**Abstract.** The middle Miocene climate transition (MMCT, ~14.5–13.0 Ma) was associated with a significant expansion of Antarctic ice, but the mechanisms triggering the event remain enigmatic. We present a new clumped isotope ( $\Delta_{47}$ ) bottom water temperature (BWT) record from 16.0 Ma to 12.2 Ma from Ocean Drilling Program (ODP) Site 747 in the Southern Ocean, and compare it to existing BWT records. We show that BWTs in the Southern Ocean were ~8–10°C during the middle Miocene greenhouse, and thus considerably warmer than today. Nonetheless, bottom water  $\delta^{18}\text{O}$  (calculated from foraminiferal  $\delta^{18}\text{O}$  and  $\Delta_{47}$ ) suggests substantial amounts of land ice throughout the interval of the study. Our dataset demonstrates that BWTs at Site 747 decreased by ~3–5°C across the MMCT. This cooling preceded the stepped main increase in global ice volume, and appears to have been followed by a transient bottom water warming starting during or slightly after the main ice volume increase. We speculate that a regional freshening of the upper water column at this time may have increased stratification and reduced bottom water heat loss to the atmosphere, counteracting global cooling in the bottom waters of the Southern Ocean and possibly even at larger scales. Additional processes and feedbacks required for substantial ice growth may have contributed to the observed decoupling of Southern Ocean BWT and global ice volume.

## 25 1 Introduction

During the Cenozoic Era (the last 65 Myr), Earth's climate transitioned from a state of expansive warmth with very limited ice to colder conditions and permanent ice sheets at the poles (Zachos et al., 2001). The middle Miocene climate transition (MMCT, ~14.5–13 Ma) represents one of the main steps of Cenozoic cooling. A substantial increase in benthic foraminiferal oxygen isotope ratios ( $\delta^{18}\text{O}$ ) during the MMCT has been interpreted to reflect a combination of decreasing bottom water temperatures (BWTs) and ice sheet expansion (increasing bottom water  $\delta^{18}\text{O}$ ) occurring in the Southern Hemisphere (Lear et al., 2015; Lewis et al., 2007). A roughly coeval decrease in atmospheric  $p\text{CO}_2$  of ~100–300 ppm was estimated based on

boron isotope and alkenone records, suggesting a coupling of  $p\text{CO}_2$  and benthic foraminiferal  $\delta^{18}\text{O}$  during this interval (Sosdian et al., 2018; Super et al., 2018). Atmospheric  $p\text{CO}_2$  also appears to be coupled to upper ocean temperatures in the North Atlantic and Southern Ocean (Leutert et al., 2020; Super et al., 2018). Conversely, several studies propose a degree of  
35 decoupling between BWT and global ice volume during the middle Miocene (Billups and Schrag, 2002; Lear et al., 2010, 2015; Shevenell et al., 2008). These studies are based on deconvolving the bottom water  $\delta^{18}\text{O}$  ( $\delta^{18}\text{O}_{\text{bw}}$ ) and temperature signals in benthic foraminiferal  $\delta^{18}\text{O}$  with independent temperature estimates based on benthic foraminiferal Mg/Ca ratios. Their results indicate a middle Miocene decrease in BWT of  $\sim 0.5\text{--}3^\circ\text{C}$ . Taking into account the  $\delta^{18}\text{O}$  increase of roughly 1 ‰ in benthic foraminifera, this cooling would imply a drop in global sea level of  $\sim 30\text{--}110$  m, based on the Pleistocene  
40 seawater  $\delta^{18}\text{O}$ -sea level calibration of  $0.08\text{--}0.11$  ‰ per 10 m sea level (Fairbanks and Matthews, 1978; Lear et al., 2010) and the oxygen isotope temperature equation (Eq. (9)) of Marchitto et al. (2014). Other approaches using backstripping and different modelling techniques suggest a sea level drop of  $\sim 20\text{--}40$  m across the MMCT (de Boer et al., 2010; Frigola et al., 2018; Kominz et al., 2008; Langebroek et al., 2009).

Although the MMCT represents one of the most fundamental reorganizations in global climate during the Cenozoic era (e.g.,  
45 Flower and Kennett, 1993; Zachos et al., 2001), there are still major uncertainties associated with estimating the magnitude and timing of BWT and global ice volume changes. These uncertainties are mainly caused by the small number of independent BWT records resulting in limited spatial and temporal coverage for the middle Miocene, but also by current limitations of the applied temperature proxies. Middle Miocene data coverage is especially poor in the Southern Ocean, where high-resolution BWT records are conspicuously lacking. An existing lower-resolution ( $\sim 200\text{--}300$  kyr) Southern  
50 Ocean proxy record based on Mg/Ca signatures of benthic foraminiferal tests from Ocean Drilling Program (ODP) Site 747 indicates a bottom water cooling of  $\sim 2\text{--}3^\circ\text{C}$  from around 15 Ma to 12 Ma (Billups and Schrag, 2002). However, the middle Miocene portion of this BWT record from ODP Site 747 does not have the temporal resolution to adequately capture the magnitude and timing of BWT changes across the MMCT. Furthermore, the application of the Mg/Ca thermometer to middle Miocene benthic foraminifera is complicated by a number of non-thermal effects. Notable amongst these are  
55 differential vital effects in foraminifera (e.g., Lear et al., 2002) and the effect of seawater Mg/Ca that has not remained constant on timescales longer than several million years (Evans and Müller, 2012). Finally, benthic foraminiferal Mg/Ca signatures can be influenced by changes in carbonate ion saturation state, especially at low saturation (Elderfield et al., 2006; Lear et al., 2010; Yu and Elderfield, 2008). Previous studies have attempted to minimize saturation state-related effects on Mg/Ca by using only infaunal foraminifera (e.g., *Oridorsalis umbonatus*) precipitating their tests in pore waters that may be  
60 buffered to some extent against carbonate saturation changes (Elderfield et al., 2006; Lear et al., 2015) and/or by correcting for changes in saturation state based on paired Mg/Ca and Li/Ca measurements (Lear et al., 2010). Nevertheless, the impact of fluctuating saturation states on middle Miocene Mg/Ca signatures remains controversial. Independent temperature records are required to better understand the mechanisms controlling the Southern Ocean climate evolution during this interval of global change.

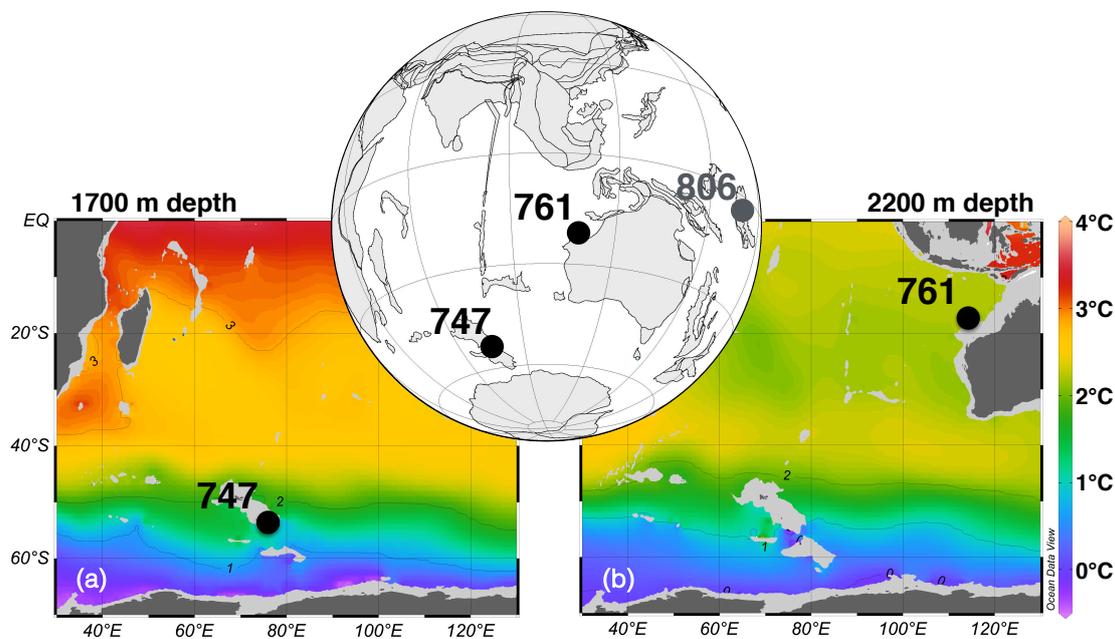

65 The carbonate clumped isotope ( $\Delta_{47}$ ) paleothermometer is based on the measured abundance of  $^{13}\text{C}$ - $^{18}\text{O}$  bonds relative to  
their stochastic distribution (Ghosh et al., 2006; Schauble et al., 2006), and is independent of the isotopic composition of the  
parent water from which the carbonate grew (e.g., Eiler, 2011). On the basis of current knowledge, other environmental  
variables such as pH and salinity appear to be of minor importance for measured  $\Delta_{47}$  values over the range of natural  
variation (Tripathi et al., 2015; Watkins and Hunt, 2015). When applied to foraminiferal calcite, the method also does not  
70 show detectable species-specific vital effects (Grauel et al., 2013; Meinicke et al., 2020; Modestou et al., 2020; Peral et al.,  
2018; Piasecki et al., 2019; Tripathi et al., 2010). Consequently, the  $\Delta_{47}$  thermometer holds great promise for reconstructing  
accurate BWTs from benthic foraminiferal tests (e.g., Leutert et al., 2019). The  $\Delta_{47}$  thermometer has been previously applied  
to middle Miocene benthic foraminifera from ODP Site 761 in the Indian Ocean yielding results that are in good agreement  
with Mg/Ca BWTs from the same site (Lear et al., 2010; Modestou et al., 2020). However, there are intervals with very low  
75 data density in the middle Miocene record from Site 761, limiting its informative value for understanding the drivers of the  
MMCT. At the same time, middle Miocene BWTs in other key regions such as the Southern Ocean remain poorly  
constrained. Here, we present  $\Delta_{47}$ -based BWTs measured on benthic foraminiferal calcites from ODP Site 747 located on the  
Kerguelen Plateau in the Southern Ocean (Fig. 1). We compare our new absolute BWT record to previous BWT estimates  
for the middle Miocene, and interpret the BWT records in the context of middle Miocene glaciation and  $\text{CO}_2$  drawdown.

## 80 2 Material and methods

### 2.1 Site details

ODP Site 747 (54°48.68'S, 76°47.64'E; 1695 m water depth) lies on the Kerguelen Plateau in the Southern Ocean (Fig. 1;  
Schlich et al., 1989). At present, the site is situated south of the Polar Front and is bathed by Circumpolar Deep  
Water (CDW) with a temperature of  $\sim 1$ – $2^\circ\text{C}$  (Belkin and Gordon, 1996; Billups and Schrag, 2002). The middle Miocene  
85 geographic position of Site 747 relative to Antarctica was similar to today (e.g., Abrajevitch et al., 2014). The clumped  
isotope record generated in this study covers the depth interval from 62.64 m below sea floor (mbsf, Sample 747A-7H-5, 14-  
16 cm) to 85.36 mbsf (Sample 747A-9H-8, 75-77 cm) in Hole 747A. 191 samples (15-20  $\text{cm}^3$ , mostly calcareous nannofossil  
ooze with foraminifera) were taken continuously with a mean temporal resolution of  $\sim 20$  kyr. We slightly rescaled the  
originally assigned shipboard sample depths to account for core expansion (Schlich et al., 1989), similar to previous studies  
90 focusing on the middle Miocene section of Hole 747A (e.g., Abrajevitch et al., 2014; Majewski and Bohaty, 2010).

**Fig. 1:** Ocean temperatures at modern water depths and paleogeographic reconstruction for 14 Ma. Modern water depths of ODP Sites 747 and 761 are ~1700 m and ~2200 m, respectively (Lear et al., 2010; Schlich et al., 1989). Annual mean temperatures at these depths are shown in (a) and (b). Temperatures from the 2013 World Ocean Atlas (Locarnini et al., 2013) visualized with Ocean Data View (Schlitzer, 2019). Inset map with paleogeographic reconstruction from the plate tectonic reconstruction service of the Ocean Drilling Stratigraphic Network (<http://www.odsn.de>).

## 2.2 Sample material

Each sediment sample was freeze-dried, washed over a 63  $\mu\text{m}$  sieve, oven-dried at 50°C and then dry-sieved into different size fractions. We mainly picked tests of *Cibicidoides mundulus* from the 250–355  $\mu\text{m}$  size fraction for our measurements. For samples with low abundances of benthic foraminifera in this size fraction, the >355  $\mu\text{m}$  size fraction was also included. The interval from ~16.0 Ma to ~15.3 Ma was additionally complemented with measurements on *Cibicidoides wuellerstorfi*. Middle Miocene benthic foraminifera (and more specifically *Cibicidoides*) from Site 747 were previously described as well preserved (e.g., Abrajevitch et al., 2014; Billups and Schrag, 2002). Our examination appears to confirm the impression of relatively good preservation of middle Miocene *Cibicidoides* at Site 747 (see Figs. S1 and S2). Similar to other studies (e.g., Billups and Schrag, 2002; Gottschalk et al., 2016; Yu and Elderfield, 2008), *C. mundulus* and *C. wuellerstorfi* are grouped into a single genus. We note that some of the analysed specimens of *C. mundulus* and *C. wuellerstorfi* closely resemble the *sensu lato* morphotype of the respective species (shown in Fig. 2 of Gottschalk et al., 2016).

Prior to isotope analysis, we cracked the picked specimens and ultrasonicated the test fragments in deionized water (3×30 seconds) and methanol (1×10–30 seconds) to remove adhering sediment. Test fragments were rinsed once between each ultrasonication step and at least three times at the end of the cleaning. The cleaned test fragments were subsequently oven-dried at 50°C.

### 2.3 Stable isotope measurements and data processing

Low abundances of carbonate ions containing both <sup>13</sup>C and <sup>18</sup>O isotopes require stringent analytical procedures and comparably large sample sizes to obtain clumped isotope temperatures that are precise enough for Cenozoic ocean temperature reconstructions. We achieve the necessary precision by averaging over ~30–40 clumped isotope values measured on small (~100 µg) carbonate samples (Fernandez et al., 2017; Hu et al., 2014; Meckler et al., 2014; Schmid and Bernasconi, 2010). Results from adjacent samples are pooled to achieve this number of measurements (e.g., Grauel et al., 2013; Rodríguez-Sanz et al., 2017), due to the generally low abundance of mono-specific benthic foraminifera (allowing for only 1–5 individual measurements per sample, Fig. S3b). Producing a low-resolution clumped isotope temperature record with this approach yields higher-resolution δ<sup>18</sup>O and δ<sup>13</sup>C time series in parallel.

Clumped isotope measurements were performed using two Thermo Scientific MAT 253 Plus mass spectrometers at the University of Bergen, Norway, and one Thermo Scientific MAT 253 mass spectrometer at ETH Zurich, Switzerland. All mass spectrometers were coupled to Thermo Fisher Scientific Kiel IV carbonate preparation devices. CO<sub>2</sub> gas was extracted from a carbonate sample with phosphoric acid at a reaction temperature of 70°C, as reported in Schmid et al. (2012). A Porapak trap included in each Kiel IV carbonate preparation system was kept at -20°C to remove organic contaminants from the sample gas (Schmid et al., 2012). Between each run, the Porapak trap was baked out at 120°C for at least one hour for cleaning. Every measurement run included a similar number of samples and carbonate standards. Four carbonate standards (ETH-1, ETH-2, ETH-3 and ETH-4) with different isotopic compositions and ordering states were used for monitoring and correction of the results (see Appendix A for details). External reproducibilities (one standard deviation) in corrected Δ<sub>47</sub> values of ETH-1, ETH-2, ETH-3 and ETH-4 were typically between 0.030 ‰ and 0.040 ‰ (Table S2). External reproducibilities (one standard deviation) for δ<sup>18</sup>O and δ<sup>13</sup>C values of the same standards (given relative to VPDB) were 0.03–0.10 ‰ and 0.02–0.06 ‰, respectively.

We converted the sample Δ<sub>47</sub> values (averages over ~30–40 separate measurements each) into temperature using a calibration based on various recent datasets from core top-derived foraminifera, corrected with the same carbonate standards as used in our study (Eq. (2) of Meinicke et al. (2020)):

$$T (^{\circ}\text{C}) = \sqrt{\frac{0.0431 \times 10^6}{\Delta_{47} - 0.1876}} - 273.15 \quad (1)$$

140 This combined calibration has been recommended for foraminifer samples (Meinicke et al., 2020). We note that the individual datasets in this compilation (Meinicke et al., 2020; Peral et al., 2018; Piasecki et al., 2019) are all in good agreement with a travertine-based calibration (Kele et al. (2015), recalculated by Bernasconi et al. (2018)) spanning a wider temperature range (6–95°C). For consistency, previously published  $\Delta_{47}$ -based ocean temperatures from ODP Sites 761 (Modestou et al., 2020) and 1171 (Leutert et al., 2020) originally based on the travertine calibration were recalculated with  
145 the calibration equation of Meinicke et al. (2020). We propagated analytical and calibration uncertainties in  $\Delta_{47}$ -based temperatures (as described in the supporting information of Huntington et al. (2009)), and report combined uncertainties as 68 % and 95 % confidence intervals.  $\Delta_{47}$ -based temperatures were used in combination with benthic foraminiferal  $\delta^{18}\text{O}$  values to calculate  $\delta^{18}\text{O}_{\text{bw}}$  (reported relative to VSMOW) with Eq. (9) of Marchitto et al. (2014).

## 2.4 Age models

150 We revised the Hole 747A age model by integrating six magnetostratigraphic tie points (Abrajevitch et al., 2014; Majewski and Bohaty, 2010) on the GTS2012 timescale (Gradstein et al., 2012), three benthic foraminiferal  $\delta^{13}\text{C}$ -based tie points associated with the “Monterey” carbon-isotope excursion (using the nomenclature of Holbourn et al. (2007)), and one peak warm event visible in benthic foraminiferal  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  (Kochhann et al., 2016) (Table S1). For the  $\delta^{13}\text{C}$ -based tie points, we used the high-resolution isotope stratigraphies of IODP Sites U1335, U1337 and U1338 in the eastern equatorial Pacific  
155 Ocean (Holbourn et al., 2014; Kochhann et al., 2016) as reference (Fig. 2c). In addition, we included a hiatus at the core break between Cores 7H and 8H, identified by previous studies (e.g., Majewski and Bohaty, 2010).  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  time series of Sites 747, 761, 806, U1335, U1337 and U1338 are shown in Fig. 2 with isotope-based age tie points for Site 747 as black crosses. The age model for Site 761 is from Leutert et al. (2020). For Site 806, we utilized a previously published orbitally tuned age model from ~14.1 Ma to ~13.3 Ma (Holbourn et al., 2013); ages for the older and younger parts of the Site 806  
160 record (~16.4–14.1 Ma and ~13.3–12.3 Ma) were derived by assuming the same mean sedimentation rate as between ~14.1 Ma and ~13.3 Ma.

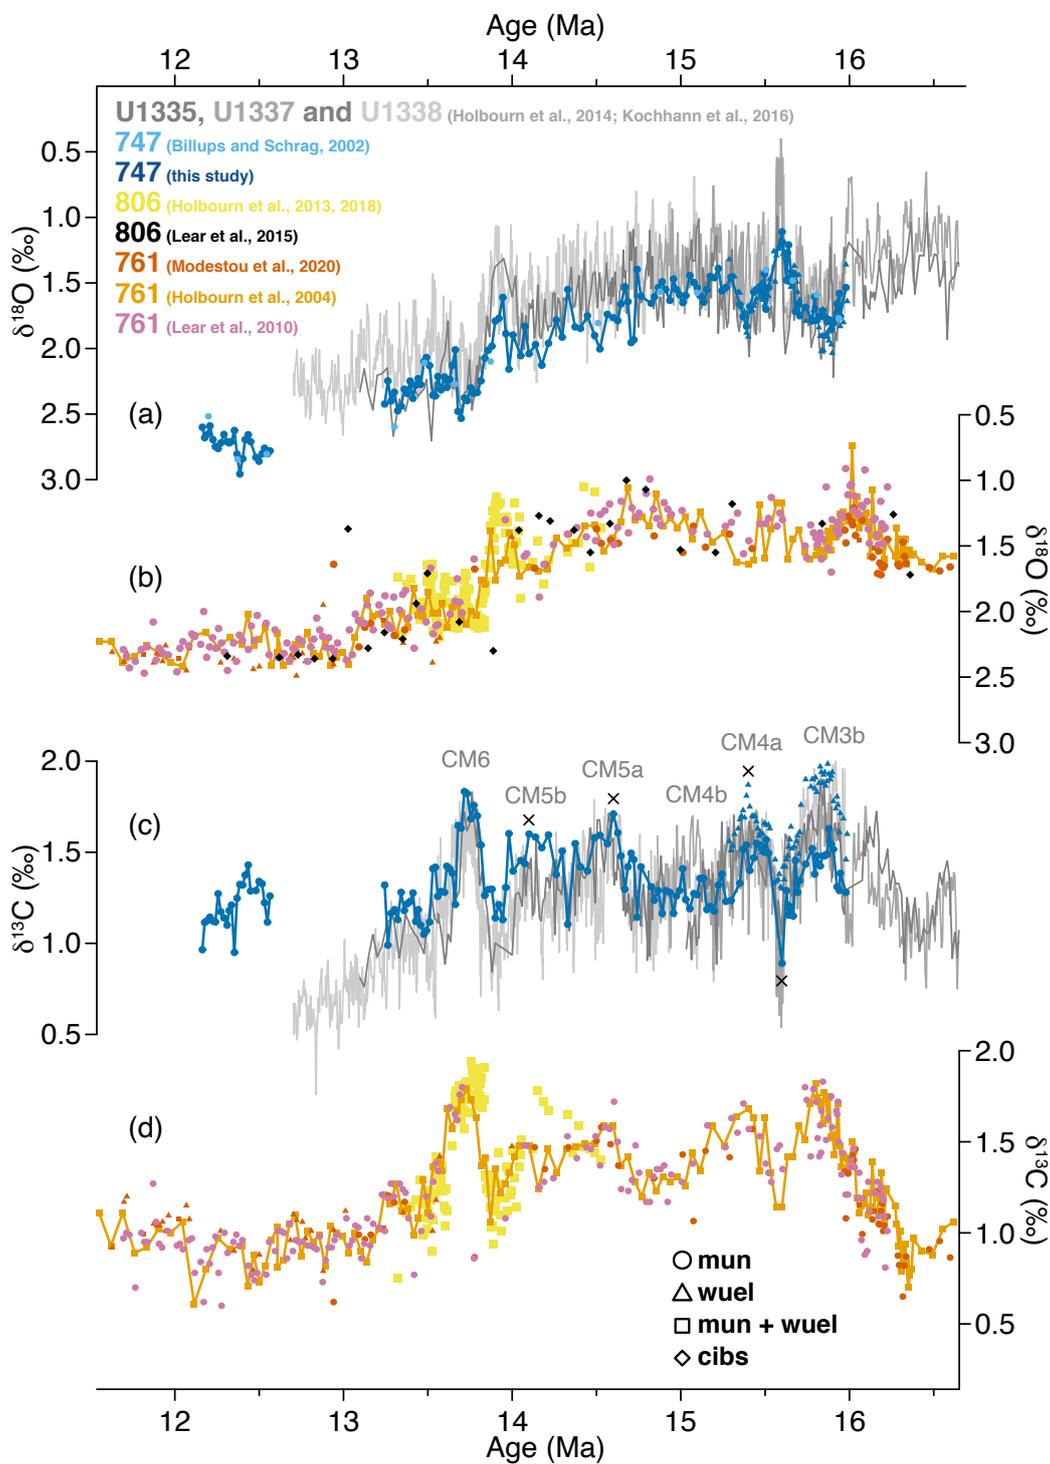

## 3 Results and discussion

### 3.1 Benthic foraminiferal $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values

The isotope record of Site 747 (Fig. 2) displays features typical of middle Miocene sequences, including the stepped increase  
165 in benthic  $\delta^{18}\text{O}$  across the MMCT and the pronounced  $\delta^{13}\text{C}$  maxima associated with the “Monterey” carbon isotope excursion (e.g., Holbourn et al., 2007, 2014; Kochhann et al., 2016; Vincent and Berger, 1985). From ~16.0 Ma to ~15.3 Ma, we analysed stable isotope compositions of both *C. mundulus* and *C. wuellerstorfi*, allowing for a direct assessment of species-specific effects on the isotopic compositions of these two different epifaunal species (Fig. 2a and c).  $\delta^{18}\text{O}$  values

170 measured on *C. mundulus* and *C. wuellerstorfi* appear indistinguishable, whereas a consistent offset of up to  $\sim 0.5$  ‰ exists between the  $\delta^{13}\text{C}$  values of these species at Site 747. Similar  $\delta^{13}\text{C}$  offsets between *C. mundulus* and *C. wuellerstorfi* have been previously observed for the sub-Antarctic Atlantic during the Quaternary (Gottschalk et al., 2016). Our  $\delta^{13}\text{C}$  values from the middle Miocene underscore the need to carefully examine inter-species offsets in  $\delta^{13}\text{C}$  before combining different species to produce a single  $\delta^{13}\text{C}$  curve.

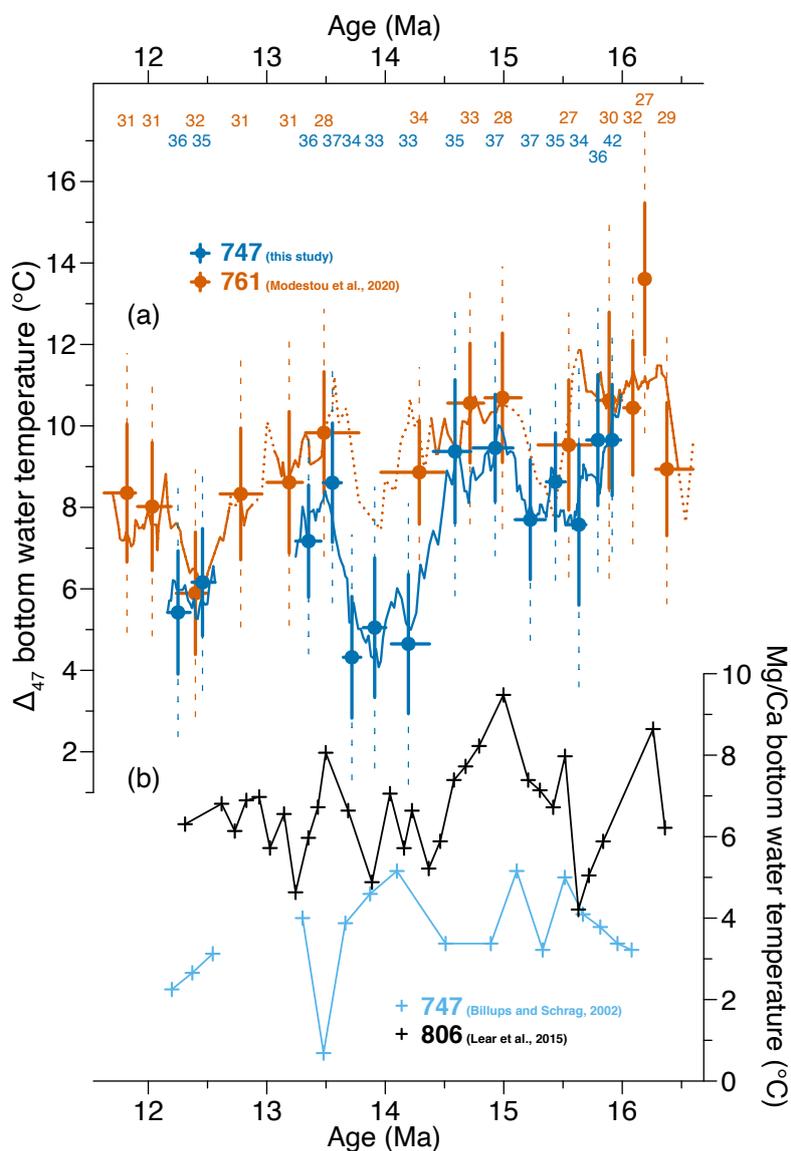

175 **Fig. 2:** Comparison of benthic isotope data. Benthic foraminiferal  $\delta^{18}\text{O}$  (a, b) and  $\delta^{13}\text{C}$  (c, d) records are shown from ODP Site 747 in the  
Southern Ocean (Billups and Schrag, 2002; this study), ODP Site 761 in the eastern Indian Ocean (Holbourn et al., 2004; Lear et al., 2010;  
Modestou et al., 2020), ODP Site 806 in the western equatorial Pacific (Holbourn et al., 2013, 2018; Lear et al., 2015) as well as IODP  
Sites U1335, U1337 and U1338 in the eastern equatorial Pacific Ocean (Holbourn et al., 2014; Kochhann et al., 2016). Correlation tie  
points for Site 747 (this study) are visualized with black crosses. We only plot  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values from Sites 747 and 761 that were  
180 measured on the species *C. mundulus* (mun) and *C. wuellerstorfi* (wuel). In contrast to Site 747, offsets in both  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  between  
these species appear minimal at Site 761 (Holbourn et al., 2004). We note that we also use  $\Delta_{47}$  values from other benthic foraminiferal  
species from Site 761 (see Modestou et al. (2020) for details), as no species-specific vital effects on benthic foraminiferal  $\Delta_{47}$  have been  
observed (Modestou et al., 2020; Piasecki et al., 2019). For Site 806, we show  $\delta^{18}\text{O}$  values of *Cibicidoides* spp. (cibs) (Lear et al., 2015), in  
addition to  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  measured specifically on tests of *C. mundulus* and *C. wuellerstorfi* (Holbourn et al., 2013, 2018).  $\delta^{18}\text{O}$ ,  $\delta^{13}\text{C}$  and  
185  $\Delta_{47}$  at Sites 747 and 761 were measured several times per sample in this study and Modestou et al. (2020). See Fig. S3 for  $\Delta_{47}$  values and  
number of replicate measurements for each sediment sample.

### 3.2 Revised estimates of bottom water temperature for the middle Miocene

As expected, the  $\Delta_{47}$  signal (Fig. S3a) is much noisier in comparison to  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  (Fig. 2), necessitating an averaging of  
190  $\Delta_{47}$  over many adjacent samples before interpreting the data in terms of calcification temperature. We have visualized our  
 $\Delta_{47}$ -based BWT values for interpretation (Fig. 3a) using two different approaches: (1) To obtain the necessary precision, we  
averaged results from around 30–40 individual measurements from neighbouring samples, avoiding averaging across  
hiatuses and intervals with no measurements. These BWT averages are shown as filled circles, with horizontal lines  
indicating the averaging intervals and vertical lines indicating 68 % (solid) and 95 % (dashed) confidence intervals. The  
195 number of measurements used for the calculation of each mean temperature value is listed at the top of Fig. 3. (2) 400 kyr-  
moving averages based on 30 or more measurements are shown as solid lines, whereas those based on fewer measurements  
are dotted. The latter approach does not require a decision on each averaging interval, and thus may be better suited for inter-  
site comparison. We note that small-scale features in the moving average curves are likely caused by the scatter in the  
underlying individual  $\Delta_{47}$  measurements, and should not be interpreted as real climate signals.

200 Independent of the averaging approach,  $\Delta_{47}$ -based BWTs at Site 747 are highest ( $\sim 8$ – $10^\circ\text{C}$ ) from around 16.0 Ma to 14.5 Ma  
during the Miocene climatic optimum (MCO), and decrease thereafter by  $\sim 3$ – $5^\circ\text{C}$  (Fig. 3a). A transient warming (by  $\sim 2$ –  
 $4^\circ\text{C}$ ) starting between 13.5 Ma and 14 Ma is followed by a return to colder conditions from  $\sim 12.6$  Ma to  $\sim 12.2$  Ma. A hiatus  
prevents us from drawing any inferences about bottom water conditions from  $\sim 13.2$  Ma to  $\sim 12.6$  Ma.

205 **Fig. 3:** Middle Miocene bottom water temperatures based on benthic foraminiferal  $\Delta_{47}$  and Mg/Ca from ODP Sites 747, 761 and 806.  
 (a)  $\Delta_{47}$ -based temperatures based on averages of  $>30$   $\Delta_{47}$  measurements each are shown as filled circles (horizontal solid lines: averaging  
 intervals, vertical solid lines: 68 % confidence intervals, vertical dashed lines: 95 % confidence intervals). The number of measurements  
 used for each average is shown at the top of the plot. The position on the x-axis shows the average age of each temperature value. 400 kyr-  
 moving averages based on at least 30 and fewer than 30 measurements are shown as solid and dotted lines, respectively. Note that rapid  
 210 fluctuations (of around 1°C) in these moving averages should not be interpreted in terms of climate (see Results and Discussion).  
 (b) Mg/Ca temperatures from Site 747 are as published previously (Billups and Schrag, 2002). For Site 806, temperatures were calculated  
 from infaunal foraminiferal Mg/Ca (Lear et al., 2015) using seawater Mg/Ca (polynomial curve fit through compiled seawater Mg/Ca  
 records) and the favored linear temperature calibration of Lear et al. (2015).

215 Comparison of our  $\Delta_{47}$ -based BWTs from Site 747 with  $\Delta_{47}$ -based BWTs from Site 761 off northwest Australia in the Indian  
Ocean (Modestou et al., 2020) reveals good agreement, where temperatures are based on at least 30  $\Delta_{47}$  measurements (solid  
lines of the moving averages), with the Site 747 BWTs being slightly lower. Temperature averages from <30 measurements  
(dotted lines) are less certain, and thus not focus of our interpretation here (see Methods). Note that we processed the  $\Delta_{47}$   
measurement values from Site 761 (Modestou et al., 2020) in the same way as our results from Site 747 (e.g., temperature  
220 calibration, smoothing) to optimize comparability of BWTs from these two middle Miocene reference sites. Similar absolute  
BWTs at Sites 747 and 761 during the Miocene may be expected from their similar present-day temperature ranges ( $\sim 1\text{--}2^\circ\text{C}$ ;  
Fig. 1). Our study confirms the similarity of BWTs at these sites for large parts of the studied interval, suggesting a close to  
modern meridional temperature gradient around 2000 m water depth in a scenario of substantially ( $\sim 3\text{--}9^\circ\text{C}$ ) warmer bottom  
waters. Unfortunately, the period of most pronounced BWT change at Site 747 is characterized by very low data density at  
225 Site 761, due to low benthic foraminiferal abundances resulting in few measurements, and possibly a hiatus (core break  
between Cores 5H and 6H from Site 761 around 14.1 Ma). This leaves open the question whether the substantial cooling  
around 14.5–14.0 Ma and the subsequent warming were restricted to particular regions in the Southern Ocean, or whether  
they were more widespread features.

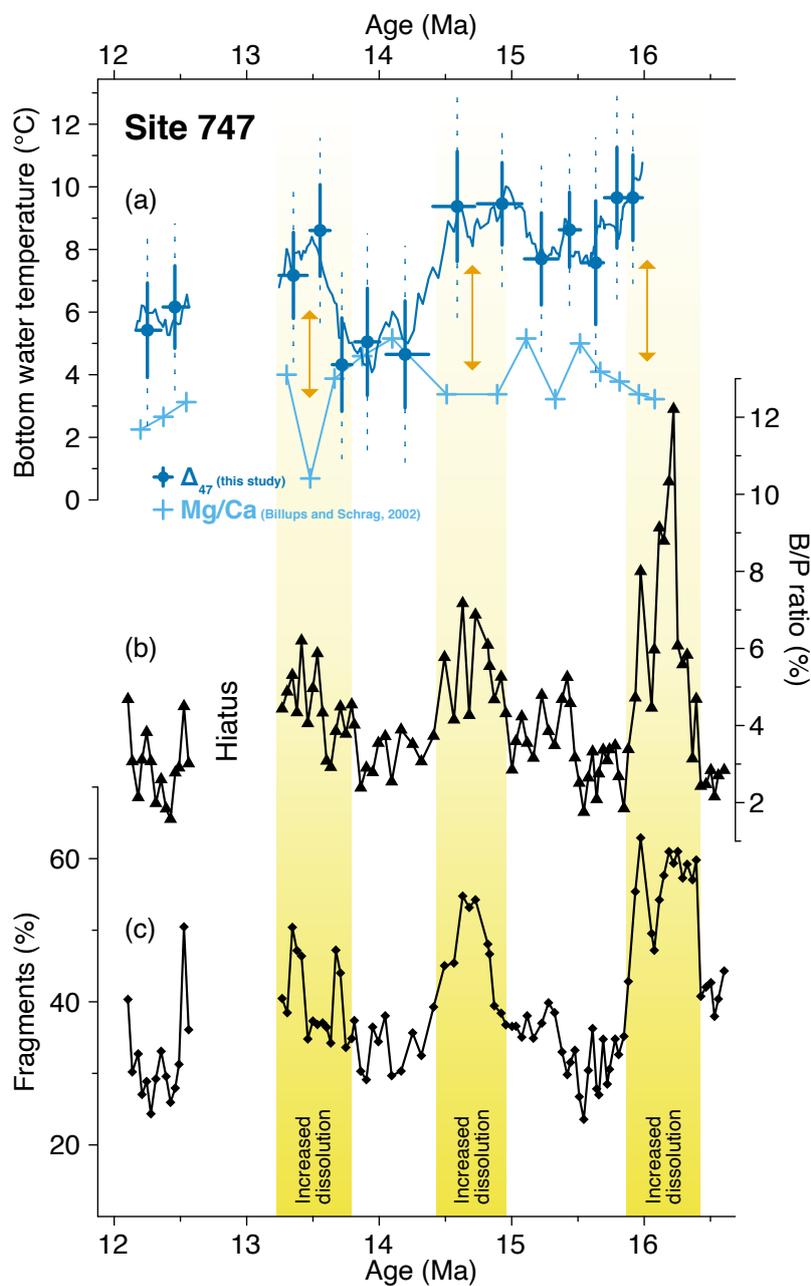

Interestingly, a Mg/Ca record of the infaunal benthic foraminifer *O. umbonatus* from ODP Site 806 in the equatorial Pacific  
230 (Lear et al., 2015) indicates BWT trends that are similar to those reconstructed from  $\Delta_{47}$  at Site 747 during the MMCT  
(Fig. 3). Even though the Site 806 Mg/Ca record is of limited temporal resolution ( $\sim 100\text{--}200$  kyr), this low latitude record  
provides evidence that the early cooling and the subsequent warming reconstructed at Site 747 could have indeed been of  
global significance.

Other available Mg/Ca-based BWT records covering the MMCT do not show the same features. Similar to Site 806, Mg/Ca  
235 ratios were also measured on the infaunal species *O. umbonatus* at Site 761 (Lear et al., 2010). This approach yields BWTs  
that are within uncertainty of those from  $\Delta_{47}$  measured at the same site (Fig. S4), regardless of whether or not the Mg/Ca-  
based BWTs have been corrected for changes in saturation state (Modestou et al., 2020). However, Mg/Ca-based BWT  
estimates from that site have been deemed less reliable than those from Site 806, due to unusual and variable pore water  
chemistry at Site 761 (Lear et al., 2015), and are compromised by reduced data density in crucial intervals (as noted above).  
240 In comparison to Sites 761 and 806 where an infaunal foraminiferal species has been used (Lear et al., 2010, 2015), Mg/Ca  
records from Southern Ocean Sites 747 (Kerguelen Plateau) and 1171 (South Tasman Rise) were measured on the epifaunal  
species *C. mundulus* (Billups and Schrag, 2002; Shevenell et al., 2008). These Mg/Ca-based BWT records also do not show  
the same temperature pattern as our  $\Delta_{47}$ -derived BWT record from Site 747 or the Mg/Ca-derived BWT record from Site 806  
(Fig. S4). The observed discrepancies suggest additional non-thermal controls on Mg/Ca and/or  $\Delta_{47}$ , which may be related to  
245 seawater chemistry during test precipitation and/or post-depositional alteration, such as dissolution.

Seawater chemistry does not appear to significantly influence  $\Delta_{47}$  signatures in foraminifera over the range of natural variation (e.g., Tripathi et al., 2015; Watkins and Hunt, 2015), whereas Mg/Ca signatures can be affected by changes in seawater Mg/Ca (Evans and Müller, 2012) and carbonate ion saturation (Elderfield et al., 2006; Yu and Elderfield, 2008). On the timescales considered here, the latter is more likely to be important. The relatively few Mg/Ca-based BWTs from Site 747 can be directly compared to our BWTs based on  $\Delta_{47}$  from the same site (Fig 4a).  $\Delta_{47}$ - and Mg/Ca-based BWTs appear to diverge most pronouncedly in times of increased dissolution (high percentage of benthic foraminiferal tests and fragments) at Site 747, indicating fluctuations in bottom water carbonate ion saturation (Diester-Haass et al. (2013); Fig. 4b and c). Mg/Ca-based temperatures from Site 747 were measured on foraminiferal tests of the epifaunal species *C. mundulus*; compared to infaunal foraminifera, this species lives in more direct contact with bottom water, and may thus be more prone to saturation state-related effects (Elderfield et al., 2006; Lear et al., 2015). The observation of diverging Mg/Ca- and  $\Delta_{47}$ -based BWTs in times of increased dissolution supports the interpretation of a possible saturation state effect on the Mg/Ca signatures of *C. mundulus* (see Fig. S5 for sensitivity study). For Site 1171, we do not have constraints on saturation state variability.

In addition to saturation state effects, variable dissolution itself (Fig. 4b and c) could have influenced foraminiferal Mg/Ca and/or  $\Delta_{47}$  signatures. For planktic foraminifera, dissolution controlled by bottom water saturation has the potential to significantly lower initial Mg/Ca signatures and thus also the estimated ocean temperatures in certain burial settings (e.g., Regenberg et al., 2014). Dissolution may also impact the Mg/Ca signatures of benthic foraminiferal tests, although the tests of benthic foraminifera appear generally denser and more resistant to dissolution than those of planktic foraminifera (e.g., Berger, 1973; Pearson et al., 2001). The effects of dissolution on benthic foraminiferal Mg/Ca have thus received little attention. Similarly, dissolution effects on benthic foraminiferal  $\Delta_{47}$  signatures have not yet been specifically assessed. While there is currently no evidence for a significant dissolution effect on foraminiferal  $\Delta_{47}$  (e.g., Breitenbach et al., 2018; Leutert et al., 2019) or variable dissolution of benthic foraminiferal calcite at Site 747 during the interval of this study (Fig. S2), a potential effect of dissolution cannot be fully ruled out. We interpret  $\Delta_{47}$ -based temperatures as unaffected by dissolution in the absence of indications otherwise, but note that this aspect warrants further study.

270

**Fig. 4:** Bottom water temperature and dissolution at Site 747. (a)  $\Delta_{47}$ - and Mg/Ca-based BWT estimates (this study; Billups and Schrag, 2002) are shown versus (b) percent benthic to planktic (B/P) foraminiferal test ratios (Diester-Haass et al., 2013) and (c) percent fragments in a sample (Diester-Haass et al., 2013). Percent fragments and B/P foraminiferal test ratios have been previously used to monitor dissolution at Site 747 (Diester-Haass et al., 2013). Intervals interpreted as affected by increased dissolution of planktic foraminifera are highlighted with yellow bars. Orange arrows indicate intervals where  $\Delta_{47}$ - and Mg/Ca-based temperature estimates appear to diverge most.

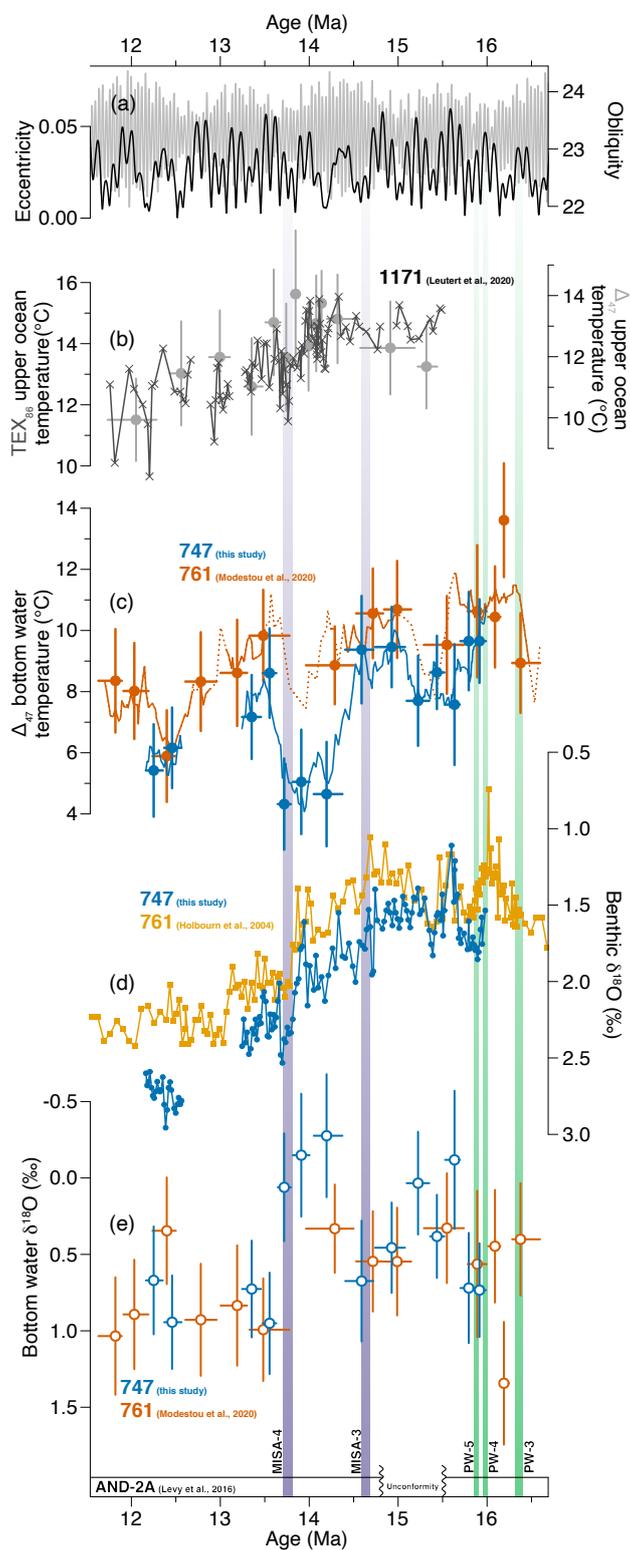

275

### 3.3 Regional and global implications

$\delta^{18}\text{O}_{\text{bw}}$  signatures have been widely used to infer the evolution of global ice volume during the Neogene (e.g., Billups and Schrag, 2002; Lear et al., 2010, 2015; Modestou et al., 2020; Shevenell et al., 2008). We calculated  $\delta^{18}\text{O}_{\text{bw}}$  values from measured benthic foraminiferal  $\delta^{18}\text{O}$  in combination with  $\Delta_{47}$ -based BWTs (Fig. 5e). Benthic foraminiferal  $\delta^{18}\text{O}$  values of the taxon *Cibicidoides* were averaged over the same intervals as have been used for  $\Delta_{47}$  averaging. For Site 747, we used the  $\delta^{18}\text{O}$  values from this study (measured on *C. mundulus* and *C. wuellerstorfi*), whereas the foraminiferal  $\delta^{18}\text{O}$  values for Site 761 were compiled from existing studies (Holbourn et al., 2004; Lear et al., 2010; Modestou et al., 2020). Due to comparably large random errors in our  $\Delta_{47}$ -based BWT estimates, the propagated uncertainties in  $\delta^{18}\text{O}_{\text{bw}}$  are also large. However, systematic biases in our  $\delta^{18}\text{O}_{\text{bw}}$  estimates may be smaller compared to other methods (e.g., paired benthic foraminiferal Mg/Ca and  $\delta^{18}\text{O}$  measurements) because  $\Delta_{47}$  signatures seem to be largely independent of complicating environmental parameters and/or foraminiferal vital effects (e.g., Leutert et al., 2019; Peral et al., 2018; Piasecki et al., 2019; Tripathi et al., 2015; Watkins and Hunt, 2015). The earliest interval of this study ( $>15.6$  Ma) is characterized by  $\delta^{18}\text{O}_{\text{bw}}$  values ranging from approximately  $-0.1$  ‰ to  $1.3$  ‰. For the later MCO (15.6–13.9 Ma), our estimates of  $\delta^{18}\text{O}_{\text{bw}}$  range from around  $-0.3$  ‰ to  $0.7$  ‰, and increase to  $\sim 0.3$ – $1.0$  ‰ after the MMCT. All reconstructed  $\delta^{18}\text{O}_{\text{bw}}$  values are consistently higher than expected for minimal ice (i.e.  $-0.89$  ‰ according to Cramer et al. (2011)). Therefore, our results suggest the presence of substantial ice sheets on Antarctica throughout the warm MCO, similar to previous estimates of middle Miocene  $\delta^{18}\text{O}_{\text{bw}}$  (e.g., Modestou et al., 2020). This interpretation is robust towards utilizing different suggested  $\delta^{18}\text{O}$ -temperature relationships (Fig. S6). However, we cannot exclude the presence of short-lived (orbital-scale) minima in global ice volume during peak MCO interglacials (e.g., Levy et al., 2016), which may not be visible in the  $\Delta_{47}$ -based records due to their temporal resolution.

Our Southern Ocean bottom water proxy record can be compared to evidence of past ice sheet variability from the Antarctic margin, in addition to orbital parameters. The stepped main increase in benthic  $\delta^{18}\text{O}$  starting between 13.8 Ma and 14.0 Ma (Fig. 5d) is associated with growing ice sheets (increasing  $\delta^{18}\text{O}_{\text{bw}}$ , Fig. 5e) and occurs in an interval of low seasonal contrast over Antarctica (declining eccentricity, decreasing amplitude variations in obliquity, Fig. 5a), as pointed out by Holbourn et al. (2005). The inferred ice volume increase recorded at Site 747 is supported by evidence for an episode of maximum ice sheet advance (MISA-4) recorded in the ANDRILL (AND)-2A drill core from the western Ross Sea, Antarctica (Levy et al., 2016). Similarly, an earlier period of maximum ice sheet advance documented in the Ross Sea around 14.7–14.6 Ma (MISA-3) corresponds to a maximum in  $\delta^{18}\text{O}_{\text{bw}}$  at Site 747 (suggesting larger global ice volume). The early MCO is characterized by several intervals of peak warmth at the ANDRILL Site (PW-3 to PW-5) (Levy et al., 2016). Unfortunately, this interval is not sufficiently covered by our Site 747 record to draw any conclusions; further proxy records are required to clarify the impact of Antarctic warming during the PW episodes on Southern Ocean bottom waters and at larger scales.

**Fig. 5:** Compilation of records for the MMCT. (a) Obliquity and eccentricity, (b)  $\Delta_{47}$ - and  $\text{TEX}_{86}$ -based upper ocean temperatures from ODP Site 1171 on the South Tasman Rise are shown with (c)  $\Delta_{47}$ -based bottom water temperatures (BWTs), (d) benthic foraminiferal  $\delta^{18}\text{O}$  and (e) bottom water  $\delta^{18}\text{O}$  ( $\delta^{18}\text{O}_{\text{bw}}$ ) from ODP Sites 747 and 761. In addition, we highlight distinct episodes of maximum ice sheet advance (MISA-3 and MISA-4, purple bars) and peak warmth (PW-3 to PW-5, green bars) around Antarctica derived from the ANDRILL (AND)-2A drill core (western Ross Sea; Levy et al., 2016).  $\Delta_{47}$ -based BWTs (Modestou et al., 2020; this study) and upper ocean temperatures (Leutert et al., 2020) are shown with 68 % confidence intervals.  $\text{TEX}_{86}$ -based temperatures (Leutert et al., 2020) are based on the subsurface calibration of Ho and Laepple (2016). Site 761 benthic  $\delta^{18}\text{O}$  values are from Holbourn et al. (2004). Eccentricity and obliquity are from Laskar et al. (2004).

Our observations suggest a decoupling between global ice volume and BWT in the Southern Ocean (Fig. 5c–e). Significantly, the stepped increase in benthic foraminiferal  $\delta^{18}\text{O}$  (and  $\delta^{18}\text{O}_{\text{bw}}$ ) around 14.0–13.7 Ma ( $\sim 0.5$ – $1.0$  ‰, interpreted as cryosphere expansion) occurs clearly (roughly 0.5 Myr) later than the BWT drop. A similar decoupling of global ice volume and BWT was discussed based on the Mg/Ca record of Site 806 (Lear et al., 2015), and suggested to be related to feedbacks and thresholds controlling Antarctic ice growth. It is possible that the bottom water temperature signal at Site 747 reflects changes in Southern Ocean hydrography, which might also have been transferred to the deep Pacific. Majewski and Bohaty (2010) measured  $\delta^{18}\text{O}$  on middle Miocene benthic (*Cibicidoides* spp.) and planktic foraminifera (e.g., *Globigerina bulloides*) at Site 747 across the MMCT. These authors documented a marked increase in calculated  $\delta^{18}\text{O}$  differences between *Cibicidoides* spp. and *G. bulloides* (vertical  $\delta^{18}\text{O}$  gradient) during the main increase in  $\delta^{18}\text{O}$ . While we cannot presently compare our Site 747 BWTs to upper ocean temperatures from the same site due to the lack of planktic foraminiferal  $\Delta_{47}$  data, we compare our BWT record to  $\Delta_{47}$ - and  $\text{TEX}_{86}$ -based upper ocean temperature records from Site 1171 located on the South Tasman Rise at slightly lower latitudes (Fig. 5b and c; Leutert et al. (2020)). Acknowledging the caveat of substantial geographical distance between these sites, we find no evidence for a strengthening in the vertical temperature gradient at high southern latitudes at that time. To the contrary, the bottom water warming starting during or slightly after the stepped increase in global ice volume diminishes the temperature gradient. Therefore, we relate the observed increase in the vertical  $\delta^{18}\text{O}$  gradient at Site 747 primarily to a freshening of the upper ocean water column relative to bottom waters associated with Antarctic ice sheet expansion, in line with the interpretation of Majewski and Bohaty (2010). An upper ocean freshening across the MMCT was also reconstructed at Site 1171 (Leutert et al., 2020). At high southern latitudes, salinity has a large effect on stratification (e.g., Kuhnert et al., 2009). Similar to Leutert et al. (2020), we hypothesize that a Southern Ocean freshening concurrent with Antarctic ice sheet expansion may have decreased convective vertical mixing resulting in a shielding of upper ocean waters from comparably warm deeper waters. This stratification mechanism may have influenced Southern Ocean BWTs during the MMCT, explaining the transient bottom water warming and the partially opposing trends of upper ocean temperature and BWT. An increase in stratification starting between 13.5 Ma and 14 Ma is supported by an increase in dissolution at that time (Figs. 4 and S5), which may be related to reduced ventilation and an increase in  $\text{CO}_2$  storage in the deep ocean.

#### 4 Conclusions

We constrain the middle Miocene BWT evolution at Site 747 in the Southern Ocean with clumped isotope thermometry. Similar to existing BWT reconstructions from lower latitude sites, we find that Southern Ocean BWTs were substantially warmer than today, despite the presence of ice sheets on Antarctica. The observed discrepancies between  $\Delta_{47}$ - and Mg/Ca-based BWTs may be caused by changes in deep water carbonate ion saturation, but further Mg/Ca and  $\Delta_{47}$  measurements are needed to conclusively test this hypothesis. We cannot fully rule out a dissolution effect on benthic foraminiferal  $\Delta_{47}$ , although there is currently no evidence for such an effect. Taken at face value, our  $\Delta_{47}$  values indicate pronounced shifts in Southern Ocean BWTs, which resemble observations at equatorial Pacific Site 806, and a long-term decrease of  $\sim 3\text{--}5^\circ\text{C}$  across the MMCT. Comparison of changes in BWT and  $\delta^{18}\text{O}_{\text{bw}}$  indicates a significant degree of decoupling and a more complicated sequence of events surrounding the MMCT than previously appreciated based on benthic  $\delta^{18}\text{O}$  alone. These findings suggest the involvement of additional feedbacks and thresholds in middle Miocene ice growth and/or regional effects on middle Miocene BWTs at Site 747. We hypothesize that a possible factor could be shifts in the vertical density structure of the Southern Ocean. Reconstructed BWTs may in part reflect changes in heat transport between upper and deep ocean, induced by growing ice sheets on Antarctica. Independent higher-resolution BWT records from additional locations in and outside the Southern Ocean would allow for examining the spatial scale of the changes observed at Site 747 as a basis for better understanding the drivers of the MMCT.

#### Appendix A: Clumped isotope methodological details

Clumped isotope data are presented in the conventional  $\Delta_{47}$  notation, which is defined as follows (e.g., Eiler, 2007; Huntington et al., 2009):

$$\Delta_{47} (\text{‰}) = \left[ \left( \frac{R^{47}}{R^{47*}} - 1 \right) - \left( \frac{R^{46}}{R^{46*}} - 1 \right) - \left( \frac{R^{45}}{R^{45*}} - 1 \right) \right] \times 1000 \quad (\text{A1})$$

$R^i$  are the measured abundance ratios of mass  $i$  relative to mass 44.  $R^{i*}$  represent the stochastic abundance ratios calculated from the bulk isotope composition of the sample ( $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$ ).

All (clumped) isotope measurements were carried out in micro-volume mode. At the University of Bergen (UiB), we followed the long-integration dual-inlet (LIDI) protocol (Hu et al., 2014; Müller et al., 2017), whereas the measurements at ETH Zurich were performed via repeated cycles of alternating reference and sample gas measurements (Meckler et al., 2014; Rodríguez-Sanz et al., 2017). For data processing, we used the community software “Easotope” (John and Bowen, 2016). The different steps for calculating the final  $\Delta_{47}$  values include a pressure-sensitive baseline correction (Bernasconi et al.,

2013; He et al., 2012; Meckler et al., 2014) and a conversion into the absolute reference frame (Dennis et al., 2011). For the conversion into the absolute reference frame, we utilized replicate measurements of three (UiB) respectively four (ETH Zurich) different correction standards from a window of  $\pm 12$ –40 standards around the sample replicate. At UiB, we used the carbonate standards ETH-1, ETH-3 and ETH-4 for correction from October 2016 to December 2016; ETH-2 was used for monitoring during this interval. From August 2018 to June 2019, ETH-1, ETH-2 and ETH-3 were used for correction and ETH-4 for monitoring. For the measurements carried out at ETH Zurich, ETH-1, ETH-2, ETH-3 and ETH-4 were all included in the correction procedure. The accepted ETH standard values are from Bernasconi et al. (2018). These ETH standard values were determined using an acid fractionation correction of +0.062 ‰ (Defliese et al., 2015). Measured  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values were drift-corrected based on three (UiB) respectively four (ETH Zurich) different correction standards (with scale “stretching” only applied for  $\delta^{18}\text{O}$  at UiB and for both  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  at ETH). All isotope data were calculated with the Brand correction parameters (Daëron et al., 2016). Further details on analytical and data processing methods can be found elsewhere (Leutert et al., 2019; Piasecki et al., 2019).

We excluded three clumped isotope measurements as outliers, based on their offset of more than four standard deviations ( $4 \times 0.037$  ‰, estimated from the long-term mean reproducibility of all standards) from the mean. Raw standard and sample measurement data are included in the supplement and will be available on EarthChem at the time of publication.

### Data availability

The data from this paper are archived in the supplement. In addition, the final temperature data will be published at Pangaea (<https://doi.pangaea.de/10.1594/PANGAEA.923258>) and the full raw data on the EarthChem Database (a link to the EarthChem dataset will be provided prior to publication).

### Author contribution

T.J.L. and A.N.M. initiated and designed the study. T.J.L. generated and analysed clumped isotope data under the oversight of A.N.M., S.M. and S.M.B. All the authors contributed to the palaeoceanographic interpretation. T.J.L. wrote the paper with contributions from A.N.M., S.M. and S.M.B.

### Competing interests

The authors declare that they have no conflict of interest.

## Acknowledgements

We thank Enver Alagoz and Inigo Müller for analytical support, Janika Jöhnck for insightful discussions and all authors who shared their published data. This research used data and samples provided by the Ocean Drilling Program (ODP) and the  
400 International Ocean Discovery Program (IODP), sponsored by the US National Science Foundation (NSF) and participating countries. Funding for the research was provided by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 638467) and by the Trond Mohn Foundation.
