulk Mo concentration (1.2-9.5 µg/g) and excess (Mo/U) ratio (0.2-5.7) in core CSH1 suggest that oxygen-depleted conditions have prevailed in the deep water of the northern OT over the last 50 ka (Figure 4m). However, increased excess Mo concentrations with higher Mo/U ratios during the last termination (18 ka-9 ka)
indicate more reducing conditions compared to the Holocene and the last glacial period, though Mo concentrations were less than 25 µg/g, a threshold for euxinic deposition proposed by Scott and Lyons (2012).

The relative abundance of benthic foraminifera species that thrive in different oxygen concentrations has also been widely used to reconstruct variations in bottom water ventilation, such as the enhanced abundance of *Bulimina aculeata*, *Uvigerina peregrina* and *Chilostomella oolina* found under oxygen-depleted conditions in the central and southern OT from 18 ka to 9.2 ka (Jian et al., 1996; Li et al., 2005). An oxygenated bottom water condition is also indicated by abundant benthic foraminifera species *Cibicidoides hyalina* and *Globocassidulina subglobosa* after 9.2 ka (Jian et al., 1996; Li et al., 2005) in cores E017 (1826 m water depth) and 255 (1575 m water depth) and high benthic δ¹³C values (Wahyudi and Minagawa, 1997) in core PN-3 (1058 m water depth) from the middle and southern OT during the postglacial period. The poorly-ventilated deep water in the middle and southern OT inferred by benthic foraminiferal assemblages during the last deglaciation correlates with the one in the northern OT referring to our RSEs (Figure 4). A link thus can be hypothesized between deep-water ventilation and sedimentary oxygenation in the OT. Overall, a combination of our proxy records of RSEs in core CSH1 with other records shows oxygen-rich conditions during the last glaciation and middle and late Holocene (since 8.5 ka) intervals, but oxygen-poor conditions during the last deglaciation.

### 6.2. Causes for sedimentary oxygenation variations

Our observed pattern of RSEs in core CSH1 suggests that drastic changes in sedimentary oxygenation occurred on orbital and millennial timescales over the last glaciation in the OT. In general, four factors can regulate the redox condition in the deep water column: (i) O₂ solubility, (ii) export productivity and subsequent degradation of organic matter, (iii) vertical mixing, and (iv) lateral supply of oxygen through intermediate and deeper water masses (Ivanochko and Pedersen, 2004; Jaccard and Galbraith, 2012). These processes have been invoked in previous studies to explain the deglacial Pacific-wide variations in oxygenation by either one or a combination of these factors (Galbraith and Jaccard, 2015; Moffitt et al., 2015;
Praetorius et al., 2015). Our data also suggest drastic variations in sedimentary oxygenation over the last 50 ka. However, the mechanisms responsible for sedimentary oxygenation variations in the basin-wide OT and its connection with ventilation of the open North Pacific remain unclear. In order to place our core results in a wider regional context, we compare our proxy records of sedimentary oxygenation ($U_{\text{excess}}$ concentration and Mo/Mn ratio) and export productivity (CaCO$_3$) (Figures 6a–6c) with abundance of *Pulleniatina obliquiloculata* (an indicator of Kuroshio strength) and sea surface temperature (Shi et al., 2014), bulk sedimentary nitrogen isotope (an indicator of denitrification) (Kao et al., 2008), benthic foraminifera δ$^{13}$C (a proxy for ventilation) in cores PN-3 and PC23A (Rella et al., 2012; Wahyudi and Minagawa, 1997), abundance of benthic foraminifera (an indicator of hypoxia) in core E017 (Li et al., 2005) and ODP Site 1017 (Cannariato and Kennett, 1999) (Figures 6d–6k).

### 6.2.1. Effects of regional ocean temperature on deglacial deoxygenation

Warming ocean temperatures lead to lower oxygen solubility. In the geological past, solubility effects connected to temperature changes of the water column thought to enhance or even trigger hypoxia (Praetorius et al., 2015). Shi et al. (2014) reported an increase in SST of around 4°C (from ~21°C to ~24.6°C) during the last deglaciation in core CSH1 (Figure 6d). Based on thermal solubility effects, a hypothetical warming of 1°C would reduce oxygen concentrations by about 3.5 μmol/kg at water temperatures around 22°C (Brewer and Peltzer, 2016), therefore a ~4°C warming at core CSH1 (Shi et al., 2014) could drive a conservative estimate of a drop of <15 μmol/kg in oxygen concentration, assuming no large salinity changes. However, given the semi-quantitative nature of our data about oxygenation changes, which seemingly exceed an amplitude of >15 μmol/kg, we suggest that other factors, e.g. local changes in export productivity, regional influences such as vertical mixing due to changes of the Kuroshio Current, and far-field effects may have played decisive roles in shaping the oxygenation history of the OT.

### 6.2.2. Links between deglacial primary productivity and sedimentary deoxygenation
Previous studies have suggested the occurrence of high primary productivity in the entire OT during the last deglacial period (Chang et al., 2009; Jian et al., 1996; Kao et al., 2008; Li et al., 2017; Shao et al., 2016; Wahyudi and Minagawa, 1997). Such an increase in export production was due to favorable conditions for phytoplankton blooms, which were likely induced by warm temperatures and maxima in nutrient availability, the latter being mainly sourced from increased discharge of the Changjiang River, erosion of material from the ongoing flooding of the shallow continental shelf in the ECS, and upwelling of Kuroshio Intermediate Water (Chang et al., 2009; Li et al., 2017; Shao et al., 2016; Wahyudi and Minagawa, 1997). On the basis of sedimentary reactive phosphorus concentration, Li et al. (2017) concluded that export productivity increased during warm episodes but decreased during cold spells on millennial timescales over the last 91 ka in the OT. Gradually increasing concentrations of CaCO₃ in core CSH1 during the deglaciation (Figure 6a) and little changes in foraminiferal fragmentation ratios (Wu et al., 2004), are indicative of high export productivity in the northern OT. Accordingly, our data indicate that an increase in export productivity during the last deglaciation, which was previously evidenced by concentrations of reactive phosphorus (Li et al., 2017) and CaCO₃ (Chang et al., 2009) from the middle OT, and thus was a pervasive, synchronous phenomenon in the entire study region at the outermost extension of the ECS.

Similar events of high export productivity have been reported in the entire North Pacific due to increased nutrient supply, high SST, reduced sea ice cover, etc. (Crusius et al., 2004; Dean et al., 1997; Galbraith et al., 2007; Jaccard and Galbraith, 2012; Kohfeld and Chase, 2011). In most of these cases, increased export productivity were thought to be responsible for oxygen depletion in mid-depth waters, due to exceptionally high oxygen consumption. However, the productivity changes during the deglacial interval, very specifically CaCO₃, are not fully consistent with the trends of excess U and Mo/Mn ratio (Figures 6b and 6c). The sedimentary oxygenation thus cannot be determined by export productivity alone.

6.2.3 Effects of the Kuroshio dynamics on sedimentary oxygenation

The Kuroshio Current, one of the main drivers of vertical mixing, has been
identified as the key factor in controlling modern deep ventilation in the OT (Kao et al., 2006). However, the flow path of the Kuroshio in the OT during the glacial interval remains a matter of debate. Planktic foraminiferal assemblages in sediment cores from inside and outside the OT indicated that the Kuroshio migrated to the east of the Ryukyu Islands during the LGM (Ujiié and Ujiié, 1999). Subsequently, Kao et al. (2006) based on modeling results suggested that the Kuroshio still enters the OT, but the volume transport was reduced by 43% compared to the present-day transport and the outlet of Kuroshio switches from the Tokara Strait to the Kerama Gap at -80 and -135m lowered sea level. Combined with sea surface temperature (SST) records and ocean model results, Lee et al. (2013) argued that there was little effect of deglacial sea-level change on the path of the Kuroshio, which still exited the OT from the Tokara Strait during the glacial period. Because the main stream of the Kuroshio Current is at a water depth of ~150 m, the SST records are insufficient to decipher past changes of the Kuroshio (Ujiié et al., 2016). On the other hand, low abundances of *P. obliquiloculata* in core CSH1 in the northern OT (Figure 6e) indicate that the main flow path of the Kuroshio migrated to the east of the Ryukyu Island (Shi et al., 2014). Such a flow change would have been caused by the proposed block of the Ryukyu-Taiwan land bridge by low sea level (Ujiié and Ujiié, 1999) and an overall reduced Kuroshio intensity (Kao et al., 2006), effectively suppressing the effect of the Kuroshio on deep ventilation in the OT. Our RSEs data show that oxygenated sedimentary conditions were dominant in the northern OT throughout the last glacial period (Figures 6b and 6c). The Kuroshio thus likely had a weak or even no effect on the renewal of oxygen to the sedimentary environment during the last glacial period. More recently, lower hydrothermal total Hg concentration during 20 ka - 9.6 ka, associated with reduced intensity and/or variation in flow path of KC, relative to that of Holocene recorded in core KX12 - 3 (1423 water depth) (Lim et al., 2017), further validates our inference.

On the other hand, the gradually increased alkenone-derived SST and abundance of *P. obliquiloculata* (Figures 6d and 6e) from 15 ka onwards indicates an intensified Kuroshio Current. At present, mooring and float observations revealed that the KC
penetrates to 1200 m isobath in the East China Sea (Andres et al., 2015). However, the effect of Kuroshio on sedimentary oxygenation was likely very limited during the glacial period and only gradually increasing throughout the last glacial termination. Therefore, while its effect on our observed deglacial variation in oxygenation may provide a slowly changing background condition in vertical mixing effects on the sedimentary oxygenation in the OT, it cannot account for the first order, rapid oxygenation changes, including indications for millennial-scale variations, that we observe between 18 ka and 9 ka.

Better oxygenated sedimentary conditions since 8.5 ka coincided with intensified Kuroshio (Li et al., 2005; Shi et al., 2014), as indicated by rapidly increased SST and\textit{P. obliquiloculata} abundance in core CSH1 (Figures 6d and 6e) and \textit{C. hyalinea} abundance in core E017 (Figure 6i). Re-entrance of the Kuroshio into the OT (Shi et al., 2014) with rising eustatic sea level likely enhanced the vertical mixing and exchange between bottom and surface waters, ventilating the deep water in the OT. Previous comparative studies based on epibenthic $\delta^{13}$C values indicated well-ventilated deep water feeding both inside the OT and outside off the Ryukyu Islands during the Holocene (Kubota et al., 2015; Wahyudi and Minagawa, 1997). In summary, enhanced sedimentary oxygenation regime observed in the OT during the Holocene is mainly related to the intensified Kuroshio, while the effect of the Kuroshio on OT oxygenation was limited before 15 ka.

6.2.4. Effects of GNPIW on sedimentary oxygenation

Relatively stronger oxygenated Glacial North Pacific Intermediate Water (GNPIW), coined by (Matsumoto et al., 2002), has been widely documented in the Bering Sea (Itaki et al., 2012; Kim et al., 2011; Rella et al., 2012), the Okhotsk Sea (Itaki et al., 2008; Okazaki et al., 2014; Okazaki et al., 2006; Wu et al., 2014), off east Japan (Shibahara et al., 2007), the eastern North Pacific (Cartapanis et al., 2011; Ohkushi et al., 2013) and western subarctic Pacific (Keigwin, 1998; Matsumoto et al., 2002). The intensified formation of GNPIW due to additional source region in the Bering Sea was proposed by Ohkushi et al. (2003) and Horikawa et al. (2010). Under such conditions, the invasion of well-ventilated GNPIW into the OT through the
Kerama Gap would have replenished the water column oxygen in the OT, although the penetration depth of GNPIW remains under debate (Jaccard and Galbraith, 2013; Max et al., 2014; Okazaki et al., 2010; Rae et al., 2014). Both a gradual decrease in excess U concentration and an increase in Mo/Mn ratio during the last glacial period (25 ka-50 ka) validate such inference, suggesting pronounced effects of intensified NPIW formation in the OT.

During HS1, a stronger formation of GNPIW was supported by proxy studies and numerical simulations. For example, on the basis of paired benthic-planktic (B-P) $^{14}$C data, enhanced penetration of NPIW into a much deeper water depth during HS1 relative to the Holocene has been revealed in several studies (Max et al., 2014; Okazaki et al., 2010; Sagawa and Ikehara, 2008), which was also simulated by several models (Chikamoto et al., 2012; Gong et al., 2019; Okazaki et al., 2010). On the other hand, increased intermediate water temperature in the subtropical Pacific recorded in core GH08-2004 (1166 m water depth) (Kubota et al., 2015) and young deep water observed in the northern South China Sea during HS1 (Wan and Jian, 2014) along downstream region of NPIW are also related to intensified NPIW formation. Furthermore, the pathway of GNPIW from numerical model simulations (Zheng et al., 2016) was similar to modern observations (You, 2003). Thus, all these evidence imply a persistent, cause and effect relation between GNPIW ventilation, the intermediate and deep water oxygen concentration in the OT and sediment redox state during HS1.

In addition, our RSEs data also suggested a similarly enhanced ventilation in HS2 (Figures 6b and 6c) that is also attributed to intensified GNPIW formation.

Hypoxic conditions during the B/A have been also widely observed in the mid- and high-latitude North Pacific (Jaccard and Galbraith, 2012; Praetorius et al., 2015). Our data of excess U concentration and Mo/Mn ratio recorded in core CSH1 (Figures 6b and 6c), together with enhanced denitrification and B.aculeata abundance (Figures 6f and 6h), further reveal the expansion of oxygen-depletion at mid-depth waters down to the subtropical NW Pacific during the late deglacial period. Based on high relative abundances of radiolarian species, indicators of upper intermediate water ventilation in core PC-23A, Itaki et al. (2012) suggested that a presence of
well-ventilated waters was limited to the upper intermediate layer (200 m–500 m) in the Bering Sea during warm periods, such as the B/A and Preboreal. Higher B-P foraminiferal $^{14}C$ ages, together with increased temperature and salinity at intermediate waters recorded in core GH02-1030 (off East Japan) supported a weakened formation of NPIW during the B/A (Sagawa and Ikehara, 2008). These lines of evidence indicate that the boundary between GNPIW and North Pacific Deep Water shoaled during the B/A, in comparison to HS1. Based on a comparison of two benthic foraminiferal oxygen and carbon isotope records from off northern Japan and the southern Ryukyu Island, Kubota et al. (2015) found a stronger influence of Pacific Deep Water on intermediate-water temperature and ventilation at their southern than the northern locations, though both sites are located at similar water depths (1166 m and 1212 m for cores GH08-2004 and GH02-1030, respectively). Higher excess U concentration and low Mo/Mn ratio in our core CSH1 during the B/A and Preboreal suggest reduced sedimentary oxygenation, consistent with reduced ventilation of GNPIW, contributing to the subsurface water deoxygenation in the OT.

During the YD, both Mo/Mn ratio and excess U show a slightly decreased oxygen condition in the northern OT. By contrast, benthic foraminiferal $\delta^{18}O$ and $\delta^{13}C$ values in a sediment core collected from the Oyashio region suggested a strengthened formation and ventilation of GNPIW during the YD (Ohkushi et al., 2016). This pattern possibly indicates a time-dependent, varying contribution of distal GNPIW to the deglacial OT oxygenation history, and we presume a more pronounced contribution of organic matter degradation due to high export productivity during this period, as suggested by increasing CaCO$_3$ content.

6.3. Subtropical North Pacific ventilation links to North Atlantic Climate

One of the characteristic climate features in the Northern Hemisphere, in particular the North Atlantic is millennial-scale oscillation during glacial and deglacial periods. These abrupt climatic events have been widely thought to be closely related to varying strength of Atlantic Meridional Overturning Circulation (AMOC) (Lynch-Stieglitz, 2017). One of dynamic proxies of ocean circulation, $^{231}$Pa/$^{230}$Th reveals that severe weakening of AMOC only existed during Heinrich stadials due to
increased freshwater discharges into the North Atlantic (Böhm et al., 2015; McManus et al., 2004). On the other hand, several mechanisms, such as sudden termination of freshwater input (Liu et al., 2009), atmospheric CO$_2$ concentration (Zhang et al., 2017), enhanced advection of salt (Barker et al., 2010) and changes in background climate (Knorr and Lohmann, 2007) were proposed to explain the reinvigoration of AMOC during the B/A.

Our RSEs data in the Northern OT and endobenthic $\delta^{13}$C in the Bering Sea (Figures 7a-7c) both show a substantial millennial variability in intermediate water ventilation in the subtropical North Pacific. Notably, enhanced ventilation during HS1 and HS2 and oxygen-poor condition during the B/A respectively correspond to the collapse and resumption of AMOC (Figure 7d). Such out-of-phase millennial-scale pattern is consistent with the results of various modeling simulations (Chikamoto et al., 2012; Menviel et al., 2014; Okazaki et al., 2010; Saenko et al., 2004), although these models had different boundary conditions and causes for the observed effects in GNPIW formation, and ventilation ages derived from B-P $^{14}$C (Freeman et al., 2015; Max et al., 2014; Okazaki et al., 2012). These lines of evidence confirm a persistent link between the ventilation of North Pacific and the North Atlantic climate (Lohmann et al., 2019). Such links have also been corroborated by proxy data and modeling experiment between AMOC and East Asian monsoon during the 8.2 ka event (Liu et al., 2013), the Holocene (Wang et al., 2005) and 34 ka–60 ka (Sun et al., 2012). The mechanism linking East Asia with North Atlantic has been attributed to an atmospheric teleconnection, such as the position and strength of Westerly Jet and Mongolia-Siberian High (Porter and Zhisheng, 1995). However, the mechanism behind such out-of-phase pattern between the ventilation in the subtropical North Pacific and the North Atlantic deep water formation remains unclear.

Increased NPIW formation during HS1 may have been caused by enhanced salinity-driven vertical mixing through higher meridional water mass transport from the subtropical Pacific. Previous studies have proposed that intermediate water formation in the North Pacific hinged on a basin-wide increase in sea surface salinity driven by changes in strength of the summer EAM and the moisture transport from
the Atlantic to the Pacific (Emile-Geay et al., 2003). Several modeling studies found that freshwater forcing in the North Atlantic could cause a widespread surface salinification in the subtropical Pacific Ocean (Menviel et al., 2014; Okazaki et al., 2010; Saenko et al., 2004). This idea has been tested by proxy data (Rodríguez-Sanz et al., 2013; Sagawa and Ikehara, 2008), which indicated a weakened summer EAM and reduced transport of moisture from Atlantic to Pacific through Panama Isthmus owing to the southward displacement of Intertropical Convergence Zone caused by a weakening of AMOC. Along with this process, as predicted through a general circulation modeling, a strengthened Pacific Meridional Overturning Circulation would have transported more warm and salty subtropical water into the high-latitude North Pacific (Okazaki et al., 2010). In accordance with comprehensive Mg/Ca ratio-based salinity reconstructions, however, Riethdorf et al. (2013) found no clear evidence for such higher salinity patterns in the subarctic northwest Pacific during HS1.

On the other hand, a weakened AMOC would deepen the wintertime Aleutian Low based on modern observation (Okumura et al., 2009), which is closely related to the sea ice formation in the marginal seas of the subarctic Pacific (Cavalieri and Parkinson, 1987). Once stronger Aleutian Low, intense brine rejection due to sea ice expansion, would have enhanced the NPIW formation. Recently modeling-derived evidence confirmed that enhanced sea ice coverage occurred in the southern Okhotsk Sea and off East Kamchatka Peninsula during HS1 (Gong et al., 2019). In addition, stronger advection of low-salinity water via the Alaskan Stream to the subarctic NW Pacific was probably enhanced during HS1, related to a shift of the Aleutian Low pressure system over the North Pacific, which could also increase sea ice formation, brine rejection and thereafter intermediate water ventilation (Riethdorf et al., 2013).

During the late deglaciation, ameliorating global climate conditions, such as warming Northern Hemisphere, and a strengthened Asian summer monsoon, are a result of changes in insolation forcing, greenhouse gases concentrations, and variable strengths of the AMOC (Clark et al., 2012; Liu et al., 2009). During the B/A, a decrease in sea ice extent and duration was indicated by combined reconstructions of
SST and mixed layer temperatures from the subarctic Pacific (Riethdorf et al., 2013). At that time, the rising eustatic sea level (Spratt and Lisiecki, 2016) would have supported the intrusion of Alaska Stream into the Bering Sea by deepening and opening glacial closed straits of the Aleutian Islands chain, while reducing the advection of the Alaska Stream to the subarctic Pacific gyre (Riethdorf et al., 2013). In this scenario, saltier and more stratified surface water conditions would have inhibited brine rejection and subsequent formation and ventilation of NPIW (Lam et al., 2013), leading to a reorganization of the Pacific water mass, closely coupled to the collapse and resumption modes of the AMOC during these two intervals.

6.4 Increased storage of CO$_2$ at mid-depth water in the North Pacific at the B/A

One of the striking features of RSEs data is higher Mo/Mn ratios and excess U concentrations across the B/A, supporting an expansion of Oxygen Minimum Zone in the North Pacific (Galbraith and Jaccard, 2015; Jaccard and Galbraith, 2012; Moffitt et al., 2015) and coinciding with the termination of atmospheric CO$_2$ concentration rise (Marcott et al., 2014) (Figure 7e). As described above, it can be related to the upwelling of nutrient- and CO$_2$-rich Pacific Deep Water due to resumption of AMOC and enhanced export production. Notably, boron isotope data measured on surface-dwelling foraminifera in core MD01-2416 situated in the western subarctic North Pacific did reveal a decrease in near-surface pH and an increase in pCO$_2$ at the onset of B/A (Gray et al., 2018), indicating that the subarctic North Pacific is a source of relatively high atmospheric CO$_2$ concentration at that time. Here we cannot conclude that the same processes could have occurred in the subtropical North Pacific due to the lack of well-known drivers to draw out of the old carbon in the deep sea into the atmosphere. In combination with published records from the North Pacific (Addison et al., 2012; Cartapanis et al., 2011; Crusius et al., 2004; Galbraith et al., 2007; Lembke-Jene et al., 2017; Shibahara et al., 2007), an expansion of oxygen-depletion zone during the B/A suggest an increase in respired carbon storage at mid-depth waters of the North Pacific, which likely stalls the rise of atmospheric CO$_2$. Our results support the findings by Galbraith et al. (2007). Given the sizeable volume of the North Pacific, potentially, once the respired carbon could be emitted to
the atmosphere in stages, which would bring the planet out of the last ice age (Jaccard and Galbraith, 2018).

7. Conclusions

Our geochemical results of sediment core CSH1 revealed substantial changes in intermediate water redox conditions in the northern Okinawa Trough over the last 50 ka on orbital and millennial timescales. Enhanced sedimentary oxygenation mainly occurred during cold intervals, such as the last glacial period, Heinrich stadials 1 and 2, and during the middle and late Holocene, while diminished sedimentary oxygenation prevailed during the Bölling-Alleröd and Preboreal. The sedimentary oxygenation variability presented here provides key evidence for the substantial impact of ventilation of NPIW on the sedimentary oxygenation in the subtropical North Pacific and shows out-of-phase pattern with North Atlantic Climate during the last deglaciation. The linkage is attributable to the disruption of NPIW formation caused by climate changes in the North Atlantic, which is transferred to the North Pacific via atmospheric and oceanic teleconnections. We also suggest an expansion of oxygen-depleted zone and accumulation of respired carbon at the mid-depth waters from previously reported subarctic locations into the western subtropical the North Pacific during the B/A, coinciding with the termination of atmospheric CO₂ rise. A step-wise injection of such respired carbon into the atmosphere would be helpful to maintain high atmospheric CO₂ levels during the deglaciation and bring the planet out of the last ice age.

Data availability. All raw data are available to all interested researchers upon request.

Author Contributions. J.J.Z. and X.F.S. conceived the study. A.M.Z. performed geochemical analyses of bulk sediments. J.J.Z., X.F.S. K.S. and X.G. led the write up of the manuscript. All other authors provided comments on the manuscript and contributed to the final version of the manuscript.

Competing interests: The authors declare no competing interests.

Table 1. Locations of different sediment core records and their source references discussed in the text.

Table 2. Age control points adopted between planktic foraminifera species Globigerinoides ruber δ18O of Core CSH1 and Chinese stalagmite δ18O (Cheng et al., 2016) for tuning the age model between 10 ka and 60 ka in this study. A linear interpolation was assumed between age control points.

Figure 1. (a) Spatial distribution of dissolved oxygen content at 700 m water depth in the North Pacific. Black arrows denote simplified Kuroshio and Oyashio circulations and North Pacific Intermediate Water (NPIW) in the North Pacific. The red thick dashed line indicates transformation of Okhotsk Sea Intermediate Water (OSIW) by cabling the subtropical NPIW along the subarctic-tropical frontal zone (You, 2003). The light brown solid line with arrow indicates the spreading path of subtropical NPIW from northeast North Pacific southward toward the low-latitude northwest North Pacific (You, 2003). Yellow solid lines with arrow represent two passages through which NPIW enter into the Okinawa Trough. This figure was created with Ocean Data View (odv.awi.de). (b) Location of sediment core CSH1 investigated in this study (red diamond). Also shown are locations of sediment cores PN-3, E017, 255 and MD012404 investigated previously from the Okinawa Trough, GH08-2004 from the East of Ryukyu Island, GH02-1030 off the east of Japan, PC-23A from the Bering Sea and ODP Site 1017 from the northeastern Pacific. Letters A to E represent the sediment cores from and near the OT. The detailed information for these cores is shown in Table 1.

Figure 2. Spatial distribution of sea surface salinity in the East China Sea. (a) summer (July to September); (b) winter (January to March). Lower sea surface salinity in summer relative to that of winter indicates strong effects of summer East Asian Monsoon.
Figure 3. (a) Lithology and oxygen isotope ($\delta^{18}$O) profile of planktic foraminifera species *Globigerinoides ruber* (*G. ruber*) in core CSH1. (b) Plot of ages versus depth for core CSH1. Three known ash layers are indicated by solid red rectangles. (c) Time series of linear sedimentation rate (LSR) from core CSH1. (d) Comparison of age model of core CSH1 with Chinese Stalagmite composite $\delta^{18}$O curve of (Cheng et al., 2016). Tie points for CSH1 core chronology (Table 2) in Figures 3c and 3d are designated by colored crosses.

Figure 4. Age versus (a) CaCO$_3$ concentration, (b) Total nitrogen (TN) concentration, (c) Total organic carbon (TOC) concentration, (d) C/N molar ratio, (e) linear sedimentation rate (LSR), (f) Al concentration, (g) Mn concentration, (h) Mo/Mn ratio, (i) Mo concentration, (j) excess Mo concentration, (k) U concentration and (l) excess U concentration and (m) (Mo/U)$_{excess}$ ratio in core CSH1. Light gray and dark gray vertical bars indicate different sediment intervals in core CSH1. 8.2 ka, PB, YD, B/A, HS1, LGM and HS2 refer to 8,200 year cold event, Preboreal, Younger Dryas, Bölling-Alleröd, Heinrich Stadial 1, Last Glacial Maximum and Heinrich Stadial 2, respectively, which were identified in core CSH1. Blue solid diamonds in Figure 4m indicate the age control points.

Figure 5. Scatter plots of Mo$_{excess}$ vs Mn concentrations and U$_{excess}$ concentration vs Mo/Mn ratio at different time intervals in core CSH1. A various correlation is present in core CSH1 at different time intervals, which shows their complicated geochemical behaviors (Figs.5a and 5b). Strong positive correlation between Mo/Mn ratio and U$_{excess}$ concentration (Fig.5c) suggest that Mo/Mn ratio is a reliable proxy to track sedimentary redox conditions in the geological past.

Figure 6. Proxy-related reconstructions of mid-depth sedimentary oxygenation at site CSH1 (this study) compared with oxygenation records from other locations of the North Pacific and published climatic and environmental records from the Okinawa
Figure 7. Proxy records favoring the existence of out-of-phase connections between the subtropical North Pacific and North Atlantic during the last deglaciation and enhanced carbon storage at mid-depth waters. (a) \( U_{\text{excess}} \) concentration in core CSH1; (b) Mo/Mn ratio in core CSH1; (c) benthic \( \delta^{13}C \) record in core PC-23A in the Bering Sea (Rella et al., 2012); (d) Indicator of strength of Atlantic Meridional Ocean Circulation \((^{231}Pa/^{230}Th)\) (Böhm et al., 2015; McManus et al., 2004); (e) Atmospheric CO\(_2\) concentration (Marcott et al., 2014). Light gray and dark gray vertical bars are the same as those in Figure 4.
