Abstract. Our understanding of climate and vegetation changes throughout the Holocene is hampered by representativeness in sedimentary archives. Potential biases such as production and preservation of the markers are identified by comparing these proxies with modern environments. It is important to conduct multi-proxy studies and robust calibrations on each terrestrial biome. These calibrations use large data base dominated by forest samples. Therefore, including data from steppe and desert-steppe sites becomes mandatory to better calibrate arid environments. The Mongolian Plateau, ranging from the Baikal area to the Gobi desert, is especially characterized by low annual precipitation and continental annual air temperature. The characterization of the climate system of this area is crucial for the understanding of Holocene Monsoon Oscillations. This study focuses on the calibration of proxy-climate relationships for pollen and glycerol dialkyl glycerol tetraethers (GDGTs) by comparing large Eurasian calibrations with a set of 49 new surface samples (moss polster, soil and mud from temporary dry pond). These calibrations are then cross-validated by an independent dataset of top-core samples and applied to four Late Holocene paleosequences (two brGDGT and two pollen records) surrounding the Mongolian Plateau: in the Altai mountains, the Baikal area and the Qaidam basin to test the accuracy of local and global calibrations. We show that: (1) preserved pollen assemblages are clearly imprinted on the extremities of the ecosystem range but mitigated and unclear on the ecotones; (2) for both proxies, inferred relationships depend on the geographical range covered by the calibration database as well as on the nature of samples; (3) even if local calibrations suffer from reduced amplitude of climatic parameter due to local homogeneity, they better reflect actual climate than the global ones by reducing the limits for saturation impact, (4) a bias in climatic reconstructions is induced by the over-parameterization of the models by addition of artificial correlation and (5) paleoclimate values reconstructed here are consistent with Mongolia-China Late Holocene climate trends, and validate the application of local calibrations for both pollen and GDGTs (closest fit to actual values and realistic paleoclimate amplitude). We encourage the application of this
surface calibration method to reconstruct palaeoclimate and especially consolidate our understanding of the Holocene climate and environment variations in Arid Central Asia.

1 Introduction

Since the understanding of the interactions between the palaeoclimate proxies, such as pollen or biomarker abundances, and General Circulation Model outputs became a major issue in future climate change modeling, resolving the issue of climate proxy calibration is crucial (Braconnot et al., 2012). Current climate changes in extremely cold environments (Masson-Delmotte, 2018), such as Mongolia and Siberia (Fig. 1), are amplified compared with other places around the world (Tian et al., 2014) and the drivers of the current degradation of Mongolian environments in diversity and biomass production still need to be understood. From a climatic point of view, Mongolia is on a junction between the westerlies which are driven by the North Atlantic Oscillation (NAO) and the East Asian Summer Monsoon which is linked to the El Niño-Southern Oscillations (ENSO) and the Inter-tropical Convergence Zone (ITCZ, An et al., 2008). The Mongolian plateau is a hinge area: the high altitude of the Altai range to the west and the Sayan range to the north-west of the country partially block both the westerlies arriving from the northern Atlantic ocean through the Baikal area and the East Asian Summer Monsoon (EASM, Fig. 2, Chen et al., 2009). The Mongolian system is thus driven by a mix of the distant drag of these two main climatic cells. The understanding of the complex interaction of these cells is necessary and palaeoclimate studies are needed to better document this region (Braconnot et al., 2012).

Lake sediment archives are commonly used to infer past variations of these climate and environmental systems associated with vegetation and human land use (Lehmkuhl et al., 2011; Felauer et al., 2012; Wang and Feng, 2013). Among the proxies available, pollen and geochemical biomarkers are used as past temperature indicators (Ter Braak and Juggins, 1993; Weijers et al., 2007b) and the combination of these proxies helps to polish lake sediment shift interpretations (Atahan et al., 2015; Watson et al., 2018; Kaufman et al., 2020). From decades the pollen signal is used to display shifts in vegetation composition and structure (Bennett and Willis, 2002) and allows quantitative reconstructions of climate parameters such as precipitation regime and temperatures (Birks et al., 2010; Ohlwein and Wahl, 2012; Wen et al., 2013; Cao et al., 2014; Marsicek et al., 2018). Since vegetation structure and pollen production are mainly influenced by climatic parameters (Zheng et al., 2008) in the absence of human influences, the paleo-pollen signal is very often interpreted as a response to the climate variations through time (Kröpelin et al., 2008; Wagner et al., 2019). Even if human activities influence pollen rain as well (Hjelle, 1997; Hellman et al., 2009a), these empirical observations of the pollen-climate relation lead to the development of semi-quantitative (Ma et al., 2008) and quantitative calibrations (Brewer et al., 2008; Salonen et al., 2019) of the signal. Different methods have been developed to reconstruct past climates (Chevalier et al., 2020):
Probability Density Functions, Assemblages approaches, Transfer Functions (TF) and methods based on vegetation models (Guiot et al., 2000; Birks et al., 2010; Bartlein et al., 2011; Ohlwein and Wahl, 2012). More precisely, these methods are: the Inverse Modelling Method (IM, Guiot et al., 2000), the Weighted Averaging Partial Least Squares regression (WAPLS, Ter Braak and Juggins, 1993; Ter Braak et al., 1993), the Artificial Neural Networks (ANN, Peyron et al., 1998), the Modern Analogue Technique (MAT, Overpeck et al., 1985; Guiot, 1990; Jackson and Williams, 2004), the Response Surface Technique (RST, Bartlein et al., 1986), Probability Density Functions (PDF, Kühl et al., 2002; Chevalier, 2019), Modified Mutual Climate Range Method (MMCRM, Klotz et al., 2003, 2004), Bayesian Hierarchical Models (BHM, Ohlwein and Wahl, 2012), the Boosted Regression Trees (BRT, Salonen et al., 2014), etc. For northern Europe and despite some problems and pitfalls, Seppä et al. (2004) demonstrated that pollen-inferred climate reconstructions are generally consistent with other independent climatic reconstructions. This study encourages us to lead multi-proxy studies to refine climate reconstruction understanding, and especially in tricky and dry context such as Mongolian plateau (Rudaya et al., 2009).

Among new promising proxies and from the three last decades, biomarkers such as the glycerol dialkyl glycerol tetraethers (GDGTs) have provided new perspectives on continental temperature reconstructions (Naafs et al., 2017a, b). Among the GDGTs, we will focus on two major groups: the isoprenoid-GDGTs (isoGDGTs, Hopmans et al., 2000) and the branched-GDGTs (brGDGTs, Sinninghe Damsté et al., 2000; Weijers et al., 2007a, b; Dearing Crampton-Flood et al., 2020). BrGDGT assemblages reflect archaeal activity in rivers (De Jonge et al., 2014b), soil (De Jonge et al., 2014a) or lake water column (Dang et al., 2018). The GDGT input origin could be traced using the BIT index (Branched and Isoprenoid Tetraether index, Hopmans et al., 2004; Pearson et al., 2011a) and the IIIa/IIa ratio (Xiao et al., 2016; Martin et al., 2019a; Cao et al., 2014).

BrGDGT environmental drivers are linked to climate parameters (Weijers et al., 2007b), soil topology and vegetation cover (Davtian et al., 2016), which in turn imply land cover and land use. Accurate determinations of the relationships between brGDGT assemblages and climate still need some improvements (Naafs et al., 2018; Wang et al., 2019, 2020) and especially on local to regional scales and in extreme environments. It has been shown empirically (Weijers et al., 2004; Huguet et al., 2013) on cultures of pure strains (Salvador-Castell et al., 2019) as well as on meso- and micro-cosm experiments (Chen et al., 2018; Martínez-Sosa et al., 2020), that organisms adjust their membrane plasticity by the degree of methylation and cyclisation of the compounds. Moreover, some studies have focused on variations in the archaeal community structure (Xie et al., 2015), the archaeal group responses to environmental changes (Knappy et al., 2011) and the GDGT occurrences in different archaeal communities (Liu et al., 2012b) to determine the potential effects of community structure on GDGT relative abundances. To evaluate the provenance and the climatic information brGDGTs bear, several indexes have been proposed in the literature (Supplementary Table S1). To monitor these changes, Cyclisation ratio of Branched Tetraethers (CBT) and Methylation index of Branched Tetraethers (MBT) indexes linked to environmental factors such as climate and soil parameters have been proposed (Weijers et al., 2007b; Huguet et al., 2013). In particular, the methylation degree, ratio of 5Rev2, 6Rev2, 7-methyl isomers (Ding et al., 2016) and 7-methyl isomers (Ding et al., 2016) (De Jonge et al., 2013) and 7-methyl isomers (Ding et al., 2016) responds to environment forcing: the 5-methyl brGDGTs mathematically correlate mainly with temperature ($R^2 = 0.76$, Naafs et al., 2017a), while 6Rev2, 7-methyl brGDGTs ($R^2 = 0.69$) and 7-methyl brGDGTs ($R^2 = 0.44$) seem to correlates with moisture and pH (Yang et al., 2015; Ding et al., 2016). More specific
indexes have been proposed by De Jonge et al. (2014a) to limit the multi-correlation systems with the withdrawal of 5-methyl compounds such as MBT$_{5Me}$ which is independent of the pH and CBT$_{5Me}$ which is more representative of the soil pH than the former version of the index (index formula in Supplementary Table S1). The statistical relevance of these indexes is a major issue in brGDGT calibration (Dearing Crampton-Flood et al., 2020). Some regional indexes for soil temperature such as Index$_1$ (De Jonge et al., 2014a) and Index$_2$ for Chinese soils (Wang et al., 2016) have been explored too, in a context of a strong local calibration demand (Ding et al., 2015; Yang et al., 2015). IsoGDGTs were first attributed to lake water column production (Schouten et al., 2012), but they were also described in significant but lower proportions in soils (Coffinet et al., 2014). The Ratio of isoGDGTs on brGDGTs ($R_{i/b}$) has been proposed as a reliable aridity proxy (Yang et al., 2014; Xie et al., 2012). It has been shown that a linear relation exists between these GDGT indexes and some climatic features at large regional scales (in the wide Chinese biome range, from tropical forest to central arid plateau, for instance, Yang et al., 2014; Lei et al., 2016).

Since multi-proxy studies become more and more accurate in both temperature and precipitation reconstruction, local to regional calibrations have been proposed for dry areas such as the Arid Central Asian (ACA) area: pollen semi-quantitative climate reconstruction (Ma et al., 2008), pollen transfer functions (Herzschuh et al., 2003, 2004; Cao et al., 2014; Zheng et al., 2014), and brGDGT regression models (Sun et al., 2011; Yang et al., 2014; Ding et al., 2015; Wang et al., 2016; Thomas et al., 2017). Even if all of these studies focus on areas surrounding the EASM line (Fig. 2, Chen et al., 2010; Li et al., 2018a), the understanding of the climate cells interaction and oscillation over time is still lacunary, and especially on the ACA upper edge. In this context, our study took place in the northernmost part of this climatic system (Haoran and Weihong, 2007). Moreover, we propose the first multi-proxy calibration exercise in ACA area based on pollen and brGDGT fractional abundances retrieved from modern samples (soil, moss litter, pond mud) in semi-arid to temperate conditions. The aim of this study is to take advantage of new, modern surface sample datasets in Baikal area and Mongolia to propose an adapted calibration of pollen and archaeal biomarker proxies for cold and dry environments. For that purpose, local calibrations are compared with global calibrations to infer the influence of calibration scale and proxy types on derived climatic parameters.

Our approach is summarized in the following steps:

1. Collection of a new set of modern surface samples for Mongolia with homogeneous characterisation of their bioclimate environment followed by pollen and GDGT pattern characterization.

2. Evaluation of the match between actual bioclimate environments and the associated pollen rain and biomarker assemblages based on mathematical criterion without eco-physiological considerations.

3. Creation of local Mongolian Plateau (MP) climate calibrations for pollen and GDGTs and comparison of local and global calibrations on the Mongolian study case.

4. Posteriori validation of the inferred relationships between proxies and ecological likelihood based on the currently developed evidences of brGDGT and pollen rain ecological significance.
5. Discussion of the implications of the calibration mismatches in terms of climatic reconstructions in arid and cold environments.

6. Testing of the new calibrations (pollen and brGDGTs) through their application on four surrounding Late Holocene records: two pollen records, Dulikhia bog (Baikal area, Bezrukova et al., 2005; Binney, 2017) and Lake D3L6 (Altai, Unkelbach et al., 2019); and two brGDGT records, NRX (Altai, Rao et al., 2020) and XRD (Qaidam basin, Sun et al., 2019).

2 Mongolian and Baikal area Study Area

2.1 Coring, Sampling Area and Sample Types

The study area lies from 52°29′N to 43°34′N in latitude and from 101°00′E to 107°06′E in longitude (Fig. 1.A). The sample sites (n = 49) are listed in the Supplementary Tables S2 with a description of the sample type, the applied analyses, the coordinates and the associated ecosystem. For each site, the Garmin eTreX10 was used to record GPS coordinates to five-meter accuracy. The surface samples were collected throughout Mongolia in 2016 following four transects (n = 29): in the Khentii mountain range (MMNT1 and MMNT2, Fig. 1.E), in the Orkhon valley (MMNT3), in the Gobi desert and the Gobi-Altai range (MMNT4, Fig. 1.D). During the same field trip, a fifth transect has been done in the Sayan range along the Angara valley, Russia (MRUT1, n = 12, on Fig. 1.G). A Khangai mountains field trip from spring 2009 enlarge this set of data with a sixth transect of surface samples (MMNT5, n = 6, on Fig. 1.F) and two lake coring from Ayrag Nuur (MMNT5C12) and Shargyl Nuur (MMNT5C11) both on Fig. 1.F. Both of these top-cores were added to the surface pollen database, while only the MMNT5C12 core has been used as cross-value to check the accuracy of the brGDGTs climate models. This core has been clipped into 62 samples of which the top-core has been replicated 6 times (samples MMNT5C12-1 to MMNT5C12-6). Into the MMNT5 transect, mud from two temporary dry ponds has been sampled. These surface muds are referred in following figures as mud. Into the other transects and depending on aridity and vegetation at each site, a soil or a moss polster was sampled. In figures, soil refers to the 3 to 5 first centimetres of the ground in dry ecosystems, while moss is a mix between soil, litter and a bryophyte (or Cyperaceae) layer in wetter environments. Moss acts as a pollen trap recording a three to five-year mean pollen signal (Räsänen et al., 2004). In drier areas, the soil surface samples have the same function, in spite of a lower pollen conservation and over-representation of some taxa (Lebreton et al., 2010). In parallel following the calibration approaches presented in De Jonge et al. (2014a), Davtian et al. (2016) and Naafs et al. (2017a, 2018) mud from temporary ponds, soil samples as well as soil part of moss litter were also used for actual GDGT analysis. To summarize, this study is based on 49 sites, 48 samples in the pollen dataset, 44 in the brGDGT dataset and 6 cross-validation samples to test the brGDGT models. In terms of sample types, the dataset consists of 30 mosses, 15 soils, 2 pond muds and 2 top-cores.
Figure 1. A: Topographic map of Mongolia (from ASTER data) with the location of surface samples and weather stations considered in the present study; B: Mean Annual Precipitation; C: Mean Annual Air Temperature; D: Focus on the samples surrounding the Taat-siin Tsagaan Lake, Gobi desert; E: Focus on the samples along a valley in the Khentii range; F: Localisation of Khangai surface samples; G: Focus on the Baikal Lake transect following the Angara valley. The Mongolian GIS Data is issued from a dataset ASTER (https://biosurvey.ku.edu/directory/nicholas-kotlinski), the meteorological dataset from WorldClim2 and infrastructures from public dataset (ALAGaC) (https://marine.rutgers.edu/cfree/gis-data/mongolia-gis-data/)
To test the reliability of our modern calibrations, we have finally selected four paleosequences within or close to the MP used as test-benches of the calibrations. For the pollen analysis, the cores D3L6 from Unkelbach et al. (2019) located in the Mongolian Altai range and the Dulikha bog (Fig. 1, Bezrukova et al., 2005; Binney, 2017) are compared to the Xiangride section (XRD) used for brGDGT sequence from Sun et al. (2019), sampled in the Chinese Qaidam Basin and the NRX peat bog (Chinese Altai, Fig. 2, Rao et al., 2020). These two cores have recorded the paleoenvironmental changes of the Late Holocene period.

### 2.2 Vegetation and Biomes

The central part of the Mongolian Plateau (MP) is characterized by a dry and cold flat mosaic of steppes and deserts with a 1220 m a.s.l. median elevation (Fig. 1.A, Wesche et al., 2016) and is intersected in its northern part by the Sayan and Khentii ranges, in its southern part by the Gobi-Altai and Qilian Shan ranges aligned along a NW-SE direction and the Altai range on the west (Windley and Allen, 1993; Sha et al., 2015). A wet and cold highland in the Khangai ranges culminates at 4000 m a.s.l. and a flatter and wetter Mongolian area, the Darkhad basin, is located in the north, close to the Russian border on the edge of the southern Siberian Sayan range. In the northernmost part of the MP, the Baikal lake area is characterized by a basin at a lower altitude (around 600 m a.s.l., Fig. 1.G, Demske et al., 2005).

The distribution of vegetation and biomes follows a latitudinal belt organization: in the North the boreal forest presents a mosaic of light-taiga dominated by *Pinus sylvestris* mixed with riparian forest dominated by birches (*Betula* spp.), alders (*Alnus* spp.) and willows (*Salix* spp., Demske et al., 2005). On the MP, the light-taiga dominated by larches (*Larix sibirica*) and few birches is mixed with dark-taiga composed of Siberian pines (*Pinus sibirica*) and spruces (*Picea obovata*, Dulamsuren et al., 2005; Schlütz et al., 2008). The Mongolian taiga is constrained to a region spanning from the Darkhad Basin to the Khentii range (Fig. 1.A). On the north face of the Khangai piedmont, the vegetation is dominated by a mosaic of forest-steppe ecosystems: the steppe is dominated by the *Artemisia* spp. associated with Poaceae, Amaranthaceae, Liliaceae, Fabaceae and Apiaceae (Dulamsuren et al., 2005). On these open-lands there are some patches of taiga forest, following roughly the broadside and the northern face of the crest letting on to the grasslands in the valley (Dulamsuren et al., 2005). The two last vegetation layers in Mongolia through the elevation gradient is an alpine meadow dominated by Cyperaceae and Poaceae with a huge floristic biodiversity and an alpine shrubland with pioneer vegetation on the summits (Klinge et al., 2018). On the southern slope of the range, the ecotone between the steppe and the desert vegetation extends hundreds of kilometers from the northern part of the Gobi desert (with water supplied by the Gobi lake area in between) to the Gobi-Altai range in the south (Klinge and Sauer, 2019). In the southernmost part of the country, the warm and dry climate conditions favour desert vegetation dominated by Amaranthaceae, Nitrariaceae and Zygophyllaceae. The vegetation cover is lower than 25% and is mainly composed of short herbs, succulent plants and a few crawling shrubs.
2.3 Bioclimate Systems

In the central steppe-forest biome, the vegetation is marked by an ecotone with short grassland controlled by grazing in the valley and larches on the slopes. The forest is gathered in patches constituting between 10% and 20% of the total vegetation cover. There are also some patches of *Salix* and *Betula* riparian forests among the sub-alpine meadows on the upper part of the range. This vegetation is characteristic of the northern border of the Palaearctic steppe biome (Wesche et al., 2016). This biome is characterised by a range of 800 to 1600 m a.s.l, a Mean Annual Air Temperature (MAAT, Fig. 1.C) between -2 and 2°C and a Mean Annual Precipitation (MAP, Fig. 1.B) from 180 to 400 mm yr$^{-1}$ (Wesche et al. (2016) based on Hijmans et al., 2005).

In Mongolia, even if the MAP are very low (MAP$_{Mongolia} \in [50;500]$ mm yr$^{-1}$), the major part of the water available for plants is delivered during late spring and early summer, in contrast to Mediterranean and European steppes (Bone et al., 2015; Wesche et al., 2016). These seasons are the optimal plant growth periods. An unknown amount of precipitation is also brought in winter as snowfall (Rudaya et al., 2020) which it is not always measured into the weather station MAP. The main part of the MP MAP occurs during the summer (climate diagrams from Dulamsuren et al., 2005). However, the precipitation origin for Mongolia is still under debate (Piao et al., 2018). Mongolian summer precipitations up to the Baikal area (Shukurov and Mokhov, 2017) seem to be controlled by the East Asian Summer Monsoon system (EASM) instead of the Westerlies’ winter precipitation stocked onto the Sayan and Altai range (Fig. 2; An et al., 2008). The alternating Westerlies / EASM domination on the MP climate system appears to fluctuate throughout the Holocene depending on the monsoon strength (Zhang, 2021): the weakest is the monsoon, the furthest the EASM bring precipitation up to the ACA hyper-continental area. The EASM force may variate in function of the MP snow cover (albedo effect on sun radiance impact, Liu and Yanai, 2002) and/or the Pacific surface temperature (Yang and Lau, 1998). Finally, Piao et al. (2018) insist on the importance of the locally evaporated water recycling within the Mongolian MAP amount.

3 Methods

3.1 Pollen Analysis, Modern Pollen Datasets and Transfer Functions

Different chemical processes were performed on the samples: bryophytic part of the moss samples were deflocculated by KOH and filtered by 250$\mu$m and 10$\mu$m sieves to eliminate the vegetation pieces and the clay particles. Then, acetolysis was performed to destroy biological cells and highlight the pollen grains. For the soil and pond mud samples, 2 steps of HCl and HF acid attacks were added to the previous protocol to remove all the carbonate and silicate components. All the residuals were finally concentrated in glycerol and mounted between slide and lamella. The pollen counts were carried out with a Leica DM1000 LED microscope on a 40× magnification lens. The total pollen count size was determined by the asymptotic behaviour of the rarefaction curve. This diagram was plotted during the pollen count using PolSais 2.0, software developed in Python 2.7 for this study. The rarefaction curve was fitted with a logarithmic regression analysis. The counter was suspended whenever the regression curve reached a flatter step (Birks et al., 1992). A threshold for the local derivation at $\frac{dx}{dy} = 0.05$
was set. For each sample, the total pollen count is usually around $n \in [350; 500]$ grains for steppe or forest and $n \in [250; 300]$ for drier environment such as desert and desert-steppe.

Among all of the pollen-inferred climate methods, the MAT and the WAPLS were applied in this study on four different modern pollen datasets, and on the D3L6 and Dulikha fossil pollen sequence to test the accuracy of these calibrations (Unkelbach et al., 2019, Figs. 1.A and 2). The MAT consists of the selection of a limited number of analogue surface pollen assemblages with their associated climatic values (Guiot, 1990); while the WAPLS uses a Weighted Average correlation method on a limited number of Principal Components connecting the surface pollen fractional abundance to the climate parameters associated (Ter Braak and Juggins, 1993; Ter Braak et al., 1993). The first dataset, called New Mongolian-Siberian Database (NMSDB), is composed of pollen surface samples analysed in this study ($N = 49$, Fig. 2 and 3). The second one is the same subset aggregated to the larger Eurasian Pollen Dataset (EAPDB) compiled by Peyron et al. (2013, 2017). From this dataset of 3191 pollen sample sites, a pollen–Plant Functional Type method was applied to determine the biome for each sample according to the actual pollen rain (Fig. 2, Prentice et al., 1996; Peyron et al., 1998). Then, only the Cold Steppe (COST) dominant samples were extracted from the main dataset and aggregated with the NMSDB to produce the COSTDB ($N = 430$ sites, figured by lozenge in Fig. 2). Finally, a scale-intermediate dataset of samples located within the Mongolian border merged with the Mongolian New dataset is presented as MDB ($N = 151$ sites). The relation between each taxon and climate parameter was checked and then the MAT and WAPLS methods were applied with the Rioja package from the R environment (Juggins and Juggins, 2019).

### 3.2 GIS Bioclimatic Data

Because Mongolia and Siberia have relatively few weather stations (Fig. 1.A), climate parameters were extracted with R from the interpolated climatic database WorldClim2 (Fick and Hijmans, 2017). We used Mean Annual Precipitation (MAP, Fig. 1.B), Mean Annual Air Temperature (MAAT, Fig. 1.C), as well as temperatures and precipitations for spring, summer and winter ($T_{spr}$, $T_{sum}$, $P_{spr}$, $P_{sum}$, $T_{win}$ and $P_{win}$), Mean Temperature of the Coldest Month (MTCO) and the Mean Temperature of the Warmest Month (MTWA) in this study to characterize the actual climate. Because the Mongolian plateau is poor in weather stations, the WorldClim2 database suffers of interpolation errors. The surface sites presenting inconsistent climate parameters (MAP < 0 or MAP < Season Precipitation) were removed from the global database. The elevation data and the topographic map originate from the ASTER imagery (Fig. 1.A). The biome type for each site derives from the LandCover database (Olson et al., 2001), classification and field trip observations.

### 3.3 GDGT Analysis and Calibrations

For consistency with the sampling process and the modelling methodologies developed for pollen analysis; soil part of the moss polsters, soil samples and pond mud were treated for GDGT analysis. After freeze drying, about 0.6 grams of material were sub-sampled. The Total Lipid Extract (TLE) was microwave extracted (MARS 6 CEM) with dichloromethane (DCM):MeOH (3:1) and filtered on empty SPE cartridges. The extraction step was processed twice. Following Huguet et al. (2006), $C_{46} \text{GDGT}^{\text{Rev2}:S}$ (GDGT$^{\text{Rev2}:S}$ with two glycerol head groups linked by $C_{20}$ alkyl chain and two $C_{10}$ alkyl chains)
was added as internal standard for GDGT quantification. Then, apolar and polar fractions were separated on an alumina SPE cartridge using hexane: DCM (1:1) and DCM/MeOH (1:1), respectively. Analyses were performed in hexane: iso-propanol (99.8:0.2) by High Performance Liquid Chromatography with Atmospheric Pressure Chemical Ionization Mass Spectrometry (HPLC-APCI-MS, Agilent 1200) proceeded in the laboratory of LGLTPE-ENS de Lyon, Lyon, following Hopmans et al. (2016) and Davtian et al. (2018).

Each compound was identified and manually integrated according to its m/z and relative retention time following the integration descriptions from Liu et al. (2012a); De Jonge et al. (2014a) for 5- and 6-methyl brGDGT and Ding et al. (2016) for 7-methyl brGDGTs Rev2. (the peak chromatogram integration is displayed in Supplementary Fig. S1). Statistical treatments on
isoGDGT (Fig. 4.A) and brGDGT (Fig. 4.B) abundances were treated following two methods presented in Deng et al. (2016), Wang et al. (2016) and Yang et al. (2019): compounds were gathered by chemical structures as cycles (CBT) or methyl groups (MBT, De Jonge et al., 2014a). brGDGTs were expressed as fractional abundance \[ x_i \] (Fig. 4.B, Sinninghe Damsté, 2016), as follows:

\[
f[x_i] = \frac{n_i}{N_{brGDGT}} \sum_{j=1}^{x_j}
\]

To infer temperatures from brGDGT abundances, two types of model were applied: linear relationships between temperature and MBT–CBT indexes, and Multiple Regression (mr) models between one climate parameter and a proportion of multiple brGDGT fractional abundances. For the simple linear regression model, a correlation matrix between climate parameters and indexes was calculated using the corplot Rcran library. For mr models, we developed in the R environment a Stepwise Selection Model (SSM, Yang et al., 2014) to determine the best fitting model connecting climate parameters with brGDGTs fractional abundances. Then we gathered some of the climate–GDGT linear relations established in previous studies (De Jonge et al., 2014a; Naafs et al., 2017a, b, 2018; Sinninghe Damsté, 2016; Yang et al., 2014, 2019) focusing on a single climatic parameter, MAAT (Supplementary Table S1). These models were clustered into 3 categories, by sample types (mosses, soils or pond muds), geographical area (regional or worldwide scale) and the statistical model (MBT-CBT based of multiple regression models). According to the type of environment from which the samples originated, there was peat, soil and lake-inferred modelling. All these models were applied to the Baikal area–Mongolian surface samples, compared with the actual MAAT value at each site and applied to the brGDGT XRD section (Fig. 2, Sun et al., 2019) and the NRX bog (Figs. 1.A and 2, Rao et al., 2020).

### 3.4 Statistical Analyses

GDGTs and pollen data were analyzed with a Principal Components Analysis (PCA) to determine the axes explaining the variance within the samples. The biotic values (pollen and GDGTs) were also compared to abiotic parameters (climate, elevation, location and soil features) by the way of a Redundancy Analysis (RDA). The regression models were run with the \( p-value < 0.05 \) (model relevance), the \( R^2 \) (correlation level between the variables), the Root Mean Square Deviation (RMSE, error on parameter reconstruction) and Akaike’s information criterion (AIC, effect of over-parameterization on multiple regression models ; Arnold, 2010; Symonds and Moussalli, 2011). A cross-validation test was performed for all the brGDGT calibrations (from this study and from the literature) using an independent set of six lacustrine samples from the lake MMNT5C12 top-core. Statistical analyses were performed with the Rcran project, using the ade4 package (Dray and Dufour, 2007) for multivariate analysis. All the plots were made with the ggplot2 package (Wickham, 2016) or the Rioja package (Juggins and Juggins, 2019) for the stratigraphic plot and the pollen clustering using the CONISS analysis method (Grimm, 1987).
Figure 3. Simplified surface pollen diagram, bio-climatically sorted, of the Siberian–Mongolian transect. The pollen taxa are expressed in %TP. The Ecosystem Units were determined with a CONISS analysis. The left hand coloured dots represent the ecosystem for each sample from light taiga–riparian forest (deep blue), light/dark taiga–birch sub-taiga, steppe-forest, alpine meadow, steppe, steppe-desert and desert (deep red). The color scale is presented in Fig. 5. The MAP and MAAT are extracted from Fick and Hijmans (2017).

4 Results

4.1 Pollen, Climate and Ecosystems Relations

4.1.1 Modern Pollen Rain and Vegetation Representation

The pollen rain (Fig. 3) is dominated by six main pollen taxa: *Pinus sylvestris*, *Betula* spp., *Artemisia* spp., Poaceae, Cyperaceae and Amaranthaceae. The pollen diagram, sorted by bio-climate from the wet and relatively warm Baikal area on the upper part to the dry-warm Gobi desert on the bottom, presents a net Arboreal Pollen (AP) decrease from 85% to 5%. 34.26% of the variance is explained by PC\textsubscript{1} extending from positive values associated with Non-Arboreal Pollen (NAP; Amaranthaceae, Poaceae and *Artemisia* spp.) to negative values associated with AP (*Pinus* undet., *Betula* spp. *Picea obovata* and *Larix sibirica*, on Fig. 5.C). This trend shows the transition between ecosystems, marked by the seven main CONISS clusters (Fig. 3) and PC\textsubscript{1} and PC\textsubscript{2} variations (Fig. 5.C). Below are the over-representative main taxa for each of the Siberian–Mongolian transect ecosystem:

1. **Light taiga–riparian forest** dominated by *Pinus sylvestris* (> 70%), *Pinus sibirica* and very low NAP (< 5%).
2. **Mixed light/dark taiga–birches sub-taiga** with an assemblage of *Larix sibirica*, *Picea obovata*, *Pinus sylvestris* and *P. sibirica*.

3. **Forest-steppe** ecotone same AP assemblages that the light/dark taiga ecosystem with 20% of *Artemisia* spp., plus occurrence of Poaceae, Cyperaceae, *Thalictrum* spp. and *Convolvulus* spp.

4. **Steppe** still dominated by *Artemisia* spp. (30%) and rising Poaceae (25%), Brassicaceae

5. **Alpine meadow** overpowered by Cyperaceae up to 50%, Poaceae, Brassicaceae, Amaranthaceae and *Convolvulus* spp.

6. **Steppe-desert** ecotone highlighting by the transition between Amaranthaceae–Caryophyllaceae community and Poaceae–*Artemisia* spp. assemblages.

7. **Desert** dominated by Amaranthaceae (from 25% to 65%) and by rare pollen-type Caryophyllaceae, *Thalictrum* spp., *Nitraria* spp. and *Tribulus* spp.

### 4.1.2 Pollen – Climate Interaction

The pollen rain trends follow similar variations than bio-climate parameters in MAP, MAAT and elevation (Fig. 3). Highest AP values are correlated to large MAP (up to 500 mm yr\(^{-1}\)) and relatively high MAAT (around 1 °C), in the low range Baikal area. Then the transition between AP and NAP dominance is marked by decreases in both MAAT (−1 °C) and MAP (300 mm yr\(^{-1}\)) connected to the high-elevation Khangai range. Finally, the dominance of NAP in the Gobi desert area is linked to very arid conditions (MAP < 150 mm yr\(^{-1}\)) and relatively warm MAAT (up to 4 °C). The correlation between the taxa themselves and climate parameters is \( R^2 = 0.38 \) (RDA, Fig. 5.D). Rise in MAAT is associated with that of Amaranthaceae, Poaceae, *Sedum*-type and Caryophyllaceae percentages. On the contrary, decrease in MAAT is associated with a rise in the AP and Cyperaceae, *Artemisia* spp. and Brassicaceae percentages. MAP, fairly related to RDA\(_1\), rises with AP and decreases with NAP (Fig. 5.D). Finally, the elevation gradient favors *Artemisia* spp. and Cyperaceae for NAP and *Salix* spp. and *Larix sibirica* for AP (Fig. 5.D).

### 4.1.3 Pollen-inferred Climate Reconstructions: MAT and WAPLS Results

To reconstruct climate parameters from pollen data, MAT and WAPLS methods were applied on the four scales, modern pollen datasets and the ten climate parameters (Table 1). All these methods can be run with \( n \in [1;10] \) parameters: the number of analogues for MAT and the number of components for WAPLS. The best transfer functions among all of them were selected by the following approach: in a first step, for each climate parameter the methods fitting with the higher \( R^2 \) and the lower RMSE were selected. Then, in case the highest \( R^2 \) and the lowest RMSE were not applied for the same number of analogues or components, we chose the method presenting the lower number of parameters. Despite the small number of parameters relative to the number of observations, the method fits well (Arnold, 2010, Table 1). MAT method gives better \( R^2 \) in bigger DB than in smaller ones. Fitting increases with the diversity and the size of DB, since MAT is looking for the closest value
Table 1. Statistical results of the MAT and WAPLS methods applied to four surface pollen datasets and ten climate parameters\(^{(a)}\).

\(^{(a)}\) Only the five better fitting regression models for each climate parameter are shown.

\(^{(b)}\) The climate parameters correspond to Mean Annual Air Temperature (MAAT), Mean Temperature of the Warmest (MTWA) and the Coldest (MTCO) months, spring temperature (Tspr), Mean Annual Precipitation (MAP) and precipitation for summer (Psum) and spring (Pspr).

\(^{(c)}\) Corresponding to the number of parameters used in the model inferring the best R\(^2\) and RMSE.

\(^{(d)}\) Number of parameters, R\(^2\), RMSE of the finally selected model.
between climate and pollen abundance. By contrast, WAPLS fits better on the local scale and especially with a smaller number of sites. In this case, the pull of data is largest and the variance is largest (Ter Braak and Juggins, 1993). WAPLS also leads to better value of RMSE than \( R^2 \), in contrast to MAT. For temperature, pollen fits better with \( T_{spr} \) or MTWA in Mongolia.

Temperatures of the warmest months indeed control both vegetation extension and pollen production (Ge et al., 2017; Li et al., 2011) and especially in very cold areas such as Mongolia. For precipitation, the significant season is the one associated with the Summer Monsoon System in Mongolia (Wesche et al., 2016). Almost all the Mongolian precipitation falls during the spring and the summer (Wang et al., 2010), and the amount of precipitation controls, among other parameters, the openness of the landscape in Mongolia (Klinge and Sauer, 2019). To simplify the confrontation of the diverse models, the MAAT and MAP were isolated from the rest of the climate parameters. Even if these two climate parameters are not the best fitting pollen methods, they are the easiest to interpret and are comparable with the GDGT regression models commonly based on MAAT and MAP. In any case, these models are mitigated by the spatial autocorrelation affecting any models made on ecological database (Legendre, 1993) and especially the MAT method more than the WAPLS (Telford and Birks, 2005, 2011).

### 4.2 GDGT – Climate Calibration

#### 4.2.1 GDGT Variance in the dataset

In the MMNT5C12 sediments, isoGDGTs are dominated by \textit{\textsuperscript{Rev2:GDGT-0}} and \textit{\textsuperscript{Rev2:crenarchaeol-crenarchaeol}} (74.6% and 9.8% in relative abundances, respectively, in Fig. 4.A, grey boxplots). These compounds \textit{\textsuperscript{Rev2:previously considered mainly}} lake-produced (Schouten et al., 2012) \textit{\textsuperscript{Rev2:existence also present}} in the moss samples (32.7% and 31.3%, green boxplots) and in soils (57.4% and 26.7%, orange boxplots). The variations of their fractional abundance in our soil and moss polster dataset are discrete and poorly linked to climate parameters (Fig. 4.A). IsoGDGT patterns in lake sediments do not really diverge from soil samples which can lead\textit{\textsuperscript{Rev2:n}} to postulate that the \textit{in-situ} production of isoGDGTs in shallow and temporary lakes like MMNT5C12 is reduced (Fig. 4.A). At least, it may show that the archaeal community both in lake and in soils is dominated by methanogenic \textit{Euryarchaeota} more than \textit{Thaumarchaeota} (Zheng et al., 2015; Li et al., 2018b; Besseling et al., 2018). Then, it appears (Fig. 4.A) that the isoGDGT produced in soils are dominated by \textit{\textsuperscript{Rev2:crenarchaeol-crenarchaeol}} in accordance with studies on high alkalinity of the soil (Li et al., 2018b) linked to the impact of aridity (Zheng et al., 2015). However, no relationship exists between the crenarchaeol concentration and MAP (\( R^2 = 0.14, p-value > 0.005 \)). The putative regio-isomer response to MAP (Buckles et al., 2016) is not evidenced in NMSDB.

The average \( [\text{brGDGT}]_{\text{tot}} \) concentrations differ depending on the sample type:

\[
[\text{brGDGT}]_{\text{tot}} \text{sed} = 25.8 \pm 8.1 \text{ ng.g}^{-1} \text{sed} \\
[\text{brGDGT}]_{\text{tot}} \text{moss} = 23.2 \pm 26.8 \text{ ng.g}^{-1} \text{moss} \\
[\text{brGDGT}]_{\text{tot}} \text{soil} = 0.3 \pm 0.14 \text{ ng.g}^{-1} \text{soil} \\
[\text{brGDGT}]_{\text{tot}} \text{all} = 16.7 \pm 23.6 \text{ ng.g}^{-1} \text{sample}
\]
brGDGT fractional abundances are consistent with each sample type: the predominant compounds are the Iₐ, IIₐ, IIₐ and IIIₐ (Fig. 4.B). These compounds explain dominantly the total variance (Fig. 5.A). Particularly, the PC₁ represents 22.8% of the total variance and distinguishes two contrasted poles: the 5-methyl group (mostly with PC₁ > −0.3) associated with steppe-forest and forest sites and the 6ₐ⁻⁻⁻⁻ and 7-methyl group on the far negative PC₁ values associated with steppe and desert sites. Even if the 7-methyl brGDGTs appear to have weak significance in the brGDGT variance explanation (Fig. 5.A), the surface samples 7-methyl average fractional abundance around 4.6% is following the normal order of magnitude (4.3% in Cameroon lakes and 6.2% for Chinese lakes, Ding et al., 2016).

![Figure 4](image_url)

**Figure 4.** Fractional abundances of (A) isoGDGTs and (B) brGDGTs for moss polsters (green), soil surface samples (orange) mud from temporary dry pond (blue) and the full sequence of the Lake MMNT5C12 as palaeo brGDGTs comparison (grey). The punctuation marks ’ and ” refer to 6ₐ⁻⁻⁻⁻ and 7ₐ⁻⁻⁻⁻ methyl, respectively.

The sediment samples from the lake MMNT5C12, used as past sequence comparison, are more homogeneous than the surface samples, especially when compared with the moss polsters that present a wide variability (Fig. 4.B). On this figure it appears that, globally, soil samples are more relevant analogues to sediments than moss polsters (especially the [IIIₐ’], [IIa] and [Ia] fractions in Fig. 4). This variability shows an influence of the sample type on brGDGT responses. On the other hand, sample type also bears in first order climate and environment information, since soil and moss polsters originate mainly from steppe to desert environments and forest/alpine meadows, respectively. About the pond mud samples, the BIT and IIIₐ/IIₐ indexes (Supplementary Fig. S2) show that a coherent soil origin is leading the brGDGT input instead of a lacustrine one (Pearson et al., 2011; Martin et al., 2019b; Cao et al., 2020).
Figure 5. Multivariate statistics for the proxies clustered by ecosystems. **A:** Principal Components Analysis (PCA) and **B** Redundancy Analysis (RDA) for brGDGT fractional abundances; **C:** PCA and **D** RDA for pollen fractional abundances. The variance percentage explained is displayed on the axis label; the size of the dataset (n) and the RDA linear regression ($R^2$) are inserted in each plot area.
4.2.2 Climate Influence on brGDGT Indexes

The brGDGT/climate RDA shows that the brGDGT variance is dominated by the MAP as the first component (Fig. 5.B: RDA1 = 10.01%). The negative values show higher precipitations and uncyclized 5-Me GDGTs, such as Ia, IIa and IIIa, while the lower MAP match with 6 or 7-Me GDGTs, such as III′a, III′′a, II′a in accordance with De Jonge et al. (2014a). The RDA2 is slightly more connected to MAAT as opposed to elevation, also clustering the methylated and cyclized GDGTs to the higher MAAT. Such as in the pollen-climate response, the elevation is a second driving factor not to neglect. The correlation between relative abundance of methylated and cyclized brGDGTs with climate parameters was not strong (Weijers et al., 2004; Huguet et al., 2013). All the MBT, MBT′, MBT′5Me and CBT, CBT′, CBT5Me relations with climate parameters were tested and showed a very low correlation with \( R^2 \in [0.1; 0.35] \) (Supplementary Fig. S3.B). Once the MBT (Supplementary Fig. S4.A) and the MBT′5Me indexes (Fig. 6) compared with the world database (Yang et al., 2014; Naafs, 2017; Dearing Crampton-Flood et al., 2019) it appears that the NMSDB set is consistent with known values instead of a while sample dispersion.

![Figure 6. MBT′5Me–MAAT relation comparison between the NMSDB surface samples and the world peat and soil database Dearing Crampton-Flood et al. (2019).](image)

4.2.3 Multi-regression Models

The Stepwise Selection Model (SSM) for climate – brGDGT modelling was applied only on the 5- and 6-methyl, because 7-methyl brGDGTs show weak significance in the variance explanation (PCA, Fig. 5.A). To guarantee the homogene-
ity of the calibration, the SSM has been applied on the total surface dataset expected the two pond mud samples (even if their GDGT input seems to be validated by the BIT and IIIa/IIa indexes in Supplementary Fig. S2). The \( N_{SSM} \) different combinations of the 15 brGDGT compounds result in \( N_{SSM} = 2^{15} = 32768 \) models possible for each climate parameter. Even the models including some minor compounds (\(|br|_i < 5\%) have been considered since, in the NMSDB, brGDGT fractional abundances are more fairly distributed than in the global database, in which few compounds overlap the majority of the compound (Supplementary Fig. S4.B). Indeed, the cumulative fractional abundance curve (Supplementary Fig. S4.C) is fairly faster to rich the asymptote line for the world peat (blue curve) and the world soil (in brown) than in the NMSDB. The world peat database needs only three brGDGTs to explain more than 85% of the fractional abundance against more than ten compounds in the NDMSDB soils. Then, the better fitting equations (with low RMSE and AIC and high R-squared) were selected for each number of parameters (number of brGDGT issued in the linear regression) for both MAAT and MAP. Within the 15 models (one model for each parameter addition), the 9 more contrasted ones were selected for discussion (Supplementary Table S3). The models with the best statistical results were comprised of between 5 to 12 parameters and present a \( R^2 \in [0.60;0.76] \), a RMSE around 1.1 °C or \( 1068 \) mm.yr⁻¹ and a \( AIC_{MAAT} \in [152.6;166.2] \) or \( AIC_{MAP} \in [503.8;503.1] \). The earlier a parameter is used in the mr models, the greater is its influence. For both \( MAAT_{mr} \) and \( MAP_{mr} \) models, IIIa, III' a, IIIb, and III' b are the most relevant compounds for the climate reconstruction (Table 2) which is consistent with the PCA and RDA observations displayed (Fig. 5.A and B). Both the \( MAAT_{mr} \) models infer a positive contribution of III' a and a negative contribution of IIIa, which confirms these models as eco-physiologically consistent with the RDA results. Moreover, except for II' b, all the compounds positively correlate with MAAT and negatively with MAP, in accordance with the MAP–MAAT anti-correlation. The \( \Delta T \) values closest to 0 reveal the best fitting model on each point (Fig. 7, panel 1). Then, the box-plot (Fig. 7, panel 2) summarises the best fitting model at a regional scale.

5 Discussion

5.1 Issues in Modelling Mongolian Extreme Bioclimate

5.1.1 Appraisal Modelling in Arid Environments

According to Dirghangi et al. (2013) and Menges et al. (2014): the commonly used brGDGT indexes (MBT and CBT) are not relevant for arid areas with \( MAP < 500 \)mm.yr⁻¹ because of the relation between low soil water content and soil brGDGT preservation and conservation interferes in the brGDGT / climate parameters (Dang et al., 2016). The \( MAAT_{mbt} \) models based on MBT and MBT' indexes provide colder reconstructions (Fig. 7.C2) as shown by De Jonge et al. (2014a), because arid soils favor 6-methyl brGDGTs (by pH raising due to low weathering effect of the weak precipitation, Dregne, 1976; Haynes and Swift, 1989) and drive the MBT to decrease towards zero. This explains the colder \( MAAT_{Ding} \) and \( MAAT_{MBT_DJ} \) reconstructed values compared to the modern ones. Moreover, the main issue in climate modelling in Mongolia is the narrow relationship between MAAT and MAP. Because of the climatic gradient from dry deserts in the southern latitudes to wet taiga

forests in the northern ones, MAAT and MAP maps are strongly anti-correlated (Fig. 1.B, C and Supplementary Fig. S5). If this correlation is not statistically determined on the range of the global database \((R^2 = 0.35, p < 0.005)\), the impact is significant on the range of the Mongolian sites \((R^2 = 0.91, p < 0.005)\). This correlation could be a bias resulting from the interpolation method of the WorldClim2 database. In fact, there are very few weather stations (Fig. 1.A, Fick and Hijmans, 2017) and their distribution on the large MP is interrupted by mountain ranges. According to Fick and Hijmans (2017) the interpolation model used in the ACA (which includes our study area) gives a strong correlation \((R^2 = 0.99)\) and a little error \((\text{RMSE} = 1.3°C)\) for MAAT and \(R^2 = 0.89\) and \(\text{RMSE} = 23\text{mm.yr}^{-1}\) for MAP. Whenever the Baikal area–Mongolian calibrations are used for palaeoclimatic reconstructions, the RMSE of the climate parameters has to be added to the RMSE model. Moreover, the relevance of the interpolation models suffers from the transition threshold made in Mongolia between the EASM and the Eurasian Westerlies (Fig. 2, An et al., 2008) and reinforced by the topographic break (Fig. 1.A). Because the mr–GDGT models have been compiled with the group of Baikal sites which are out of the MAAT–MAP strong auto-correlation range (Supplementary Fig. S5), the reliability of the independence of the MAAT and MAP models seems to be guaranteed.

The topographic fence in Mongolia also affects the pollen and brGDGT distributions by it-self, as seen in both RDA analyses (Fig. 5.B and D) where elevation appears to be a main ecophysiological parameter. Elevation affects vegetation and pollen rain not just because of its influence on local MAAT and MAP but also because it drives other ecophysiological
parameters such as O₂ concentration, wind intensity, slopes and creeping soils, snow cover and exposure (Stevens and Fox, 1991; Hilbig, 1995; Klinge et al., 2018). Elevation as one of the main brGDGT drivers could also be explained by the archaeal community responses to pH, moisture and soil compound variations along the altitude gradient (Laldinthar and Dkhar, 2015; Shen et al., 2013; Wang et al., 2015) and the vegetation shifts (Lin et al., 2015; Davtian et al., 2016; Liang et al., 2019).

In any case, a better understanding of the archaeal community’s response to ecophysiological parameter variations will considerably improve the brGDGT calibration process (Xie et al., 2015; Dang et al., 2016; De Jonge et al., 2019).

5.1.2 Particularity of the southern Siberian–Mongolian climate system

Both GDGT and pollen calibrations show that the precipitation calibrations are more reliable than temperature ones (Tables 1, 2, Figs. 3, 8 and 7), reflecting that the southern Siberian-Mongolian system seems to be mainly controlled by precipitation. This dominance of precipitation could be due to seasonality. Even if the brGDGT production is considered to be mainly linked to annual temperature means (Weijers et al., 2007a, b; Peterse et al., 2012), the high pressure Mongolian climate system (Zheng et al., 2004; An et al., 2008) favors a strong seasonal contrast: almost all the precipitation and the positive temperature values happen during the summer (Wesche et al., 2016). Consequently, for the NMSDB pollen transfer functions, the seasonal parameters such as MTWA, T_sum and P_sum better describe the pollen variability than MAAT and MAP climate parameters (better R² and RMSE in Table 1). While the opposite is found on EAPDB and COSTDB models, the calibration made on large scale databases. The Mongolian permafrost persists half the year in the northern part of the country (Sharkhuu, 2003) and acts on vegetation cover and pollen production (Klinge et al., 2018). Furthermore, the effects of frozen soils on soil archaeal and bacterial communities and GDGT production are thought to be important (Kusch et al., 2019) since the archaeal community seems to be shifting with abrupt temperature modifications (De Jonge et al., 2019). This seasonality leads to a quasi equivalence between MAP and P_sum (if P_win ≈ 0 then MAP ≈ P_sum) while MAAT is torn apart by the large T_sum – T_win contrast (because the MAAT is an average value and not a sum as for MAP). The mathematical consequences of the seasonality on these two climate parameters are not the same. Finally, the MAP appears to be the most reliable climate parameter for southern Siberian-Mongolian climate studies according to the NMSDB sites (with MAAT < 5°C). Even if the brGDGTs seem to respond to summer temperature (Wang et al., 2016; Kusch et al., 2019), the summer mr-models are not significantly improving the calibration compared to the MAAT mr ones. For instance, the best T_sum_mr is selected by its AIC, T_sum_mr6 is inferred using 6 brGDGTs fractional abundance (R² = 0.63 and RMSE = 1.53°C). This lack of seasonality effect, expected in such cold areas, is consistent with temperate Chinese sites (brGDGT reconstructions, Lei et al., 2016).

5.1.3 Extreme Bioclimatic Condition Modelling Lead to a Better Global Climate Understanding

To reduce the signal/noise ratio, a wider diversity of sample sites should be added as initial inputs in the models. This raises the question of the availability of reliable samples in desert areas. The soil samples in the steppe to desert biomes are often...
very dry and these over-oxic soil conditions are the worst for both pollen preservation (Li et al., 2005; Xu et al., 2009) and GDGT production (Dang et al., 2016). brGDGT concentrations in moss polsters and temporary dry pond muds are thus higher than in soils in our database (equation 2 and Fig. 4). The explanation of the signal difference between the three types of samples could also originate from the in-situ production of brGDGTs inside the moss predominant over the wind-derived particles brought to the moss net. As well, it seems that the pool of moss polster is associated with a similar trend than the worldwide peat samples from Naafs et al. (2017b) (Supplementary Fig. S4.A and Fig. 6). Moreover, in the steppe or desert context of poor availability in archive sites, the edge clay samples or top-cores of shallow and temporary lakes could be a solution for palaeo-sequence studies. The two pond mud samples of the NMSDB are included within the soil-moss trend for all models (Fig. 5, Supplementary Fig. S4 and S3). Even if the brGDGT production and concentrations are different in soils than in lakes due to lake in-situ production (Tierney and Russell, 2009; Buckles et al., 2014), this effect is function of the lake depth (Colcord et al., 2015), consequently negligible for shallow lakes, and almost absent for lake edge samples as shown by Coffinet (2015) for Lake Masoko in Tanzania.

The soils of the Gobi desert also have a high salinity level which is also a parameter of control on brGDGT fractional abundances (Zang et al., 2018). This taphonomic bias (also climatically induced) could explain part of the histogram variance of Fig. 4 related to the sample type as well as the shift of the soil–cluster from the regression line in the cross-value plot of brGDGT MBT'/CBT models in Supplementary Fig. S3. Even if the impact of salinity on sporopollenin is not well understood, salt properties may affect pollen conservation in soils (Reddy and Goss, 1971; Gul and Ahmad, 2006).

Finally, the saturation effect of the proxies when they reach the limits of their range of appliance is also to be taken into considerations. Since both pollen and brGDGT signals are analysed in fractional abundance (i.e. % of the total count of concentration), these proxies evolve in a [0;1] space. The saturation effect appears when extreme climatic conditions are reached (Naafs et al., 2017a, b). For instance, in a tropical context, temperature values are too high to be linearly linked to fractional abundances (Pérez-Angel et al., 2019). Considering pollen–climate relationships, the inferior limit of pollen percentage is critical: for the majority of pollen types, whenever MAAT or MAP reaches a very high or low threshold, the pollen fractional abundance approaches zero (Fig. 9). These limit areas need to be closely investigated, which legitimises the local calibration methods.

5.2 Statistical Tools for Best Model Selection

5.2.1 Over-Parameterization and Best Models Selection

Among the possible methods, statistical values help to select the most reliable ones for palaeoclimate reconstruction. However, the correlation ($R^2$) and errors (RMSE) are not informative enough to discriminate between methods and to point to the most suitable ones for palaeoclimate modelling. This is especially true for the multi-parameter methods (such as brGDGT multi-regression models and pollen transfer functions). Indeed, the more input parameters in the method, the more accurate
it is (Tables 1, Supplementary Table S3 and Fig. 8.A and 8.B). All the regression models improve with parameter additions, and especially the less fitting methods improve exponentially (lower limit of the $R^2$ area, Fig. 8.B). The best R-squared-models for each parameter number (Fig. 8.A) correspond to the upper limit of the $R^2$ area (Fig. 8.B). This figure shows that the $R^2$ vs. parameter number trend follows a logistic regression (both for MAAT$_{mr}$ and MAP$_{mr}$ models). However, and especially for MAAT$_{mr}$ regression models, this logistic curve becomes asymptotic early, similar to the RMSE decrease. The over-parametrization of the models has proven to produce artefacts in ecological modelling (Arnold, 2010; Symonds and Moussalli, 2011). The issue is thus to identify the threshold in the parameter numbers selected. We used Akaike’s Information Criterion (AIC) to determine the better model without over-parameterization for brGDGT regression models: the lower the AIC, the better the model (Supplementary Table S3 and Table 2). The trend of AIC versus the parameter number is however more complex (Fig. 8.C). For MAAT$_{mr}$, the regression model becomes more accurate from one to five parameters rapidly, but then slowly decreases. The AIC curve takes an asymmetrical hollow shape around five parameters with a steeper slope on the left side (Fig. 8.A). The AIC values for MAAT$_{mr6}$ and MAAT$_{mr7}$ are almost identical (Fig. 8.A). The MAP$_{mr6,7,8}$ have almost equivalent AIC values, while the AIC curve shapes differ for the other MAP$_{mr}$ models (asymmetrical hollow shape around five with a steeper slope on the left side, Fig. 8.A). To summarize, the most universal models are MAAT$_{mr5}$ and MAP$_{mr7}$ (Table 2) but the closed models are also valuable in some local contexts, and especially in similar dry-cold regions.

We need to determine the cross-values of these models to select the appropriate ones for the southern Siberian-Mongolian context.

### 5.2.2 Assessment of the Calibration Feedback

The cross-values of the nine best MAAT$_{mr}$ regression models (Fig. 7.A1 and 7.A2) and the best MAP$_{mr}$ regression models (Fig. 7.B1 and 7.B2) were tested. The MAAT reconstructions provide different responses to the three main bio-climate areas (parcel A1): if they properly estimate temperatures in the Baikal area, they overestimate and underestimate them for the center of the northern Mongolian mountains and the Gobi desert, respectively. For precipitation (parcel B1), all the MAP$_{mr}$ calculated with local to regional databases also misrepresent the extreme values: precipitation values are too high and too low for the Gobi desert and the Baikal area, respectively. To conclude, the wider the dataset extension, the more alleviated the extreme values.

Both on MAAT$_{mr}$ and MAP$_{mr}$ models, the 95% interval shrinks with parameter addition, but the mean values do not necessarily get closer to the measured value of the climate parameter (the dashed line in Fig. 7.A2 and B2). Therefore, if the tests on the AIC point toward the MAAT$_{mr4}$ and the MAP$_{mr7}$ regression models, the back-cross plots suggest the MAAT$_{mr5}$, MAP$_{mr6}$, the MAAT$_{mr6}$, MAP$_{mr5}$, and MAP$_{mr7}$ regression models (Supplementary Table S3, coloured in blue and Table 2) provide the best estimates for climate reconstruction in lacustrine archives ($\Delta$MAP = 0 and best fitting temperature for the mean value of all samples, Fig. 7.B2 and Fig. 7.B1).
Figure 7. Validation of brGDGT-climate models on the study sites: reconstructed values for literature MAAT (A), NMSDB mr–MAAT (B) and MAP (C). Models are tested on the NMSDB sites (I) and the box-plot statistics (2) are provided. Sites are clustered in 4 groups: cross-value on the 6 first samples of the independent core MMNT5C12, Arkhangai; moss polsters from Mongolian steppe-forest; Gobi steppe-desert soil samples and moss polsters from Baikal area. Values are plotted in anomaly.
Figure 8. Statistical values plotted against the number of parameters of the different mr–GDGT models: the $R^2$, the RMSE normalized on the highest RMSE value and the AIC also normalized. A: selection of the two best multi-regression models for each number of parameters; B: combination of the $R^2$ (B) and the AIC (C) values for of all the mr models. The blue dots are for the MAP-models, orange dots for the MAAT one.

5.2.3 Global vs. Local Calibration

Whatever proxy is used, when reconstructing temperatures and precipitation from past records in a given location, there is the issue of basing reconstructions on calibrations based on local or global datasets (among others, Tian et al., 2014; Cao et al., 2014; Ghosh et al., 2017; Dearing Crampton-Flood et al., 2019). We tested both approaches on our datasets with a cross-value run on the NMSDB-independent set of MMNT5C12 core samples. The global brGDGT - climate calibration artificially reaches higher R-squared than local ones due to the larger range of values of the involved climate parameters. Since the world soil database in Naafs et al. (2017) covers a wide temperature range (MAAT $\in [-5;30]$), counter to the NMSDB (MAAT $\in [0;5]$), then its signal/noise ratio gets lower (Fig. 6). Despite the relatively lower R-squared of $R_{\text{rev2}}=0.62\div0.66$ scored by the MAAT$_{\text{mr5}}$ compared with world calibrations (Pearson et al., 2011; De Jonge et al., 2014a; Naafs et al., 2017a, b), the boxplots for the all MAAT$_{\text{mr}}$ calculated from the NMSDB are mostly centered on the MAAT average value with the shortest variance spreading for all the sites (Fig. 7.C1 and 7.C2). These local calibrations fit best with the MAAT$_{\text{Ding}}$ from Ding et al. (2015) which is also a local calibration made on the Tibet-Qinghai plateau database. The global databases made on worldwide sites (De Jonge et al., 2014b, a; Naafs et al., 2017a, b) provide MAAT$_{\text{model}} > $MAAT$_{\text{real}}$ and large standard deviation (SD). These global calibration also attenuate the extreme MAAT values: the very cold MP sites are reconstructed with warmer temperatures up to +5 to +10 °C, while the warm Gobi desert sites are down by up to -3 to -5 °C. On the other hand, the local calibrations performed on subtropical to tropical Chinese transects (Yang et al., 2014; Thomas et al., 2017) have smaller SD but largely overestimate MAAT values due to the warmer conditions of the initial database sites. In brief, the lake core sediment samples match the best to the modern MAAT and MAP value with the brGDGTs mr–models which invite
us to consider that these local brGDGT calibrations present a robust way to approach past climate.

Similarly, for pollen transfer functions, the geographic range of the surface samples on which the calibration relies is a relevant parameter to take into account for the reliability of the paleoclimate reconstructions. The choice of the maximum value of this geographic range has been discussed previously for vegetation modeling, for example, the Relevant Source Area of Pollen (RSAP, Prentice, 1985; Hellman et al., 2009a, b; Bunting and Hjelle, 2010). For MAT and WAPLS regression models, the same issue holds true. The responses of the eight over-represented taxa to climate parameters are different in the three geographic ranges (NMSDB, COSTDB and EAPDB). The linear tendency allows for checking the main trends between taxa distribution and climate parameters, despite the weak linear regressions ($p$-value > 0.005 and $R^2$ < 0.4, in Fig. 9). For the majority of these taxa, the trend is the same, independent of the database size (Larix spp. and Cyperaceae percentages increasing with weaker MAAT, or Amaranthaceae and Pinus sylvestris percentages increasing with higher MAAT). However, due to the shift between pollen types and their associated vegetation (i.e. Poaceae-pollen signal similar for a wide diversity of Poaceae communities with very contrasted ecophysiological features), trends are controlled in some peculiar cases by the geographical clipping of the DB. Thus, Poaceae have a positive response to MAP on the global scale but not inside the Mongolian area. The human influence on pollen rain is also dependent on the biogeographical context, thus, Artemisia spp. is not considered as much human influenced in the Asian steppe environment (Liu et al., 2006) than in the European one (Brun, 2011).

Concerning transfer functions, WAPLS performs better for the local database than for the COST and EAP databases (Table 1). On these subsets, the WAPLS RMSE and R-square values are even higher than for the MAT approach. The major difficulty resides in the reconstructions of precipitation. Even if the RMSE and $R^2$ values are higher for all models of MAP than MAAT, the influence of precipitation on vegetation cover is not well understood. In Mongolia it is clear that the precipitation controls the treeline in mountainous areas (Klinge and Sauer, 2019) and the global openness in the steppe - forest ecotone (Wesche et al., 2016) as well as human land-use (Tian et al., 2014), but the risk of autocorrelation between MAAT and MAP signals is important, even if the RMSE and $R^2$ values are higher for MAP regression models than for MAAT ones (Telford and Birks, 2009; Cao et al., 2014). Tangibly, for the two proxies, even if the global calibrations can operate on our study area, the local calibrations reach higher accuracy.

### 5.2.4 Test-bench of the Local Calibrations on Two Paleosequences

To test the reliability of our local calibrations, the pollen transfer function and the brGDGT mr-models have been applied on four paleo-sequences. Because there is still no available core analyzed both for pollen and brGDGTs either in ACA or in the MP, the Dulikha bog (pollen, Baikal, Bezrukova et al., 2005; Binney, 2017), the Lake D3L6 (pollen, Altai, Unkelbach et al., 2019), the NRX bog (Altai, GDGTs, Rao et al., 2020) and the XRD section (Qaidan, GDGTs, Sun et al., 2019) are used. The actual values of the climatic parameters are first compared to the top-core reconstructed climatic parameters (Fig. 10, dashed lines). The amplitude of the variations through time has then to be assessed with regards to the expected regional ranges (Zheng et al., 2004). Finally, reconstructions on known short term climate events are tested for the last 5000 years. They are
Figure 9. Relationships between the eight major pollen taxa (%TP) and MAP (mm yr⁻¹, upper part of the facet plot) and MAAT (°C, lower part). The black line is the linear fitting for all samples (EAPDB), the orange for all the samples from steppe biome (COSTDB) and the blue only for the NMSDB samples presented in this article.
namely the Little Ice Age, Warm Medieval Period, Dark Ages Cold Period, Roman Warm Period, 3.5k cooling and 4.2k year event (respectively LIA, WMP, DACP, RWP, 3.5ky and 4.2ky ; Zhang et al., 2008; Chen et al., 2015; Aichner et al., 2019).

For the pollen transfer function (Fig. 10.A and B), the inferred reconstruction approaches display similar trends during the 5000 years with larger amplitude for MAT than for WAPLS. MAT is also more sensitive to the initial calibration dataset selected than WAPLS (Fig. 10.A and B) which is in agreement with previous multi-methods studies (Brewer et al., 2008). Indeed, the COSTDB and EAPDB are over-reactive in front of local calibration, while the WAPLS display same amplitude for each calibration with a different offset. Particularly, the NMSDB consistently displays the values closest to the actual climate parameter values both for MAT and WAPLS. For the D3L6 precipitations, all models seem to drive away from the actual value. This shift highlights the WorldClim2 interpolation issues in the Altai mountains (few weather stations and not accounting for snow melt). For the Dulikha bog precipitation, only the NMSDB has a same trend for WAPLS and MAT. The other datasets are more sensitive to the method used.

On Fig. 10.C and D, about brGDGTs, the local calibrations (NMSDB applied to XRD section and NRX peat) provide the closest surface reconstructed temperature values to the actual ($\Delta$MAAT < 2°C, Fig. 10.C and D on the left panel) compared to the global calibration ($\Delta$MAAT $\in [6;10]$°C, De Jonge et al., 2014a; Naafs et al., 2017a, b). For XRD section, this is explicable by the high similarity between the type of sediment from the XRD section (dry taphonomy) and a large proportion of the NMSDB surface samples (especially from Gobi desert). For NRX peat, it is due to the similar high elevated and arid condition both for NRX and NDMSB. Moreover, the NMSDB calibrations present a more realistic amplitude: 6 °C over 5000 years (similar to pollen-inferred amplitude) as opposed to 10 to 20 °C amplitude for global calibrations in XRD and + 4 °C for NMSDB against around + 7 °C for global databases in NRX. About the precipitation, the brGDGTs mr–models show a decreasing trend along the Holocene, particularly well-marked between 1000 and 2000 yr BP followed by a bounce on the last 1000 years on both brGDGT records (tendency consistent with the WAPLS pollen MAP). All brGDGT calibrations exhibit consistent shifts during the LIA (cold-wet), the WMP (warm-dry) and the 4.2ka event (cold-wet). These variations are also exaggerated with global calibrations. To conclude, general trends are consistent for all calibration datasets, except for the drying-warming trend inferred by the calibration from De Jonge et al. (2014a).

Even if the pollen-based and brGDGT-based climate reconstructions were not conducted on the same core, the D3L6 and NRX records (Fig 10.B and C) are nearby into the Altai range. These two signals allow to discuss the pollen / brGDGT difference in reconstruction output. Except for a few globally calibrated reconstructions ($MAP_{WAPLS-EAPDB}$ for pollen and $MAAT_{mr-DJ}$ for brGDGT), the climate inferred follows a similar trend. The main difference between the proxy is the amplitude of the climate shifts: brGDGT-inferred models seem to provide higher amplitude responses both for the Late Holocene trends than the centennial oscillations.
Figure 10. ACA climate reconstruction for the 5000 year cal BP. (A): climate–pollen inferred for the Dulikha peat bog (Bezrukova et al., 2005; Binney, 2017) and (B) Lake D3L6 (Unkelbach et al., 2019) comparing two transfer function methods (WAPLS and MAT) and the 4 databases (EAPDB, COSTDB, MDB and NMSDB) ; (C) climate–brGDGT inferred from the XRD section (Sun et al., 2019) and (D) the NRX peat bog (Rao et al., 2020) comparing local (NMSDB) and global calibrations (De Jonge et al., 2014a; Naafs et al., 2017a, b). The climate periods correspond to Little Ice Age (LIA), Warm Medieval Period (WMP), Dark Ages Cold Period (DACP), Roman Warm Period (RWP), 3.5k year and 4.2k year event according to Zhang et al. (2008), Aichner et al. (2019) and Sun et al. (2019). Dashed lines represent the actual surface climate parameters for each cores (from WorldClim2, Fick and Hijmans, 2017).
Fig. 10 shows that realistic reconstructed surface values are consistent with literature Holocene trends and validate the application of local calibrations for both pollen and brGDGTs. Furthermore, abrupt oscillations and overall amplitudes of temperature and precipitation variations are realistic, in accordance with regional appraisal (Wu et al., 2020). These results permit us to improve our understanding on the MP and ACA Late Holocene climate variations. Overall, on the 5000 year period the climate appears to follow a drier–warmer trend. More precisely, except for Dulikha bog and both for pollen and brGDGTs the local calibration shows an anti-correlation between temperature and precipitation short-period oscillations: the LIA seems to be colder and wetter than the warm and dry WMP. The same cold-wet behavior is observed for the 4.2ka event. This conclusion is important and situate the Dulikha, D3L6, NRX and the XRD sequences in the same trend that the majority of the ACA paleosequences (Chen et al., 2010, 2015; Wu et al., 2020), connecting the Altai range and the Qaidam basin to the EASM vs. Westerlies Holocene oscillations.

6 Conclusions

The palaeoenvironmental and palaeoclimatic signals may present several uncertainties (differential production, preservation...) which can misguide the interpretation of past variations. This study shows how both a multi-proxy approach and an accurate calibration are important in preventing these biases. We propose a new calibration for Mean Annual Precipitation (MAP) and Mean Annual Air Temperature (MAAT) from brGDGTs as well as a new pollen surface database available for transfer functions. The correlations between pollen rain and climate on one hand and brGDGT soil production and climate on the other are visible but are still mitigated by the complex climate system of Arid Central Asia and the diversity of soils and ecosystems. Precisely, each of our proxies seems to be more narrowly linked to precipitation (MAP) than temperature (MAAT) counter to the majority of calibrations in the literature. This is validated on both modern and past sequences for pollen and brGDGTs. The nature of the samples considered (soil, moss polster and mud from temporary dry pond) also greatly affected these correlations. The calibration attempt for the extreme bio-climates of the MP is difficult because of the low range of climate values, despite the climate diversity ranging from cold and slightly wet (north) to the arid and warm (south) conditions. Even if global and regional calibrations could be applied in such a setting, local calibrations provide enhanced accuracy and specificity. The MAAT and MAP values do not remarkably spread in the vectorial space, which makes harder to distinguish the linear correlation against variance noise. Moreover, this range of values is close to the lower saturation limit of the proxies, which makes the accurate local calibration tricky but necessary. The local calibrations also suffer from the reduced size and small geographic extent of the dataset. The vegetation cover, extending from a high cover taiga forest to bare soil desert cover, also buffers the climate signal and the GDGT / pollen response. The correlations between climate parameters and GDGT / pollen proportion are therefore lower than they could be at global scale. Nonetheless, and despite the lower correlation of the local calibration, these local approaches appear to be more accurate to fit the actual climate parameters than the global ones: both for pollen transfer functions and brGDGT multiple regression models. It is especially the case during the short Late Holocene period which is not suffering from abrupt ecosystems changes. These positive model results have
to be considered in light of over-parameterization limits. Too many parameters in mr–brGDGT models or in pollen MAT or WAPLS transfer function can add artificially to the linear relation between climate and proxies and lead to misinterpretation of palaeoclimate records. Akaike’s information criterion associated with RMSE and $R^2$ values is a fair way to select the best climate model. These local calibrations applied to Dulikha, D3L6, NRX and XRD paleosequences highlighted the temperature and precipitation variation throughout the Late Holocene. The next step will be to test our calibrations on pollen and GDGTs records available from the same core. We encourage wider application of this local multi-proxy calibration for a more accurate constraint of these central Asian climatic systems, a crucial improvement to properly model the fluctuations of the Monsoon Line since the Holocene Optimum.

**Author contributions.** LD conducted the analytical work, LD, SJ, OP, GM designed the study. All the authors contributed to the scientific reflection as well as to the preparation of the manuscript.

**Competing interests.** The authors declare having no competing interests.

**Acknowledgements.** We want to thank the editor and the two anonymous referees for their relevant recommendations. We thank also all the direct and indirect contributors to the global surface pollen dataset as well as the Laboratory of Ecological and Evolutionary Synthesis of the National University of Mongolia for its support during the field trip. We also express gratitude to Laure Paradis for her GIS advice, Marc Dugerdil for the help with Python fixing, Jérôme Magail and the Monaco–Mongolia joint mission for their technical and financial support in providing top cores and sediment samples from Arkhangai, Salomé Ansanay-Alex for her spectrometer expertise and La Tendresse for its support. We are grateful to the ISEM team DECG for financial support. For the analytical work completed at LGLTPE-ENS de Lyon, this research was funded by Institut Universitaire de France funds to GM.
