19 **Abstract**

20 The Pacific-North American (PNA) teleconnection is one of the most important climate
21 modes in the present climate condition, and it enables climate variations in the tropical Pacific to
22 exert significant impacts on North America. Here, we show climate simulations that the PNA
23 teleconnection was largely distorted or broken at the Last Glacial Maximum (LGM). The
24 distorted PNA is caused by a split of the westerly jet stream, which is ultimately forced by the
25 thick and large Laurentide ice sheet at the LGM. Changes in the jet stream greatly alter the
26 extratropical wave guide, distorting wave propagation from the North Pacific to North America.
27 The distorted PNA suggests that climate variability in the tropical Pacific, notably, El Niño and
28 Southern Oscillation (ENSO), would have little direct impact on North American climate at the
29 LGM.

42 **1 Introduction**

43 The Pacific-Northern-American (PNA) teleconnection is the major atmospheric
44 teleconnection mode that links climate variations from the tropical Pacific to North America for
45 the present-day climate state (Horel and Wallace, 1981; Wallace and Gutzler, 1981). Especially,
46 climate variability associated with El Niño and Southern Oscillation (ENSO) exerts great
47 impacts on the North American climate through the PNA teleconnection (Henderson and
48 Robinson, 1994; Lau, 1997; Leathers et al., 1991; Straus and Shukla, 2002). It is well known that
49 the PNA is largely constrained by extratropical atmospheric flows, notably, the extratropical
50 wave guide (Held, 1983; Held et al., 2002; Hoskins and Karoly, 1981; Jin and Hoskins, 1995).
51 Thus, changes in extratropical atmospheric flows should alter the PNA under different climate
52 conditions.

53 It has been shown that greenhouse warming leads to a strengthening and a shift of the PNA
54 due to altered extratropical atmospheric flows (Allan et al., 2014; Chen et al., 2017). There has
55 also been a large body of works that demonstrated significant differences in extratropical
56 atmospheric circulations in cold climates, notably, the Last Glacial Maximum (LGM). It was
57 shown that during the LGM the Aleutian low pressure system was enhanced in winter, the
58 Pacific high pressure system was weakened in summer (Yanase and Abe-Ouchi, 2007; Yanase
59 and Abe-Ouchi, 2010), the westerly jet shifted southward (Braconnot et al., 2007; Otto-Bliesner
60 et al., 2006), and transient waves were weakened over the North Pacific and strengthened over
61 the North Atlantic (Justino and Peltier, 2005; Justino et al., 2005). These works suggest that the
62 PNA could be changed for different climate regimes. Therefore, a natural question is whether the
63 PNA is also significantly altered due to atmospheric circulation changes at the LGM.

64 The LGM occurred between 23,000 and 19,000 years ago (Clark et al., 2009; Clark and
65 Mix, 2002). One of the most significant climatic characteristics at LGM is the maximum
66 expansion of mid-latitude ice sheets. Extensive ice sheets grew over North America and
67 northwestern Europe, with the Laurentide ice sheet over North America, in particular, of an ice
68 thickness of 3 to 4 kilometers (Marshall et al., 2002). Early simulations have shown that the thick
69 and large Laurentide ice sheet forced a split of the extratropical westerly jet stream into the
70 northern and southern branches (Cohmap, 1988; Kutzbach and Wright, 1985; Rind, 1987), and
71 that the jet split leads to regional climate changes over the globe, especially over North America.
72 Proxy records showed that there were more storms and precipitation associated with the southern
73 branch, causing high lake levels and increased woodlands in the southwestern United States
74 (Cohmap, 1988; Kutzbach and Wright, 1985).

75 Recent modeling studies showed that the Arctic Oscillation and storm tracks at LGM
76 differ significantly from the present (Justino and Peltier, 2005; Lañ  t al., 2009; Li and Battisti,
77 2008; L   et al., 2010; Rivi  re et al., 2010), and that the Laurentide ice sheet can also influence
78 the Southern-Hemisphere atmospheric teleconnection and climate variability over West
79 Antarctic (Jones et al., 2018). Therefore, it is possible that changed atmospheric circulations at
80 LGM might also significantly alter the PNA and thus climate linkage between the tropical
81 Pacific and North America.

82 In the present paper, using climate simulation results, we show that the PNA is largely
83 distorted or even broken by the Laurentide ice sheet at LGM, and that ENSO had little direct
84 impact on North American climates. We will also address how the PNA is altered by the
85 Laurentide ice sheet.

86 **2 Models and data**

87 The simulation results from the Paleoclimate Modeling Intercomparison Project 2 (PMIP2)
88 (Braconnot et al., 2012; Braconnot et al., 2007) and 3 (PMIP3) (Abe-Ouchi et al., 2015) are
89 utilized in this study. By comparing the PNA patterns in the Preindustrial condition (PIC) with
90 LGM simulations as well as our own sensitivity simulations, the changes in the PNA pattern at
91 LGM are identified. The horizontal resolution of the models we use are listed in table S1. For
92 comparison, we also use the NCEP/NCAR reanalysis data from 1988 to 2017 (Kistler et al.,
93 2001), with horizontal resolution of $2.5^{\circ} \times 2.5^{\circ}$. We shall mainly focus on the simulation results
94 from the Community Climate System Model version 3 (CCSM3) (Collins et al., 2006; Jones et
95 al., 2018; Otto-Bliesner et al., 2006; Yeager et al., 2006), since our sensitivity simulations are
96 performed with the same model.

97 To understand the impact of the topography of the Northern-Hemisphere glacial ice sheets
98 on the PNA, we performed a series of sensitivity simulations with different ice sheet thicknesses,
99 which are 0%, 20%, 40%, 60%, 80%, 100%, and 150% of the ice sheet thickness that was used
100 in PMIP2. Note that different ice sheet reconstructions were used in PMIP2 and PMIP3
101 simulations. PMIP2 simulations used the ICE-5G (VM2) reconstruction (Peltier, 2004), while
102 PMIP3 simulations used the ICE-6G reconstruction. In general, the ice sheet thickness in ICE-
103 6G reconstruction is approximately equal to 80% of ICE-5G for most parts of the North
104 American region (Figure S1). In our sensitivity simulations, the case of 0% ice sheet thickness
105 means that the thickness of the ice sheet is set to zero, but the surface albedo remains ice albedo.
106 All other conditions are the same as that in the LGM simulations of PMIP2. The model for our
107 sensitivity simulations is a lower-resolution version of CCSM3 (T31), with horizontal a
108 resolution of $3.8^{\circ} \times 3.8^{\circ}$. It differs from the PMIP2 models (T42), with a horizontal resolution of
109 $2.8^{\circ} \times 2.8^{\circ}$. Although the horizontal resolution in CCSM3 T31 is lower, it can well reproduce the

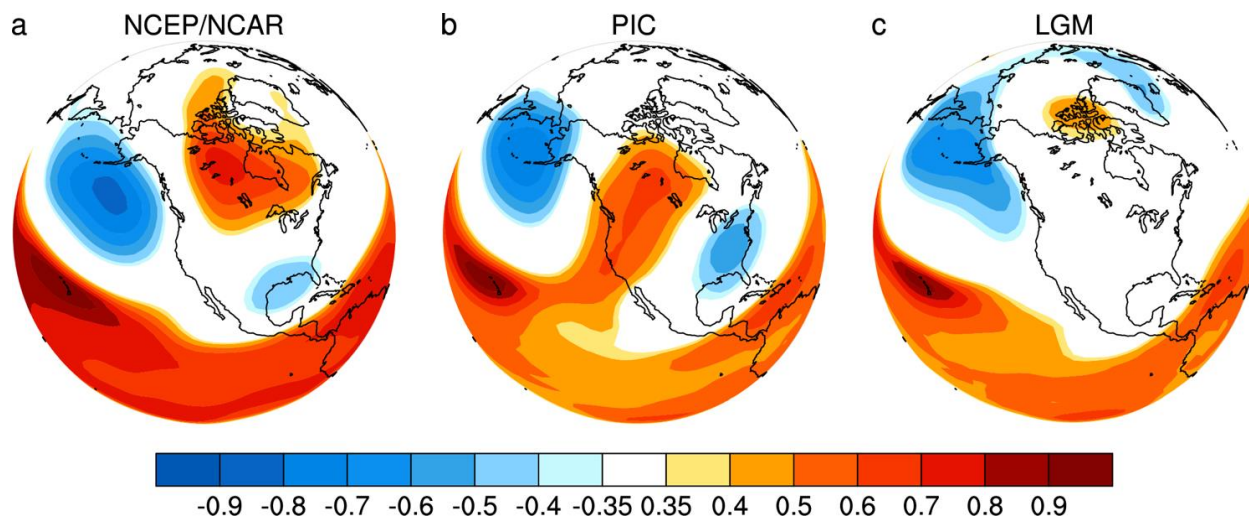

110 present-day PNA pattern in the PIC simulation, consistent with the results in Magnusdottir and
111 Haynes (1999) and L öfverstr öm et al. (2016). Therefore, the results here are not sensitive to
112 model resolutions.

113 Following Horel and Wallace (1981) and Wallace and Gutzler (1981), the PNA
114 teleconnection is characterized by the pointwise correlation method. The four base points that
115 represent the centers of action are located near Hawaii (20 °N, 160 °W), North Pacific (45 °N,
116 165 °W), Alberta (55 °N, 115 °W), and the Gulf Coast (30 °N, 85 °W), respectively. The four
117 base points were objectively derived with teleconnectivity analysis (Sherriff-Tadano and Itoh,
118 2013; Wallace and Gutzler, 1981). To examine whether models can reasonably simulate the
119 PNA in PIC simulations and whether the PNA pathway is altered in LGM simulations, we
120 loosely define a circular region around each of the centers of North Pacific, North America and
121 the Gulf Coast (the base point is near Hawaii), with a radius of 10 degrees. For PIC simulations,
122 if a model cannot generate statistically significant correlations (coefficients greater than 0.35)
123 within the circular regions, the model is considered to have poor performance in simulating
124 PNA. For these models with good performance in simulating PNA their PIC simulations, if their
125 LGM simulations shows absence of significant correlations in the three circular regions, the PNA
126 pathway is considered to be distorted or broken at LGM. Because the PNA is most active in DJF,
127 our analysis below will mainly focus on the December-January-February (DJF) season.

128 In the present paper, all correlation analyses are conducted with monthly-mean model
129 outputs of the last 30-year simulations. Correlation coefficient 0.35 corresponds to the 95%
130 confidence level for 30-year correlations.

131 **3 Results**

132 Fig. 1 shows one-point correlation maps of 500 hPa geopotential heights in DJF, with the
 133 base point near Hawaii. The correlation maps in Figs. 1a and 1b exhibit similar wave-train
 134 patterns, with centers of positive and negative correlations extending from Hawaii to North
 135 Pacific, Alberta, and finally to the Gulf Coast, respectively. Hence, the present-day PNA is
 136 reproduced reasonably well in CCSM3. In contrast, this PNA pattern is altered dramatically in
 137 the LGM simulation of CCSM3 (Fig. 1c). The negative correlation over North Pacific is reduced,
 138 and the center of positive correlation is rather weak and shifted to the Arctic. The most striking
 139 feature in Fig. 1c is that the center of negative correlation near the Gulf Coast completely
 140 disappears. The results in Fig. 1 indicate that the PNA teleconnection is largely distorted at
 141 LGM. This is the most important point of the present paper.

142
 143 **Fig. 1.** One-point correlation maps of 500 hPa geopotential heights in DJF in NCEP/NCAR
 144 reanalysis and PMIP2 CCSM3 simulations. (a) NCEP/NCAR, (b) PIC, and (c) LGM. The base
 145 point is near Hawaii. The correlation coefficient of 0.35 corresponds to the 95% confidence level
 146 for 30-year correlations.

147 This distorted PNA at LGM can also be seen from correlation maps for the other three base
 148 points. When the base point is located over North Pacific (Fig. S2c), the center of positive
 149 correlation over North America is shifted to northern Canada. For the base point over North

150 America (Fig. S2f), the negative correlations over North Pacific and the Gulf Coast are all
151 largely reduced, and the center of positive correlation near Hawaii disappears. This result
152 indicates a disconnection between North America and the tropical Pacific. For the base point
153 near the Gulf Coast (Fig. S2i), a wave train is established from North Pacific to the Gulf Coast,
154 while the center of positive correlation over North America is largely reduced, and the center of
155 positive correlation near Hawaii is absent.

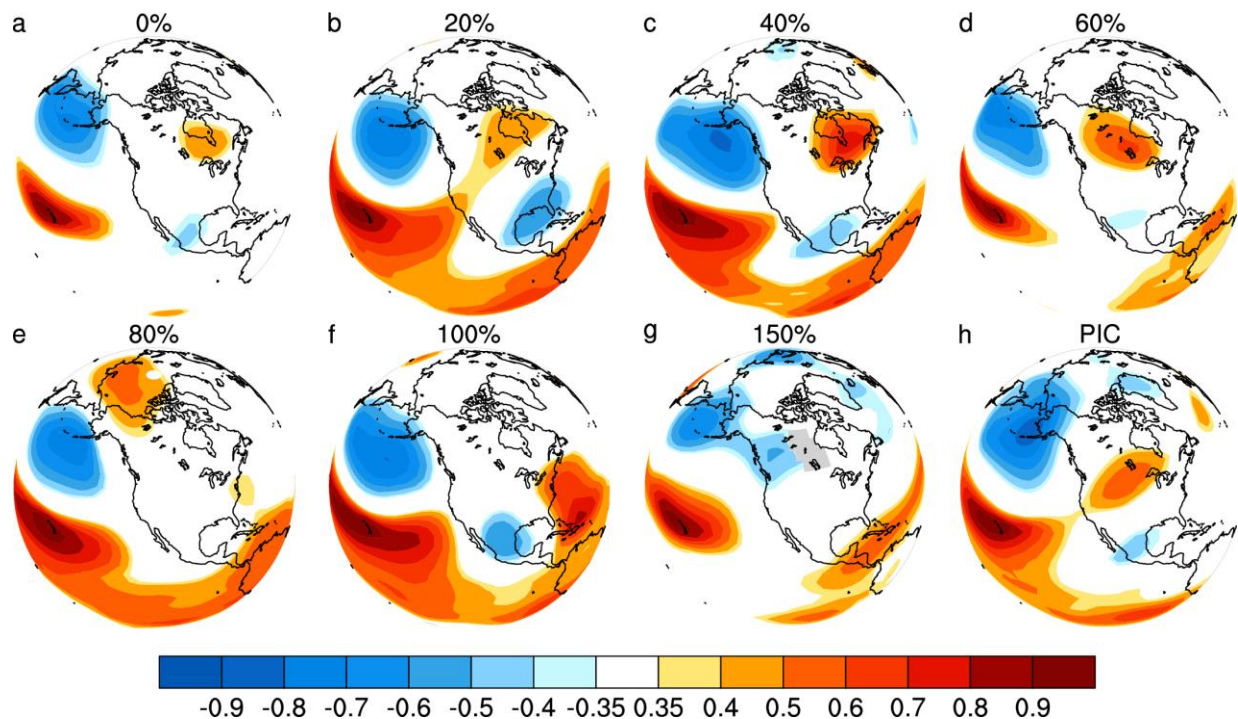

156 The PNA teleconnection at LGM is even completely broken in other PMIP2 models. There
157 are seven PMIP2 models that have simulations available online. According to our definition,
158 CCSM3, ECBILTCLIO, HadCM3M2, and CNRM-CM33 can reasonably reproduce the PNA in
159 their PIC simulations (Fig. 1b and Figs. S3a-c), whereas IPSL-CM4-V1-MR, FGOALS-1.0g,
160 and MIROC3.2 have poor performance. In LGM simulations, the center of negative correlation
161 over North Pacific still exists in ECBILTCLIO, HadCM3M2, and CNRM-CM33 (Figs. S3d-f),
162 although they all shift away from the North Pacific base point and are largely reduced. However,
163 the center of positive correlation over North America completely disappears in these plots.
164 Moreover, the center of negative correlation near the Gulf Coast also disappears in the three
165 models.

166 PMIP3 simulations are also used to demonstrate the changes in the PNA teleconnection at
167 LGM. There are eight PMIP3 models that have LGM simulations available online. Again,
168 according to our definition, CCSM4, MRI-CGCM3, and MIROC-ESM can reasonably reproduce
169 the PNA in their PIC simulations (Figs. S4a-c). The LGM simulations of CCSM4 and MRI-
170 CGCM3 show the absence of the center of positive correlation over North America (Figs. S4d
171 and e). The center of positive correlation in MIROC-ESM is weak and biased toward the Arctic
172 (Fig. S4f). The center of negative correlation near the Gulf Coast is absent in MRI-CGCM3 and

173 MIROC-ESM. Although there is a negative center in CCSM4 (Fig. S4d), it is more like a result
174 of the subtropical wave train, rather than a part of PNA. Thus, the LGM simulations in PMIP3
175 models demonstrate that the PNA is either distorted or completely broken.

176 We have also done Empirical Orthogonal Function (EOF) and rotated EOF (REOF) analysis
177 to examine the PNA pattern for both LGM and PIC simulations (figures not shown here). It is
178 found that the second REOF modes in both the NCEP reanalysis and the CCSM3 PIC simulation
179 all well represent the loading pattern of the present-day PNA. However, the second REOF in the
180 CCSM3 LGM simulation does not show the PNA pattern. The third and fourth REOFs in the
181 LGM simulation show teleconnections between North Pacific and Arctic as well as between
182 North Pacific and the southern part of North America.

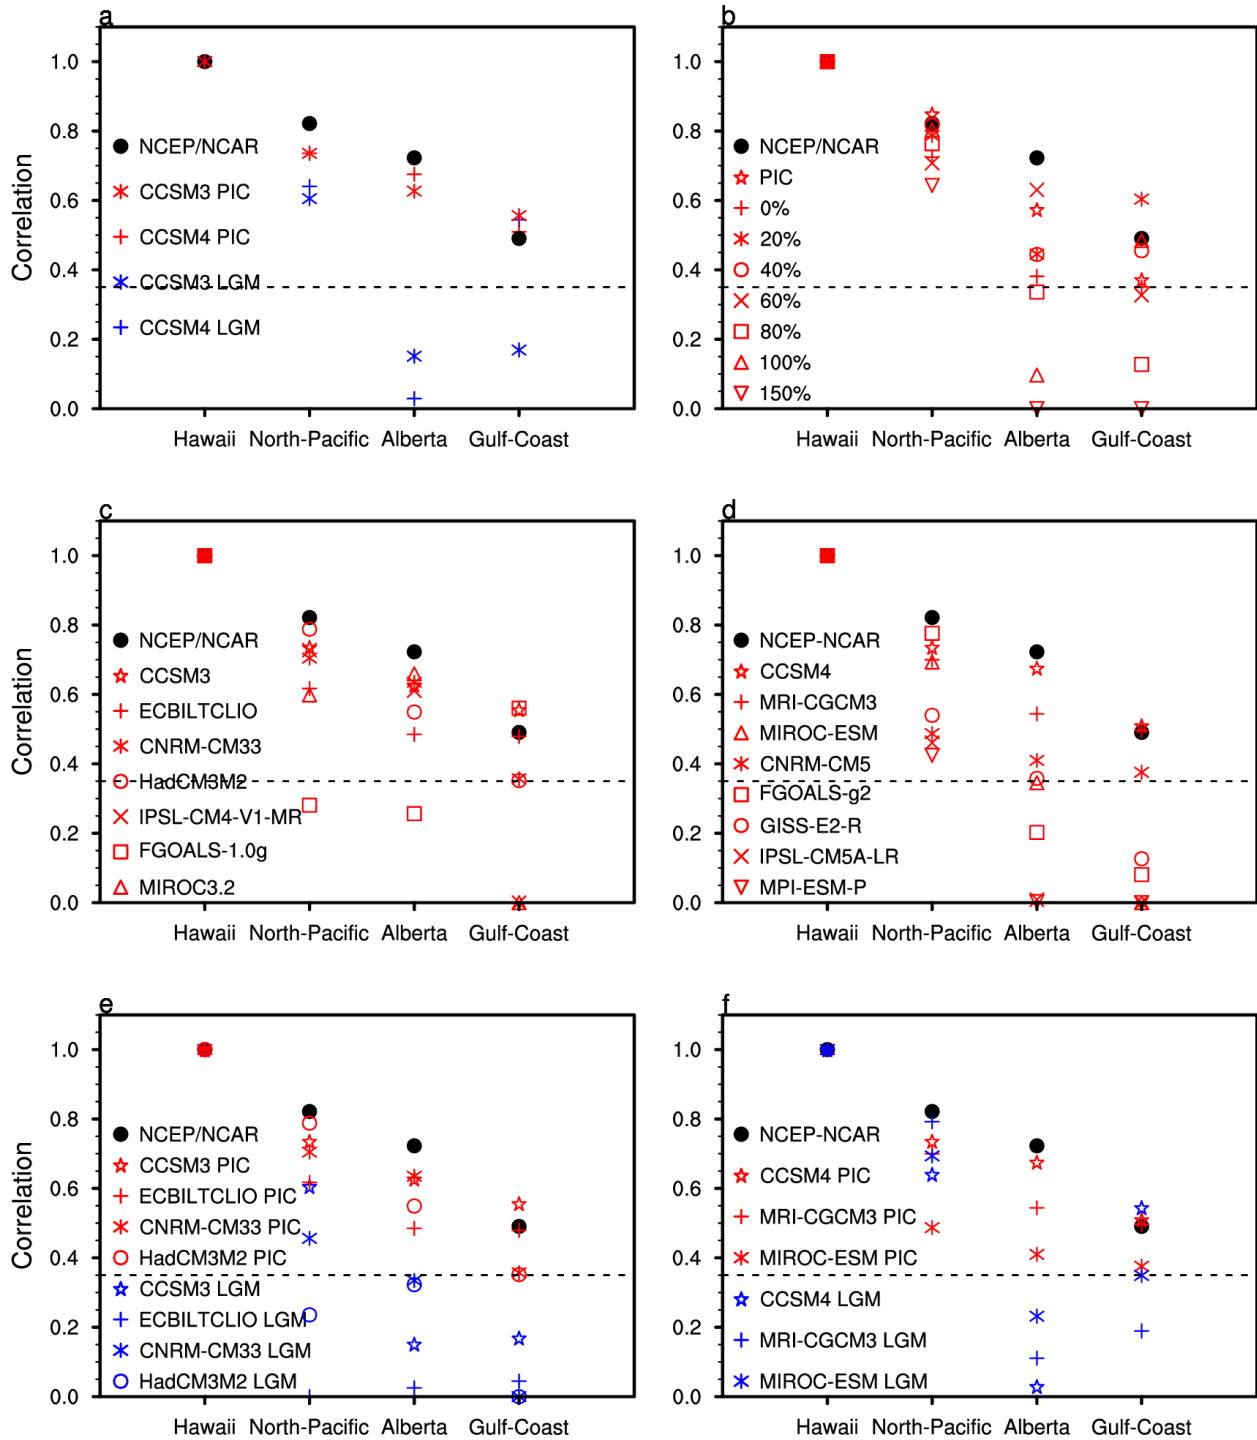

183 Fig. 2 illustrates PNA responses to different ice sheet thicknesses in sensitivity simulations.
184 The PNA pattern remains for ice sheet thicknesses no more than 60% of that in PMIP2 (Figs. 2a-
185 d). In contrast, the PNA is distorted as ice sheet thickness is increased to 80%. The center of
186 positive correlation is shifted to the Arctic, and the center of negative correlation near the Gulf
187 Coast disappears (Fig. 2e). As ice sheet thickness is further increased to 100 % and 150% (Figs.
188 2f-g), the center of positive correlation over North America disappears. Again, the center of
189 negative correlation is more like a part of the subtropical wave train. These results of sensitivity
190 simulations suggest that the PNA is distorted or even broken as the Laurentide ice sheet is
191 sufficiently thick.

192

193 **Fig. 2.** One-point correlation maps of 500 hPa geopotential heights in DJF in sensitivity
 194 simulations, with different ice sheet thicknesses. The base point is near Hawaii. (a) 0%, (b) 20%.
 195 (c) 40%, (d) 60%, (e) 80%, (f) 100%, (g) 150%, and (h) PIC. The correlation coefficient of 0.35
 196 corresponds to the 95% confidence level for 30-year correlations.

197 Fig. 3 summarizes correlation coefficients around the four base points for PMIP2,
 198 PMIP3, and our sensitivity simulations, according to our definition above. In Fig. 3a, both
 199 CCSM3 and CCSM4 show statistically significant correlations at all the four points in the PIC
 200 simulations. In contrast, they all demonstrate insignificant correlations near Alberta in LGM
 201 simulations. The significant correlation of CCSM4 LGM simulation near the Gulf coast is a
 202 result of subtropical wave train (Fig. S4d), as mentioned above. In Fig. 3b, the correlation
 203 coefficient near Alberta becomes less significant as ice sheet thickness reaches 80%. Correlation
 204 coefficients at the Gulf coast are insignificant for 80% and 150% ice sheet thickness. The
 205 significant correlation for 100% ice sheet thickness is a result of subtropical wave train, as shown
 206 in Fig. 2f.

207

208 **Fig. 3.** Correlation coefficients at the four PNA action centers in PIC and LGM simulations for
 209 PMIP2 and PMIP3 models, with the base point near Hawaii. The negative values over North
 210 Pacific and the Gulf Coast are reversed to positive. The dashed lines correspond to 0.35, which
 211 represent the 95% confidence level. (a) CCSM3 and CCSM4, (b) sensitivity simulations, (c) PIC
 212 simulations of PMIP2 models, (d) PIC simulations of PMIP3 models, (e) LGM and PIC

213 simulations for well-performing PMIP2 models, and (f) LGM and PIC simulations for well-
214 performing PMIP3 models.

215

216 Figs. 3c and d shows that most PMIP2 and PMIP3 models are able to reproduce the
217 center of negative correlations over the North Pacific in their PIC simulations, except for
218 FGOALS-1.0g. FGOALS-1.0g that generates insignificant correlations at either North Pacific or
219 Alberta. CNRM-CM33 and MIROC3.2 cannot generate significant correlations near the Gulf
220 coast. Fig. 3d shows that CCSM4, MRI-CGCM3, and MIROC-ESM are able to reproduce
221 significant correlations at all four points in their PIC simulations, whereas the other 5 models
222 have insignificant correlations at either Alberta or the Gulf Coast. Figs. 3e and f show that
223 PMIP2 and PMIP3 models, which have good performance in simulating the PNA teleconnection
224 in PIC simulations, all cannot reproduce significant positive correlations at Alberta or even
225 negative correlations near the Gulf coast in the LGM simulations. These results all suggest that
226 the PNA was distorted or broken at LGM.

227 Because the PNA pattern is characterized by a quasi-stationary wave train from the
228 tropical Pacific to North America, the above simulation results suggest that the PNA wave-train
229 propagation is largely altered at LGM. This can be confirmed by activity fluxes of stationary
230 waves at 500 hPa calculated, using [equation 7.1 in Plumb \(1985\)](#) (Fig. 4), which represents the
231 propagation direction of stationary waves (Plumb, 1985). At present, the wave activity fluxes
232 have two branches for wave propagation from the North Pacific toward North America (Fig. 4a).
233 The major branch propagates northeastward, forming the PNA teleconnection, while the minor
234 branch propagates southeastward. At LGM, however, wave propagation is altered drastically.
235 Wave propagation is deflected toward the subtropics (Figs. 4b and c). This is consistent with the
236 correlation map in Fig. S2i that shows a wave train from North Pacific to the Gulf Coast.

237 Therefore, the distorted or broken PNA at LGM is mainly due to the deflection of wave
238 propagation toward the southeast.

239

240 **Fig. 4.** Stationary wave activity fluxes in PMIP2 CCSM3 simulations at 500 hPa. (a) PIC, (b)
241 LGM, and (c) LGM – PIC. Length scales of wave activity vectors are marked in plots. Wave
242 activity vectors are plotted as their length scales are greater than $12 \text{ m}^2 \text{ s}^{-2}$ in plots (a) and (b) and
243 $6.5 \text{ m}^2 \text{ s}^{-2}$ in plot (c). Here, stationary wave activity fluxes are calculated with monthly-mean
244 data.

245 Wave propagation is oriented by the extratropical wave guide, which in turn is
246 determined by extratropical zonal flows (Hoskins and Karoly, 1981; Jin and Hoskins, 1995).
247 Therefore, the deflection of stationary wave propagation at LGM is caused due to changes in
248 extratropical zonal flows. A comparison of zonal winds between PIC and LGM simulations
249 shows several major differences (Figs. 5a vs. 5b). First, the zonal jet stream is much stronger at
250 LGM than at present. Second, the jet is shifted equatorward at LGM, and the jet is turned
251 southeastward as it approaches the North American continent, in contrast to the northeast
252 orientation at present. Third, similar to that in early studies (Cohmap, 1988; Kutzbach and
253 Wright, 1985; Rind, 1987), the jet splits over North America with the much stronger branch
254 located in the subtropics, leaving the much weaker branch over northern Canada. These features
255 can be seen more clearly in differences of zonal winds between LGM and PIC simulations (Fig.
256 5c).

257

258 **Fig. 5.** Maps of 500 hPa zonal winds in DJF in PMIP2 CCSM3 simulations. (a) PIC, (b) LGM,
 259 and (c) LGM – PIC. Color interval: 5 m s⁻¹.

260

261 Differences of zonal winds over North America can also be illustrated with the vertical cross-

262 sections along 100 °W (Fig. 6). The single subtropical westerly jet in the PIC simulation (Fig.

263 6b) is split into two jets at LGM (Fig. 6c): a subtropical jet at 30 °N and 200 hPa, and a subpolar

264 jet at 63 °N and between 400 and 300 hPa. The subtropical jet is intensified to a maximum wind

265 speed of 40 m s⁻¹ and is located at a lower latitude, and it is much stronger than that in the PIC

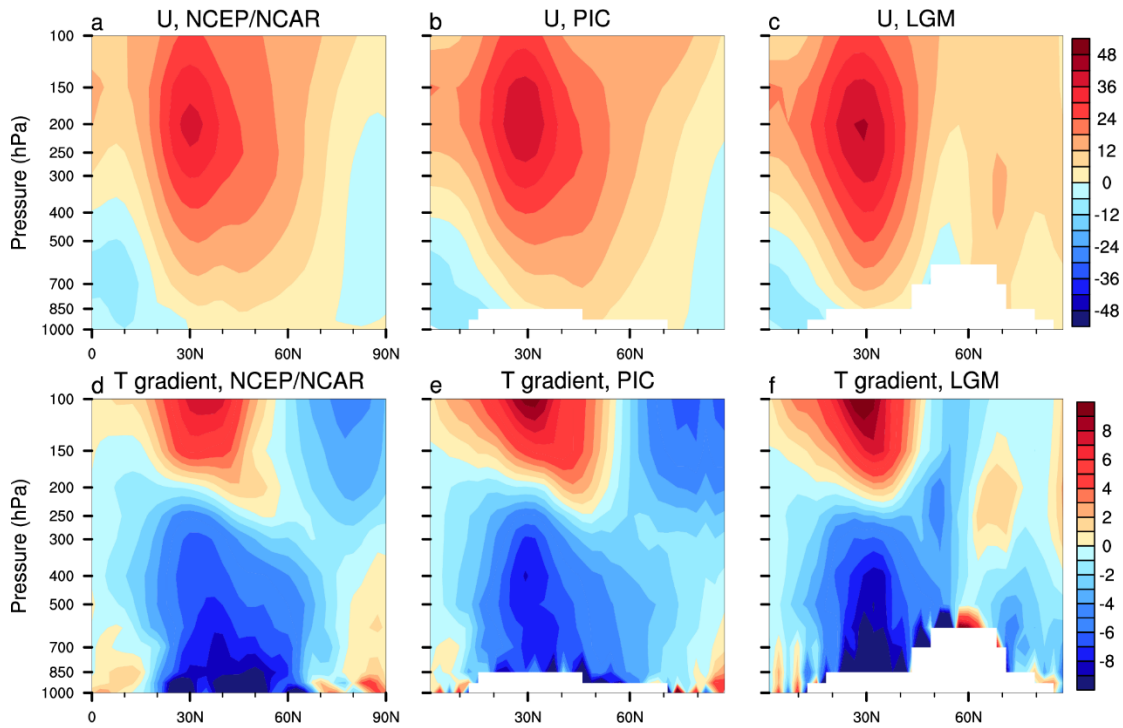

266 simulation (~ 30 m s⁻¹). The subpolar jet is much weaker, with a maximum speed of about 12 m

267 s⁻¹. The differences in zonal winds are associated with different thermal structures between LGM

268 and PIC simulations. Comparison of Figs. 6f with 6e shows that latitudinal temperature gradients

269 in the subtropics are sharper at LGM than at present. Thus, the stronger subtropical jet is

270 associated with the sharper temperature gradient.

271

272 **Fig. 6.** Vertical cross sections of DJF zonal winds and meridional temperature gradients along the
 273 longitude of 100°W in the NCEP/NCAR reanalysis and PMIP2 CCSM3 simulations. Top panels:
 274 zonal winds, and bottom panels: temperature gradients. Left panels: NCEP/NCAR, middle panels:
 275 PIC, and right panels: LGM. Zonal-wind unit is ms⁻¹, and temperature gradient unit is K/(1000
 276 km).

277

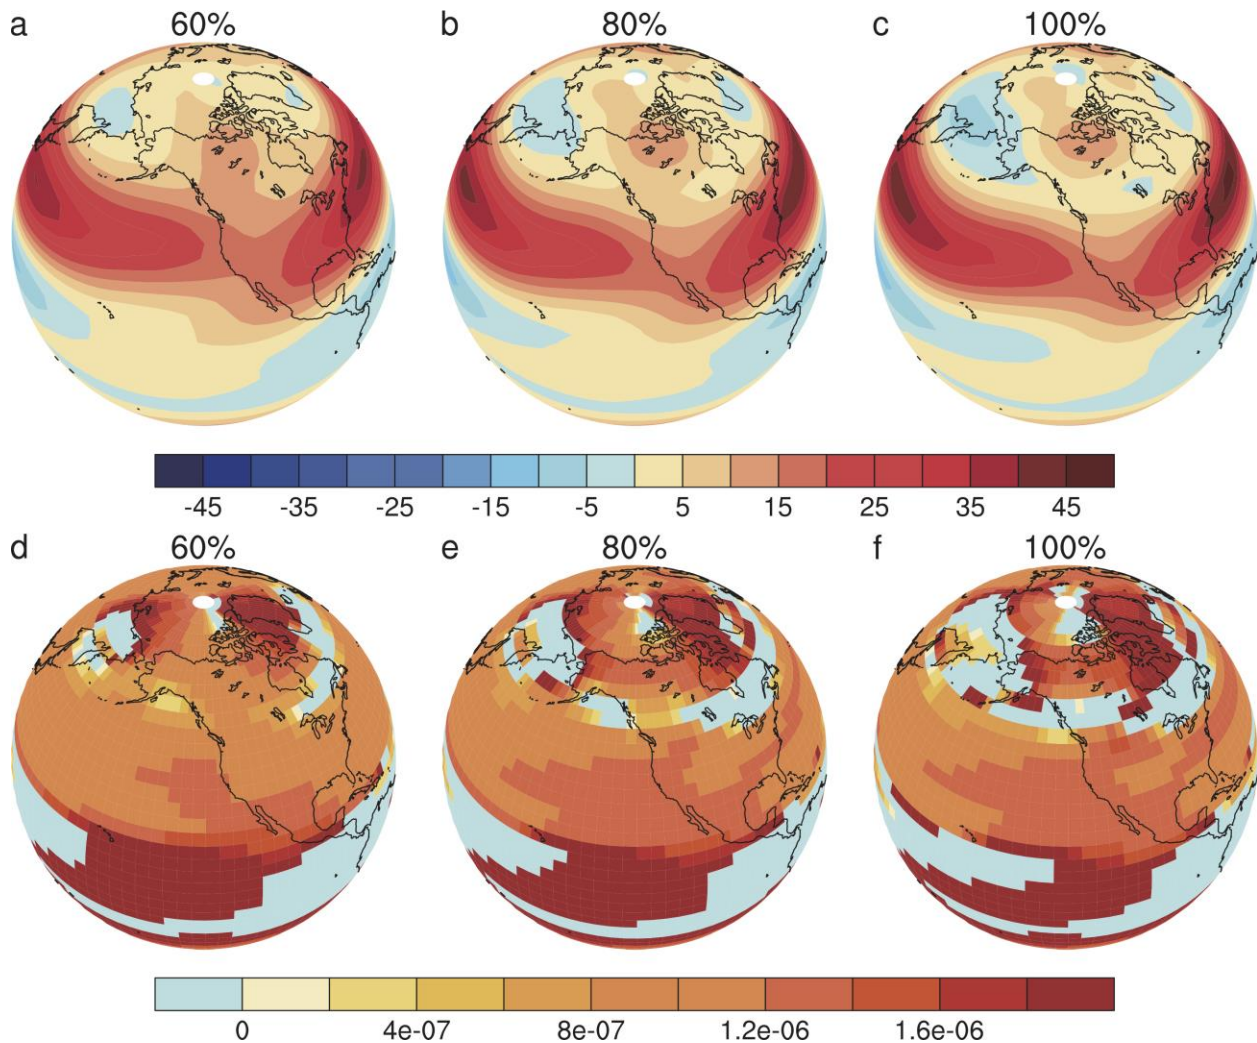

278 The jet split and the equatorward shift of the major jet branch are caused by the orographic
 279 forcing of the large and thick Laurentide ice sheet. Fig. S5 shows how the westerly jet responds
 280 to the ice sheet thickness in the sensitivity simulations. In the case with 0% ice sheet thickness,
 281 there is only a single jet in the subtropics (Fig. S5a), almost the same as that in the PIC
 282 simulation. As ice sheet thickness is increased, the jet is strengthened associated with the sharper
 283 meridional temperature gradient (Fig. S6), and the core of the jet becomes narrower. Significant
 284 jet splitting occurs as ice sheet thickness reaches 80% (Fig. S5e). It is the reason why the
 285 distortion of the PNA occurs as ice sheet thickness reaches 80%. As the ice sheet thickness is
 286 increased to 100% and 150%, the jet split becomes more significant, and easterly winds begin to
 287 develop over the ice sheet.

288 Note that the orographic forcing is further reinforced by the thermal forcing of the large ice
289 sheet (Liakka, 2012). The high albedo of the ice sheet causes cold air aloft, resulting in sharper
290 latitudinal temperature gradients in the subtropics at LGM. Thus, this enhanced temperature
291 gradient causes a stronger subtropical jet through the thermal wind relation. Our sensitivity
292 simulations also show that subtropical temperature gradients become sharper with increasing ice
293 sheet thicknesses.

294 The split of the westerly jet acts as wave guides to orient wave propagation, as shown in Fig.
295 4. The major path of wave propagation is associated with the major jet branch. Both Figs. S2c
296 and S2i all show that a southern wave train is established along the southern jet branch from
297 North Pacific sweeping across the southern US. This wave train would lead to more storms and
298 precipitation in the American Southwest, consistent with proxy records and previous modeling
299 studies (Cohmap, 1988). The minor path of wave propagation toward the Arctic is along with the
300 northern branch (Fig. 1c), but of a much reduced strength. As such, a southern wave guide is
301 established along the subtropical jet, while the northern wave guide is either distorted toward the
302 Arctic or completely broken.

303 Our sensitivity simulations demonstrate dramatic changes in the PNA wave train between
304 80% and 100% ice sheet thicknesses (Fig. 2e vs. Fig. 2f). The dramatic changes are associated
305 with the occurrence of easterly winds over the Laurentide ice sheet (Figs. 7a-c). For the case of
306 80% ice sheet thickness, westerly winds remain between the two jet streams (Fig. 7b). In
307 contrast, easterly winds appear over the ice sheet as the ice sheet thickness is increased to 100%
308 (Fig. 7c). The zero-wind line between easterly and westerly winds acts as the critical layer to
309 reflect stationary waves (Held, 1983). This can be addressed with calculations of critical
310 stationary wavenumbers (Fig. 7 d-f) (eq. 6.29 in Held (1983)). The orange-red shading indicates

311 the areas where stationary waves can propagate, while the shallow-blue shading indicates the
 312 areas with imaginary wavenumbers, in which propagation of stationary waves is prohibited.
 313 These shallow-blue areas are associated with the easterly winds. When the ice sheet thickness is
 314 60% (Fig. 7d), North Pacific and North America are dominated with positive wavenumbers, and
 315 the PNA remains. For 80% ice sheet thickness, imaginary wavenumbers occur in Northeast
 316 Pacific and North America (Fig. 7e), and it forces the PNA wave train distorted toward the
 317 Arctic. For 100% ice sheet thickness, the subpolar region is dominated with imaginary
 318 wavenumbers (Fig. 7f). It causes stationary waves reflected southeastward, leading to the
 319 establishment of the southern wave train and the breaking up of the northern wave train.

320

321 **Fig. 7.** Distributions of zonal winds and stationary wavenumbers for different ice sheet
 322 thicknesses in sensitivity simulations in DJF. Top panels: zonal winds, and bottom panels:
 323 stationary wavenumbers. (a, d) 60%, (b, e) 80%, and (c, f) 100%. Zonal-wind unit is m s^{-1} , and
 324 stationary wavenumber unit is m^{-1} . The shallow-blue areas in the bottom panels have imaginary
 325 wavenumbers.

326

327 The occurrence of easterly winds can be further illustrated with the geopotential heights at
 328 500 hPa (Fig. 8). In both NCEP/NCAR reanalysis and the PIC simulation, there is only a weak
 329 ridge along the west coast of North America (Figs. 8a and b). In contrast, the ridge at LGM is
 330 largely enhanced and shows northwestern tilting (Fig. 8c). It is this strong ridge that leads to
 331 altered zonal flows. The major branch moves equatorward, and the minor branch flows around
 332 the ridge northward, resulting in the formation of easterly winds over the ice sheet and North
 333 Pacific. It also can be seen in the sensitivity simulations that the west-coast ridge increases with
 334 increasing ice sheet thickness (Fig. S7).

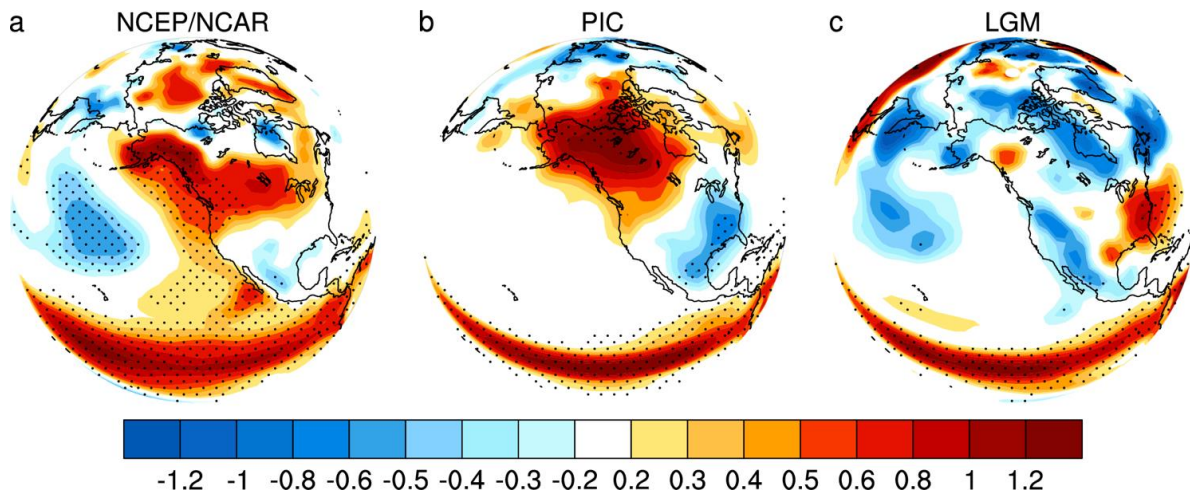

335

336 **Fig. 8.** Climatological mean 500 hPa geopotential heights in DJF in NCEP/NCAR reanalysis and
 337 PMIP2 CCSM3 simulations. (a) NCEP/NCAR, (b) PIC, and (c) LGM. The unit is meter.

338

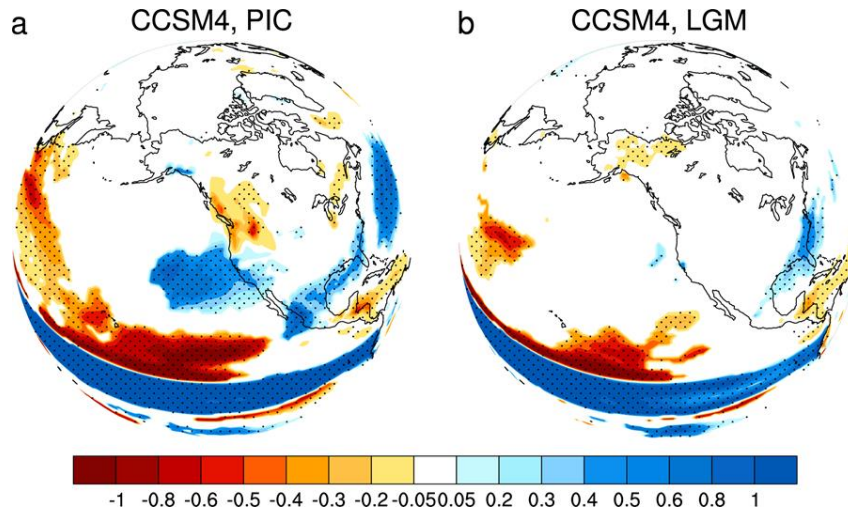

339 The distorted or broken PNA teleconnection at LGM suggests a disconnection of climate
 340 variability from the tropical Pacific to the North American continent, such that ENSO would

341 have little direct influence on North American climates. Fig. 9 shows regression maps of surface
342 air temperatures (SATs) on the Nino3.4 index in DJF. At present, the remote ENSO impacts on
343 North American SATs through the PNA teleconnection can be identified clearly (Figs. 9a and
344 9b), which is characterized by an anomalously warm climate over the northwestern North
345 America and an anomalously cold climate over the southeastern United State. However, there are
346 no significant regressions of SATs over North America at LGM (Fig. 9c), except for the positive
347 values near the east coast.

348
349 **Fig. 9.** DJF SAT regressions on the Nino3.4 index in NCEP/NCAR reanalysis and PMIP2
350 CCSM3 simulations. (a) NCEP/NCAR reanalysis, (b) PIC, and (c) LGM. The regression value
351 of 0.21 corresponds to the 95% confidence level for 30-year regressions.
352

353 At present, ENSO also has important influences on North American precipitation. Similar
354 features can also be seen from regression maps of precipitation (Fig. 10). Fig. 10a shows
355 precipitation regression on the Nino3.4 index in the PIC simulation. The wave train pattern of
356 precipitation is clearly shown in the plot. However, the wave train of precipitation is absent in
357 the LGM simulations (Fig. 10b).

358

359 **Fig. 10.** Precipitation regressions on the Nino3.4 index in the CCSM4 PMIP3 simulations. (a) PIC,
 360 and (b) LGM. Dotted areas indicate significant regressions for the 95% confidence level for 30-

362

363 **4 Conclusions and Discussion**

364 We have shown in climate simulations that the large and thick Laurentide ice sheet at
 365 LGM forced jet splitting and the formation of easterly winds over North America. It
 366 consequently causes altered wave guides and distorted or broken PNA. It appears that the PNA
 367 was separated into two teleconnections at LGM. One is from North Pacific to Arctic, and the
 368 other one is from North Pacific to the southern part of North America.

369 This result suggests that ENSO would have little direct influence on North American
 370 climates at LGM. Our study provides a dynamic framework to understand the PNA
 371 teleconnection not only at LGM but also in other glacial periods. This understanding may help us
 372 interpreting proxy records in the past. For example, a previous study on varve record in New
 373 England linked the change of the intensity of interannual variability in the northeastern US
 374 during the early glacial period to the change of ENSO intensity (Rittenour et al., 2000). Our
 375 study suggests that this interannual variability is unlikely to be caused by the climate variability

376 from the tropical Pacific, because of the distorted or broken PNA teleconnection; instead, it
377 reflects mainly the change of local climate variability (Liu et al., 2014). Much further work is
378 needed in developing proxy records of high temporal resolutions to identify the PNA change in
379 paleoclimate records.

380 Previous works have shown weaker ENSO variability at LGM (Merkel et al., 2010; Zhu
381 et al., 2017), and that the weaker ENSO leads to altered teleconnection patterns. How the weaker
382 tropical variability would impact climates over extratropics and high-latitudes, through the
383 altered atmospheric teleconnections, deserves future studies.

384

385 **Acknowledgements**

386 We thank the international modeling groups of the PMIP2 and PMIP3 projects who make
387 the simulation data available. We also thank modeling groups of CMIP3 and CMIP5 whose pre-
388 industry simulation data are used here. NCEP Reanalysis data are provided by the
389 NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site at
390 <http://www.cdc.noaa.gov/>. Y. Hu and Y. Xia are supported by the National Natural Science
391 Foundation of China (NSFC) under grants 41888101 and 41761144072, and Z. Liu is supported
392 by NSFC under grant 41630527. We thank the Editor and two anonymous reviewers for their
393 insightful comments on the paper.
