18 **Abstract**

19 The Ancient Silk Road played a crucial role in cultural exchange and commercial  
20 trade between western and eastern Eurasia during the historical period. However, the  
21 exchanges were interrupted in the early 16th century AD, during the Ming dynasty.  
22 Various causes for the decline of the Ancient Silk Road have been suggested. Unlike  
23 social factors, natural factors have not been adequately addressed. In this study, we use  
24 evidence from a sedimentary site (XSW) in Dunhuang oasis, together with analysis of  
25 historical archives, to demonstrate the occurrence of extreme droughts and desertification  
26 events in the Dunhuang area post ~1450 AD, which persisted for decades at least. The  
27 desertification may have closely associated with the accessibility of the ancient Silk Road  
28 in the area, which was responsible for a steep fall in the volume of trade as well as  
29 political chaos and mass migrations. Therefore, besides socio-economic factors, climate  
30 change may have played an important role in trade exchange between the Ming  
31 government and the West, and may even have influenced the rise and decline of the  
32 ancient Silk Road.

33 **Keywords:** Dunhuang; desertification; trade exchange; climate change; Ming dynasty

## 35 1. Introduction

36 The Ancient Silk Road was the most important link between nations in Eurasia from  
37 the 2<sup>nd</sup> century BC to the 16<sup>th</sup> century AD, and thus it indirectly shaped the politics,  
38 cultures and economies of populations across the Eurasian continent. The route not only  
39 linked commercial trade between the East and West but it also facilitated the spread of  
40 religion, technology and even diseases such as the plague (Jones et al., 2011; Chen et al.,  
41 2015; Schmid et al., 2015; Frankopan, 2015; An et al., 2017; Dong et al., 2017a; Hao et  
42 al., 2019; Afzaal, 2020). The Chinese section of the Ancient Silk Road passes through one  
43 of the driest regions on Earth and the logistical operation of the road depended directly on  
44 the oases that developed along the foot of the high mountain ranges (the Qilian, Kunlun  
45 and Tianshan), mainly as a result of precipitation supplied as streamflow from the  
46 highlands. Cities and towns emerged and developed in association with oases, such as  
47 Jiayuguan, Dunhuang, Hami and Ruoqiang, which functioned as logistical stations for  
48 trade between East and West along the Ancient Silk Road. The Jiayuguan Pass is at the  
49 western end of the Great Wall in the Ming dynasty. Located at the narrowest point of the  
50 Hexi Corridor, the Jiayuguan Pass was also a critical location on the primary routeway  
51 between the western Gobi Desert and the domains of the Ming dynasty. Dunhuang  
52 commandery was 300 km from the Jiayuguan Pass and the traffic hub which constituted  
53 the historic junction of several routes along the Ancient Silk Road in Central Asia (Huang,  
54 2008). It passed to the control of the central government in 1372 AD, in the early Ming  
55 dynasty. As a routeway, the Ancient Silk Road reached a peak in the Tang dynasty  
56 (618–907 AD), but its importance declined substantially in the 16<sup>th</sup> century AD with the  
57 closure of the Jiayuguan Pass by the central government in China and the abandonment of  
58 Dunhuang city in the Ming dynasty (1368–1644 AD). This event was an important  
59 marker in terms of the severance of cultural exchange and trade between East and West,  
60 and the decline of the Ancient Silk Road as an historically important routeway.

61 Socioeconomic-related hypotheses have been proposed to explain the decline of the  
62 Ancient Silk Road during the later Ming Dynasty. For example, frequent wars in the  
63 Dunhuang area have been suggested (Chen, 2011; Li and Zheng, 2013). In order to  
64 consolidate the frontier territory, from the early Ming dynasty onwards, the Ming  
65 governor successively established seven garrisons in the Jiayuguan-Dunhuang area and  
66 transferred the leadership to Mongolia which governed the seven garrisons (Chen, 2000).  
67 In the Middle and Late Ming dynasty, national power declined due to political corruption  
68 and financial stresses, but the bordering nations such as Oirat and Turpan continued to  
69 expand (Zhang, 1974). Agri-nomadic wars (conflict between agriculturalists and nomads)  
70 and conflict between the seven garrisons and invasions by nomadic tribes in the Hexi

71 Corridor were frequent. The border policy of the administration weakened and there was a  
72 gradual isolation of the governance especially after “the Tumubao Campaign” in ~1450  
73 AD, which was widely regarded as a turning point in the trajectory of the Ming  
74 government from prosperity to decline (Research Institute of History and Language of the  
75 Central Academy of Taiwan, 1962a; Zhang, 1974), and as a consequence the  
76 seven-garrisons region, including Dunhuang city, was abandoned. The re-opening of the  
77 Maritime Silk Road in the southern part of Ming territory was suggested to be another  
78 cause of the interruption of the Ancient Silk Road on land (Xie et al., 2007; Qian and Jin,  
79 2010; Zhai, 2017). Additionally, in terms of the international geopolitical situation, after  
80 capturing Constantinople in 1453 AD, the Ottoman Empire continued to expand across  
81 the Balkans, the Middle East and North Africa, when its power and influence reached a  
82 peak in the 16<sup>th</sup> century. A large and powerful state such as the Ottoman Empire may have  
83 blocked trade between the European and the Chinese Ming government along the ancient  
84 Silk Road (Faroqi et al., 1994; Beckwith, 2009; Liu, 2014).

85 On the other hand, a pollen record from the sediments of Lake Tian’E in the Qilian  
86 Mountains reveals the occurrence of a distinctly drier climate during 1350–1600 AD, and  
87 therefore an environmental-related hypothesis has also been suggested for the timing of  
88 the decline of the Ancient Silk Road (Zhang et al., 2018). Previous high-resolution  
89 tree-ring records from the Qilian Mountains revealed the occurrence of drought in the  
90 Hexi Corridor during 1450–1550 AD (Gou et al., 2015a, b; Yang et al., 2014),  
91 corresponding to the onset of a cold climate during the Little Ice Age (LIA), during AD  
92 1450–1850 (Mann et al., 2009). However, these tree ring and lake sediment records are  
93 from the eastern part of the Hexi Corridor, and there are no reliable paleoclimatic records  
94 from the Dunhuang area in the western part. Throughout human history, climate change  
95 has been regarded as an important and sometimes critical factor for the rise and fall of  
96 ancient civilizations (Wang et al., 2018; Tan et al., 2021), such as in the cases of  
97 Mesopotamia (Weiss, 1993), the Maya (Kennett et al., 2012; Medina-Elizalde and  
98 Rohling, 2012; Nooren et al., 2018), Angkor (Buckley et al., 2010), and the decline of the  
99 Loulan Kingdom on the Ancient Silk Road (Fontana et al., 2019; Fig. 1).

100 In the present study, we focus on the role that paleoenvironmental variations may  
101 have played on the ancient Silk Road in the Duanhuang-Jiayuguan area, which in terms of  
102 the physical environment is the most inhospitable section of the Ancient Silk Road, being  
103 dominated by sandy and Gobi deserts. First, the results of a detailed sedimentary  
104 investigation of Xishawo site (near Dunhuang city) are presented and the  
105 paleoenvironmental change are evaluated. Second, the relevant available literature is  
106 reviewed and a sociopolitical analysis of the historical archives in Dunhuang and the

107 surrounding areas and in Ming China are used to determine environmental and  
108 sociopolitical changes in the area during the study period. Finally, the influence of the  
109 natural environment on the trade exchange between the Ming dynasty and western  
110 countries, on the abandonment of the Dunhuang area, and on the official closure of the  
111 Ancient Silk Road in the early 16<sup>th</sup> century AD are reviewed.

## 112 2. Study area

113 The Hexi Corridor (92°21'to 104°45'E, 37°15' to 41°30'N) is located to the north of  
114 the Qilian Mountains and south of Beishan Mountain. It is long and narrow and stretches  
115 for over 1,000 km from Wushaoling Mountain in the east to the boundary of Gansu and  
116 Xinjiang provinces in the west, but it extends for only tens to some hundreds of  
117 kilometers in the North-South direction (Fig. 1). The area corresponds to the zone of  
118 climatic interaction between arid Central Asia and monsoonal Asia and is climatically  
119 characterized by a continental-monsoon climate influenced by both the westerlies and the  
120 monsoon. The annual precipitation is no more than ~200 mm but the evaporation ranges  
121 from 1,500 mm to 3,000 mm (Huang et al., 2017). The annual temperature is ~0–10 °C.  
122 The Hexi Corridor consists of three independent landlocked river systems: the Shule  
123 River Basin, the Heihe River Basin, and the Shiyang River Basin, from west to east. The  
124 flow of the three rivers is generated by the glaciers of the Qilian Mountains and is  
125 consumed in the middle and lower reaches of Owase Lake or in the deserts within the  
126 basin. Diverse landscapes of mountains, oases, deserts and Gobi are alternately distributed  
127 in the area. The unique topography and location of the Hexi Corridor were largely  
128 responsible for its great strategic and military importance to historical dynasties over the  
129 past 2,000 years. It was also known as the key routeway (the Ancient Silk Road) for  
130 cultural and merchandise exchanges between Chinese and western countries for thousands  
131 of years ago until the present.

132

133 *[Fig. 1 is near here]*

134

135 The oasis ecological system in arid areas is fragile because of the closed environment,  
136 sparse vegetation and water scarcity. However, the bead-like distribution of oases played  
137 a crucial role in the exchange of merchandise in Eurasia. Jiayuguan city was the  
138 northwestern gateway of the Ming domain and a key fortress along the routeway of  
139 East-West economic exchange. Dunhuang city and Guazhou city (~120 km northeast of  
140 Dunhuang) are located in the eastern Gobi Desert to the west of the Jiayuguan pass (Fig.  
141 1). The Ancient Silk Road split into three branches in a westerly direction from the region.

142 The northern branch led to the northwest of Hami oasis and the oasis cities of Turfan,  
143 Yanqi, Qiuci and Gumo, and then to Central Asia. The central branch passed through  
144 Loulan city (300 km west of Dunhuang) which was abandoned in ~330 AD because of  
145 eolian activity (Yuan and Zhao, 1999; James, 2007; Fontana et al., 2019). The southern  
146 branch connected many cities along the southern edge of the Taklimakan Desert, such as  
147 Ruoqiang, Qiemo, and Yutian, on the northern piedmont of the Altyn-Tagh and the  
148 Kunlun Mountains (Fig. 1). As can be seen in Fig. 1, the location of Dunhuang oasis led  
149 to its importance as the only logistical station between Hami oasis/Ruoqiang oasis and  
150 Jiayuguan oasis during the Ming dynasty.

151 The XSW section in this study is located near the ancient city of Xishawo in the  
152 modern Gobi Desert area of the Shule River Basin. The site is in the middle of the  
153 Dunhuang and Guazhou oasis, ~50 km northeast of Dunhuang city (Fig. 1). The Xishawo  
154 site was previously an ancient oasis with cultural sites, ancient cities and beacon towers.  
155 Relict river channels are present at several locations, although most of them are buried by  
156 sand dunes (Li, 1990; Cheng, 2007). The modern annual mean precipitation and annual  
157 mean temperature of the area are 45.3 mm and 8.8° C, respectively. Previous research  
158 has revealed that the Xishawo site was occupied during ~900–1400 AD, and the  
159 inhabitants cultivated barley, broomcorn and foxtail millet during this period (Li et al.,  
160 2017). Wind-eroded landforms are common in the region as a consequence of the arid  
161 climate, sparse vegetation cover and frequent sandstorms. The exposed part of the XSW  
162 section is ~3-m thick and consists mainly of a sand dune which is fixed by the dead roots  
163 of *Salix* and therefore preserved. The surface of the profile was cleaned to remove  
164 contamination by modern sediments and plant roots. The stratigraphic description of  
165 XSW section from the top to 270-cm depth is as follows: (1) 0–10 cm, fine sand. (2)  
166 10–46 cm, dark-gray paleosol, with a 4 cm-thick black cultural layer at 30–34 cm. (3)  
167 46–100 cm, light-yellowish loess. (4) 100–125 cm, loess-like paleosol. (5) 125–185 cm,  
168 dark gray clay with Fe-Mn nodules. (6) 185–250 cm, yellow fine sand. (7) 250–270 cm,  
169 black silty clay. A total of 135 samples were collected at a 2-cm interval for  
170 measurements of weight loss-on-ignition (LOI), grain size, and element contents. One  
171 wood sample (at the depth of 10 cm, labeled XSW-10) and one charcoal sample (from the  
172 cultural layer at 32 cm, labeled XSW-32) were collected for accelerator mass  
173 spectrometry radiocarbon (AMS <sup>14</sup>C) dating. Two eolian samples for optically stimulated  
174 luminescence (OSL) dating from the fine yellow sand layer (188 cm and 248 cm, labeled  
175 XSW-188, XSW-248, respectively) were collected by hammering stainless-steel cylinders  
176 into the section vertically, which were immediately sealed with opaque tape after removal.

### 177 3. Methodology

#### 178 3.1 Laboratory analyses

##### 179 (1) Chronology

180 AMS  $^{14}\text{C}$  and OSL dating were used to establish a chronological framework for the  
181 XSW section. The charcoal and wood samples for AMS  $^{14}\text{C}$  dating was prepared by the  
182 acid-base-acid procedure at the MOE Key Laboratory in Lanzhou University and  
183 measured at the AMS  $^{14}\text{C}$  dating laboratory of Peking University. The IntCal13 curve,  
184 Libby half-life of 5,568 years and OxCal 4.2 were used to calibrate all of the dates  
185 (Reimer et al., 2013). All ages reported are relative to 1950 AD (referred to as “cal BC”  
186 and “cal AD”).

187 OSL dating was conducted at the OSL Laboratory at the MOE Key Laboratory of  
188 Western China’s Environmental System, Lanzhou University. Two OSL dating samples  
189 were collected from the XSW section. The pretreatment procedure followed that  
190 described in Aitken (1998). OSL measurement of coarse-grained (90–125  $\mu\text{m}$ ) quartz  
191 were performed using an automated Risø TL/OSL DA-20 reader. Laboratory irradiation  
192 was carried out using  $^{90}\text{Sr}/^{90}\text{Y}$  sources. The quartz OSL signal was detected by a  
193 photomultiplier tube through two 3-mm-thick Hoya U-340 filters and the K-feldspar IRSL  
194 signal was detected using a package of Corning7-59 and BG-39 filters. The purity of the  
195 quartz extracts was checked using the IR depletion ratio test (Duller et al., 2003). A single  
196 aliquot regenerative protocol (Murray and Wintle, 2003) was applied to quartz samples to  
197 obtain the equivalent dose (De). The concentrations of the radioactive elements uranium  
198 ( $^{238}\text{U}$ ), thorium ( $^{232}\text{Th}$ ) and potassium ( $^{40}\text{K}$ ) were measured by neutron activation analysis  
199 (NAA) to calculate the dose rate. The cosmic ray contribution was calculated according to  
200 the burial depth and altitude of the samples (Prescott and Hutton, 1994). A water content  
201 of  $10 \pm 5\%$  was used to the calculate ages of sand-loess sediments.

##### 202 (2) Analysis of climatic proxies

203 Measurements of LOI, grain size and element contents were made at the MOE Key  
204 Laboratory of Western China’s Environmental System Lanzhou University. LOI  
205 measurements were used to determine the organic matter content of the sediments. The  
206 measurements were made at a 2-cm interval and calculated as  $\text{LOI}_{550}$   
207  $(\%) = (m_{105} - m_{550}) / m_{105} \times 100\%$ , where  $m_{105}$  is the sample weight after oven drying at  $105^\circ\text{C}$ ,  
208 and  $m_{550}$  is the sample weight after combustion at  $550^\circ\text{C}$  for 4 hr in a muffle furnace.

209 Samples for grain-size analysis were pre-treated with 10% H<sub>2</sub>O<sub>2</sub> and 10% HCL to  
210 remove organic matter and carbonates, respectively. The samples were then dispersed by  
211 ultrasonication with the addition of 10% sodium hexametaphosphate. Grain-size  
212 distributions were measured with a Malvern MS 2000 laser grain-size analyzer.

213 Samples for the analysis of element contents were pretreated as follows. All samples  
214 were oven-dried for 24 hr and then pulverized into a powder. About 4 g of powder was  
215 then pressed into a 4–6 mm–thick and 30 mm–diameter pellet under 30 t/m<sup>2</sup> of pressure.  
216 The major, minor and trace element contents were measured with a Magix PW2403  
217 Wavelength-Dispersive XRF Spectrometer. Elemental concentrations of 0.1 ppm to 100%  
218 could be analyzed. Rb/Sr ratios were calculated for paleoenvironmental reconstruction.

### 219 3.2 Analysis of published paleoenvironmental records and documentary evidence for the 220 region

#### 221 (1) Previous paleoclimatic records from the region

222 All available high-resolution paleoclimatic records for the study area and the adjacent  
223 region were reviewed and compared. They include records of regional temperature,  
224 precipitation, and river flow. In addition, documentary evidence of climate change in the  
225 region during the Ming dynasty was investigated.

#### 226 (2) Sociohistorical archives

227 Sociohistorical records such as of the politics and economic and military activity of  
228 the Ming dynasty were analyzed (Zhang, 1974; Chinese Military History Writing Group,  
229 2003; Yu, 2003), together with sociohistorical records of the Jiayuguan-Dunhuang area.

## 230 4. Results and discussion

### 231 4.1. Effects of warfare on the Ancient Silk Road

232 The Jiayuguan-Dunhuang area experienced frequent political turmoil and conflicts in  
233 Ming dynasty (Zhang, 1974). Warfare in the northwestern part of the Ming domain was  
234 suggested to be the main cause for the repeated (twice) closure of the Jiayuguan Pass and  
235 the severance of the Ancient Silk Road (Gao and Zhang, 1989; Chen, 2011). The  
236 Jiayuguan Pass was established in 1372 AD in the early Ming dynasty to resist the  
237 remaining elements of the Yuan dynasty (1271–1368 AD), and the Hexi Corridor was  
238 under the total control of the Ming government during the Ming dynasty. In addition, the  
239 Ming dynasty government established seven garrisons in the west of Jiayuguan Pass to  
240 reduce pressure on the border (Zhang, 1974). The Jiayuguan Pass was not only a military

241 fastness, but also the primary pass on the Ancient Silk road to the Western Regions.

242 In order to investigate the relationship between conflict and the closure of the  
243 Jiayuguan Pass, the frequency of agri-nomadic conflict in the Dunhuang area was  
244 estimated based on historical archives (Chinese Military History Writing Group, 2003; Yu,  
245 2003). The incidence of agri-nomadic conflicts in the Hexi Corridor was also summarized  
246 for comparison (Fig. 2a). The classification of agri-nomadic conflict was adopted because  
247 it directly reflects the conflict between the central government and nomadic peoples. The  
248 frequency of tribute trade and the number of tribute states in the Western Regions are  
249 illustrated in Fig. 2b and 2c (Chinese Military History Writing Group, 2003; Yu, 2003). All  
250 of the data were grouped into 5-year intervals. It is evident that conflicts between  
251 agriculturalists and nomads occurred constantly from 1368 AD, in the early Ming dynasty,  
252 until 1520 AD. However, conflicts ceased in the Dunhuang area after 1520 AD, which  
253 shows that the final closure of the Jiayuguan Pass in 1539 AD substantially reduced the  
254 frequency of nomad incursions in the Dunhuang area. However, evidence is still needed  
255 to confirm that that agri-nomadic conflicts were responsible for the closures of the  
256 Jiayuguan Pass in 1524 AD and 1539 AD, and for the decline of the Ancient Silk Road.  
257 For example, it is unclear why—if agri-nomadic conflicts no longer occurred after 1520  
258 AD—the Jiayuguan Pass was closed decades later in 1539 AD. It is also unclear why  
259 there was a lull in political unrest and violence in the Dunhuang area from 1450 AD.

272

273

274

275

276

277

Reference to Fig. 2b and 2c shows that tribute exchange between the Ming government and the Western Regions has no obvious relationship with the frequency of conflicts. The tribute trade frequency and the number of tribute states both reached a peak during 1400–1450 AD, but then decreased sharply after 1450 AD and subsequently maintained a low level. As Fig. 2a demonstrates, there were frequent agri-nomadic conflicts during 1400–1450 AD, which were followed by a truce which lasted for about 20 years. However, the tribute trade declined substantially during the truce (1450–1470 AD) and there was no obvious revival until the collapse of the Ming dynasty (Fig. 2b and Fig. 2c).

It has been determined that the Jiayuguan Pass – Dunhuang city route was the crucial routeway connecting the Western Region to the domestic territory during the Ming dynasty (Zhang, 1974). The absence of a relationship between the frequency of wars in the Dunhuang area and variations in the amount of tribute trade demonstrates that an

278 increase in the frequency of warfare was probably not the primary or single cause of the  
279 collapse of trade along the Ancient Silk Road.

280 Moreover, war was not solely responsible for the closure of the Jiayuguan Pass. The  
281 first closure of the Jiayuguan Pass in 1524 AD may have been a consequence of wars in  
282 the Dunhuang area, although wars also occurred frequently during periods when trade  
283 flourished (1400–1450 AD) (Fig. 2a). However, subsequently there was a continuous  
284 state of peace in the Dunhuang area which lasted for decades and the city was only  
285 abandoned by the final closure of the Jiayuguan Pass in 1539 AD. Therefore, we conclude  
286 that an increase in the frequency of warfare is not a tenable explanation for the decline of  
287 the Ancient Silk Road.

288

## 289 4.2. Influence of climate change on the Ancient Silk Road

### 290 *4.2.1 Paleoclimatic record of the XSW section*

291 The paleoclimatic record of the XSW section in the Dunhuang area was used to  
292 assess the possible role of climate change in the decline of the Ancient Silk Road. The  
293 results of the analysis of various climatically-sensitive parameters, together with the  $^{14}\text{C}$   
294 and OSL chronology, are illustrated in Fig. 3. The  $^{14}\text{C}$  dates for the fine sand layer  
295 (XSW-10) and the cultural layer (XSW-32) are  $499\pm 10$  cal yr BP (1440–1460 cal AD)  
296 and  $701\pm 27$  cal yr BP (1224–1278 cal AD), respectively. The two OSL samples from the  
297 sand layer are dated to  $2.6\pm 0.2$  ka (800 $\pm$ 300 BC) and  $2.8\pm 0.2$  ka (600 $\pm$ 200 BC) (Table 2).  
298 Profiles of grain size, LOI and Rb/Sr ratio are shown in Fig. 3a, 3b, 3c and 3d,  
299 respectively. The increase in median grain size and of the  $>63$   $\mu\text{m}$  fraction indicate an arid  
300 environment and intense wind activity in the Dunhuang area during 800–600 BC and at  
301  $\sim$ 1450 AD. The LOI record reflects variation in organic matter content and the Rb/Sr ratio  
302 of eolian sediments is positively correlated with weathering intensity. The Rb/Sr ratio of  
303 the two sand layers is very low (Fig. 3), and therefore the effects of weathering are minor  
304 (Gallet et al., 1996; Chen et al., 1999), suggesting that precipitation in the Dunhuang area  
305 was low during  $\sim$ 800–600 BC and after  $\sim$ 1450 AD. A comparison of the LOI and Rb/Sr  
306 profiles indicates that during 800–600 BC and after  $\sim$ 1450 AD, the organic matter content  
307 of the section was low and chemical weathering was weak. These results suggest the  
308 occurrence of overall arid conditions, frequent dust storms, and associated desertification  
309 events during 800–600 BC, i.e. the Spring and Autumn period (771–476 BCE) of the  
310 Eastern Zhou Dynasty, and after  $\sim$ 1450 AD (the Ming dynasty). These conditions would  
311 have been very unfavorable for human habitation of the area.

312

313  
314

*[Fig. 3 is near here]*

315       The two desertification events recorded in the XSW section were not solely local  
316 events. A cold and dry climate at these times is also evident in palaeoclimatic records  
317 from the nearby Qilian Mountains and the Tibetan Plateau. A tree ring record from the  
318 Qilian Mountains suggests that precipitation was low during 900–550 BC (Yang et al.,  
319 2014). A pollen record from Juyanze lake indicates the low representation of tree pollen at  
320 the same time (Herzschuh et al., 2004). The  $\delta^{18}\text{O}$  record from the Agassiz ice cap in the  
321 high Arctic indicates relatively low temperatures during ~800–600 BC (Lecavalier et al.,  
322 2017), which is correlative with records from the Guliya ice core in the Tibetan Plateau  
323 (Thompson et al., 1997). The timing of the second desertification event in the Dunhuang  
324 area, in ~1450 AD, coincides well with changes in a tree-ring record from mountains in  
325 the western Hexi corridor, which suggests an interval of persistent low precipitation  
326 during 1430–1540 AD (Fig. 2f, Gou et al., 2015a). An interval of reduced precipitation  
327 during this time is also widely recorded in other high-resolution tree ring records from the  
328 northern Tibetan Plateau (Gou et al., 2015b; Yang et al., 2014), and in the laminated  
329 sediments of Sungan lake in the western Qaidam Basin (Qiang et al., 2005). A decrease in  
330 global temperature at ~1450 AD has also been widely detected in high-resolution  
331 paleoclimatic records from various locations (Thompson et al., 1997; Wilson et al., 2016;  
332 Lecavalier et al., 2017), and is also recorded in historical documentary records from China  
333 (Ge et al., 2003). This evidence indicates the occurrence of two desertification events in  
334 the Dunhuang area and elsewhere, during ~800–600 BC and after ~1450 AD, which were  
335 related to regional-scale climatic and environmental deterioration.

336       As mentioned earlier, the oasis ecological system in arid regions is relatively fragile,  
337 with the major limiting factor being water availability (Qian and Jin, 2010). At the present  
338 time, vegetation survival in the oasis of the Hexi Corridor depends mainly on runoff from  
339 the Qilian Mountains, which is derived firstly from precipitation in the highlands and  
340 secondly from glacier meltwater (Liu et al., 2010; Yang et al., 2011; Sakai et al., 2012).  
341 The prominent long interval of reduced precipitation and temperature in the Qilian  
342 Mountains and in the Tibetan Plateau during ~800–600 BC and at ~1450 AD caused a  
343 large decrease in runoff to the lowlands of the Hexi Corridor, which in turn caused  
344 vegetation degradation and the extension of Gobi and sandy desert. Compared to other  
345 oasis cities along the Ancient Silk Road, which were much closer to the high mountain  
346 glaciers (above 4,500 m.a.s.l., Fig. 1) which provided a constant supply of meltwater,  
347 Dunhuang oasis was located much closer to the center of the Gobi, and therefore it  
348 experienced severe desertification which may have resulted in its abandonment.

349 **4.2.2 Archaeological evidence of climate change in the Dunhuang area**

350 The relatively dense distribution of prehistoric sites in the Hexi Corridor reflects the  
351 past intensity of human settlement in the area as well as the habitability of the surrounding  
352 environment (Bureau of National Cultural Relics, 2011; Yang et al., 2019). The Hexi  
353 Corridor was extensively settled from the Majiayao period (3300–2000 BC) (Li, 2011),  
354 and foxtail millet and broomcorn millet, which were domesticated in north China, were  
355 cultivated (Zhou et al., 2016; Dong et al., 2018). Innovations in agricultural technology  
356 facilitated the rapid development of Bronze cultures in the Hexi Corridor and the  
357 surrounding areas in the succeeding millennium (Dong et al., 2016; Zhou et al., 2016).  
358 However, there is a gap in radiocarbon dates during ~850–650 BC in the western Hexi  
359 Corridor and eastern Xinjiang Province (Fig. A1), which suggests a hiatus in cultural  
360 evolution and exchange during this period. This hiatus corresponds well to the  
361 desertification event in the Dunhuang area of the western Hexi Corridor during  
362 ~800–600 BC (Fig. 3). However, even though the climate fluctuated substantially in  
363 northwest China during the Bronze Age, human settlement was continuous in the eastern  
364 Hexi Corridor at the same longitude (Fig. A1), which suggests that human occupation of  
365 the Hexi Corridor was primarily determined by the environmental conditions.

366 The second desertification event occurred at ~1450 AD and is recorded both in the  
367 sand layer of the XSW profile and in the historical and cultural literature. The drought in  
368 the Dunhuang area at this time was described as “The wind shakes the Tamarix in  
369 thousands of miles of uninhabited land” and “the moon shines on the quicksand on each  
370 departed day” (Huang and Wu, 2008). The Yugur minority ancestors, who originally  
371 settled in the Dunhuang area after the abandonment of Dunhuang, sang folk songs about  
372 the human migrations through the Jiayuguan Pass during the Ming dynasty (Chen, 2011).  
373 An epic of the migration of the Yugur minority history contains the following passage:  
374 “Violent winds swept livestock away, sand dunes submerged tents and houses, rivers  
375 dried up, grassland was devastated” (Wang, 1992; Editorial Group of a Brief History of  
376 the Yugur minority, 2008). From these descriptions it can be deduced that the prolonged  
377 drought at ~1450 AD may have led to the disappearance of the oasis. The altered  
378 eco-environment would have reduced the productivity of  
379 agriculture and animal husbandry, which would have caused a local food shortage. The  
380 deteriorated environment was very likely another cause of mass migration in addition to  
381 warfare. The changing geopolitical situation in the western Hexi Corridor and eastern  
382 Xinjiang Province was an important factor in the abandonment of the Dunhuang area by  
383 the Ming government, and the extreme and the persistent drought event after ~1450 AD  
384 may have intensified the social upheaval and chaos (Fig. 2d, blue triangles highlight mass

385 migrations), which triggered this significant historical event. Notably, a significant  
386 relationship has been observed between decreased precipitation, wars and the  
387 abandonment of cultivated land in the region during the last 2,000 years (Li et.al. 2019).

#### 388 ***4.2.3 Desertification events in the Ancient Silk Road area***

389 Various indicators of climatic variations, wars and the tribute trade are plotted in  
390 Fig. 2 versus the chronological sequence of the Ming dynasty (1368–1644 AD). Under the  
391 premise that at ~1450 AD the environment was characterized by a cold and dry climate  
392 with intense sandstorms (Fig. 2e), low precipitation (Fig. 2f) and decreased streamflow  
393 (Fig. 2g), there is a possibility that climate change played a role on the tribute trade of the  
394 Ancient Silk Road. There was an abrupt decrease in the frequency of tribute trade at  
395 ~1450 AD, but not during the two closures of the Jiayuguan Pass, in 1524 AD and 1539  
396 AD (Fig. 2b and 2d). In addition, at this time there was a lull in conflicts in the Dunhuang  
397 area (Fig. 2a). Therefore, it is proposed that environmental deterioration likely contributed  
398 to the decline of the tribute trade and the cessation of hostilities. Climatic perturbations  
399 and environmental degradation may not necessarily be a direct trigger of a societal crisis,  
400 but they may instead result in institutional failure caused by the lack of a centralized  
401 response to an environmental crisis (Feng et al. 2019). Social disturbance associated with  
402 migrations and chaos in the Ming dynasty was likely an indirect consequence of  
403 environmental changes. For example, the consequences of a deteriorating environment  
404 would include the shrinkage of the habitat and agricultural land necessary for human  
405 survival, multiple waves of human migrations into the eastern part of the Hexi Corridor,  
406 and the shift of the frontier from Dunhuang to the Jiayuguan pass. Thus, the population  
407 decline in the Dunhuang area during the early Ming Dynasty was most probably a  
408 “domino effect” (Feng et al. 2019).

409 The influence of the desertification event in ~1450 AD on the streamflow of the  
410 Qilian Mountains gradually decreased after the 1520s AD (Fig. 2f and Fig. 2g). However,  
411 the formation and evolution of an oasis is a long-term process (Stamp, 1961; Zhang and  
412 Hu, 2002; Li et al., 2016), and the ecological response of an oasis to climatic drying  
413 would not be to disappear immediately (Fan, 1993). Moreover, it takes at least 15-20  
414 years for the recovery of a degraded oasis following destruction by ~1–3 years of human  
415 activity (Zhang and Hu, 2002). Therefore, the regeneration of a degraded oasis would take  
416 much longer than a change in the streamflow. Overall, we propose that the abrupt  
417 decrease in tribute exchange and prosperity, or even the decline of the ancient Silk Road,  
418 may have been affected by the deterioration of the environment along the routeway in the  
419 Ming dynasty (Fig. 2b and Fig. 2c).

420 We now address the issue of how the desertification at ~1450 AD in the Dunhuang  
421 oasis and adjacent regions may have affected the functioning of the Ancient Silk Road.  
422 First, trading in the arid environment of the Ancient Silk Road led to the increase in the  
423 importance of oasis cities. Camel caravans needed supplies of grain and water from an  
424 oasis as they traversed the extensive desert along the road. The desertification events  
425 recorded in the XSW section and in the adjacent regions indicate that Dunhuang oasis and  
426 Guazhou oasis were not functioning at ~1450 AD. This lengthened the distance from the  
427 Jiayuguan oasis in the Hexi Corridor to the western oasis in Xinjiang (Fig. 1). According  
428 to several researchers, camel caravans in deserts areas were able to travel a maximum  
429 distance of ~30 km/day (Shui, 1990; Wang et al., 2000). In addition, the metabolism of a  
430 domesticated camel will decrease within 20 days from the beginning of water deprivation  
431 (Chen, 1982). Under working conditions, camels can go for ~10–15 days without water  
432 under a mean ambient temperature of 35°C (Kataria et al., 2001). A camel caravan took  
433 59 days to traverse the 1,400 km of the Taklimakan Desert in 1993 AD under modern  
434 climatic conditions, which are much more favorable than in ~1450 AD, and the maximum  
435 distance was 24 km in one day (Blackmore, 2000). The maximum distance for a caravan  
436 in the water-limited environment on the Silk Road was 30 km/day×15 days = 450 km.  
437 The distances of Hami, Ruojiang and Jiayuguan to Dunhuang, where are Gobi Desert  
438 without high mountains, are already close to or above this limit, which is barely sufficient  
439 for camel travel (shown by the dots in Fig. 1, near the Dunhuang and Shazhou oasis). On  
440 the other hand, the distances between the oases along the routes on the piedmonts of the  
441 high mountain ranges (Qilian, Kunlun and Tianshan) are generally less than 200 km as the  
442 high mountain ranges provide meltwater. After the desertification event, the distances  
443 between Jiayuguan and Hami oases (the northern route of the ancient Silk Road) and  
444 between Jiayuguan and Ruoqiang oases (the southern route) increased to ~600 km and  
445 ~1,000 km, respectively. This is close to the maximum distance that a camel caravan can  
446 achieve (~450 km) without a water supply, and would have substantially increased the  
447 difficulty of travel across the region and was likely to be the physical cause of the decline  
448 of the Ancient Silk road during the periods of desertification.

## 449 5. Conclusion

450 We have systematically investigated a possible climatic cause of the interruption of  
451 the operation of the Ancient Silk Road during the Ming Dynasty. A compilation of the  
452 results of absolute dating and high-resolution paleoclimatic records from the SXW site in  
453 the Dunhuang area, and historical archives, reveals that two desertification events  
454 occurred, at ~800–600 BC and ~1450 AD. The later desertification event was consistent

455 with the immediate fall in tribute trade that occurred in ~1450 AD, which indicates that  
456 environmental deterioration may have disrupted the trading exchanges by draining the  
457 oases in Dunhuang and Guazhou city, which were strategic logistical stations in the vast  
458 Gobi Desert. This resulted in travelling distances between supply stations exceeding the  
459 physical limit for camel caravans and an irreversible decline in trade exchange. On the  
460 other hand, the incidence of agri-nomadic conflicts from historical archives suggests that  
461 warfare alone is not the best explanation for the severance of exchanges between Western  
462 countries and the Ming government. Hence, we propose that climate change also played a  
463 potentially important role in explaining the decline of the Ancient Silk Road trade.

#### 464 **Acknowledgements**

465 We thank Dr. Teng Li and Dr Shengda Zhang for their suggestions and discussions which  
466 inspired this study. We also thank Dr Jan Bloemendal for improving the English. This

672 Figure 1. Location of the study area and cities along the Ancient Silk Road (dotted circles  
673 are oasis cities which were already abandoned before the Ming dynasty; solid circles  
674 are oasis cities which still existed during the Ming dynasty; the cities in parentheses  
675 were under Ming governorship; the dotted area is Gobi Desert near Dunhuang and  
676 Guazhou) (The base map was captured from ©Google Maps)

677 Figure 2. Comparison of records of wars, climate change and cultural events in the  
678 Dunhuang area during the Ming-Qing dynasties. (a) Frequency of agri-nomadic wars  
679 in the Dunhuang area. (b) Tribute trade through the Jiayuguan Pass between the  
680 Ming government and Western countries. (c) Number of tribute states of Western  
681 countries. (d) Major events in the Ming dynasty (blue triangles are mass migrations;  
682 red triangles indicate the closure of the Jiayuguan Pass; the green triangle indicates  
683 the abandonment of Dunhuang city). (e) Grain size (>63- $\mu\text{m}$  fraction) of the XSW  
684 section (this study). (f) Tree-ring based precipitation record from the western Qilian  
685 Mountains (after smoothing) (Gou et al., 2015a). (g) Tree-ring based streamflow  
686 record from the upper reaches of the Heihe River (after smoothing) (Yang et al.,  
687 2012).

688 Figure 3. Lithology,  $^{14}\text{C}$  and OSL ages, and climatic proxies for the XSW section. (a)  
689 Median grain size (Md). (b) >63- $\mu\text{m}$  fraction. (c) Loss on ignition (LOI). (d) Rb/Sr  
690 ratio.
