**Abstract.** During the early last glacial termination (17.2-15 ka) atmospheric  $\delta^{13}\text{C}$  declined sharply by 0.3-0.4‰ as atmospheric  $\text{pCO}_2$  rose. This was the initial part of the atmospheric  $\delta^{13}\text{C}$  excursion that lasted for multiple thousand years. A similar  $\delta^{13}\text{C}$  decline has been documented in marine proxy records from both surface and thermocline-dwelling planktic foraminifera. The  
15 foraminiferal  $\delta^{13}\text{C}$  decline has previously been attributed to a flux of respired carbon from the deep ocean that was subsequently transported within the upper ocean (i.e. ‘bottom up’ transport) to sites where the signal is recorded. Here, we provide modeling evidence that when respired carbon upwells in the Southern Ocean, negative  $\delta^{13}\text{C}$  anomalies in the global upper ocean were instead transferred from the atmosphere (i.e. top down transport). Due to this efficient ‘atmospheric bridge’, the pathway of  $\delta^{13}\text{C}$  transport was likely to be different from nutrient transport during the early deglaciation. This implies that the usage of  
20 planktic  $\delta^{13}\text{C}$  records for identifying the carbon source(s) responsible for the atmospheric  $\text{pCO}_2$  rise during the early deglaciation is limited. The model results also suggest that thermocline waters in upwelling systems like the eastern equatorial Pacific, and even upper deep waters above 2000m, can be affected by this atmospheric bridge during the early deglaciation. Our results imply that caution must be applied when interpreting early deglacial marine  $\delta^{13}\text{C}$  records from depths that are potentially affected by the atmosphere.

## 1 Introduction

Atmospheric pCO<sub>2</sub> increased by 80-100 ppm from the last glacial maximum (LGM) to the Holocene (Marcott et al., 2014; Monnin et al., 2001). The mechanisms and the chain of events that were responsible for this pCO<sub>2</sub> rise are not well understood. High resolution ice core CO<sub>2</sub> and δ<sup>13</sup>C records provide valuable constraints on the timing and magnitude of this  
30 deglacial history. During the initial ~35ppm rise in pCO<sub>2</sub> rise between 17.2 to 15 ka, ice core records have documented a 0.3‰ decrease in atmospheric δ<sup>13</sup>C (Bauska et al., 2016; Schmitt et al., 2012). This millennial-scale trend was punctuated by a rapid 12ppm pCO<sub>2</sub> increase between 16.3-16.1 ka (Marcott et al., 2014) and a -0.2‰ decrease in atmospheric δ<sup>13</sup>C (Bauska et al., 2016). A contemporaneous δ<sup>13</sup>C drop is recorded by both surface and thermocline dwelling foraminifers (e.g. Hertzberg et al., 2016; Lund et al., 2019; Spero & Lea, 2002) as well as by benthic foraminifera from shallow depths (e.g. Lynch-Stieglitz  
35 et al., 2019; Romahn et al., 2014; Stott et al., 2019; this study) around the global ocean. The planktic δ<sup>13</sup>C records have been previously interpreted to reflect a spread of high nutrient, low δ<sup>13</sup>C waters that upwelled in the Southern Ocean, and then transported throughout the upper ocean via a so-called intermediate water teleconnection (Martínez-Botí et al., 2015; Pena et al., 2013; Spero & Lea, 2002). According to this hypothesis, formerly sequestered carbon from deep waters were upwelled in the Southern Ocean (Anderson et al., 2009) in response to a breakdown of deep ocean stratification (Basak et al., 2018) and  
40 this carbon was then carried by Antarctic Intermediate Water (AAIW) and Southern Ocean Mode Water (SAMW) to low latitudes where it then outgassed to the atmosphere in upwelling regions like the eastern equatorial Pacific (EEP). This hypothesis implies that the upper ocean at lower latitudes acts as a conduit for <sup>13</sup>C-depleted carbon to the atmosphere. Here we term this scenario ‘bottom up’ transport.

Recently, it has been suggested that a negative δ<sup>13</sup>C decline occurring initially in the atmosphere (i.e. as recorded by  
45 the ice cores) may have left an isotopic imprint on the global surface ocean through air-sea exchange (Lynch-Stieglitz et al., 2019). That signal could then be transmitted to thermocline depths and maybe even reach intermediate depths. Here we term this alternative scenario ‘top down’ transport.

The two scenarios have different implications. In the ‘bottom up’ transport scenario, a significant portion of <sup>13</sup>C-depleted carbon from the deep ocean was outgassed at low latitudes and contributed to the atmospheric pCO<sub>2</sub> rise, while in the  
50 ‘top down’ transport, <sup>13</sup>C-depleted carbon from the ocean could be outgassed to the atmosphere from anywhere (e.g. the high

latitude Southern Ocean and low latitude upwelling regions), and the subsequent  $\delta^{13}\text{C}$  decline in the global upper ocean does not necessarily contribute to atmospheric  $\text{pCO}_2$  variability.

Here, we analyze a transient deglacial simulation conducted with the Earth system model LOVECLIM (Menviel et al., 2018). In this experiment, sequestered respired carbon in the deep and intermediate waters are ventilated through the Southern Ocean and this leads to a sharp decline in atmospheric  $\delta^{13}\text{C}$ , consistent with ice core records. We evaluate the two  $\delta^{13}\text{C}$  transport scenarios by partitioning the simulated carbon pool and its stable isotope signature into a preformed and a remineralized component (Methods). The preformed component is dominated by surface processes such as air-sea thermodynamic equilibrium and primary productivity. The remineralized component reflects gain/loss of respired carbon due to changes in residence time and export productivity, or a transient input of respired carbon from the deep ocean. If the ‘top down’ transport scenario was the mechanism responsible for the  $\delta^{13}\text{C}$  decline seen in marine proxy records, the preformed signal should dominate in the upper 1000m, while a remineralized signal would dominate the ‘bottom up’ scenario. Our approach requires an accurate representation of the preformed and remineralized component. The LOVECLIM transient experiment does not simulate preformed or remineralized carbon explicitly and our offline calculation (see Methods) is likely subject to errors. However, the LOVECLIM results are complemented by sensitivity experiments performed with another Earth System model (cGENIE), wherein the preformed tracers are explicitly simulated.

The partitioning framework is not new, previous studies have used this framework to study the mechanisms that lead to lower glacial atmospheric  $\text{CO}_2$  (Ito & Follows, 2005; Khatiwala et al., 2019) and processes that control atmospheric and marine  $\delta^{13}\text{C}$  (Menviel et al., 2015; Schmittner et al., 2013). This diagnostic framework has also been applied to study the carbon cycle perturbation in response to a weaker AMOC (Schmittner & Lund, 2015), however in that study the experiments were performed under constant pre-industrial conditions. To our knowledge, the origin of the early deglacial  $\delta^{13}\text{C}$  perturbation has not been established.

We also present a new benthic  $\delta^{13}\text{C}$  record from the upper western equatorial Pacific (WEP) to expand the deglacial benthic  $\delta^{13}\text{C}$  dataset of the upper ocean isotope excursion (e.g. Lynch-Stieglitz et al., 2019).

## 2 Methods

### 2.1 LOVECLIM deglacial transient simulation

The LOVECLIM model (Goosse et al., 2010) consists of a free-surface primitive equation ocean model ( $3^\circ \times 3^\circ$ , 20 vertical levels), a dynamic–thermodynamic sea ice model, an atmospheric model based on quasi-geostrophic equations of motion (T21, three vertical levels), a land surface scheme, a dynamic global vegetation model (Brovkin et al., 1997) and a marine carbon cycle model (Menviel et al., 2015). To study the sensitivity of the carbon cycle to different changes in oceanic circulation, a series of transient simulations of the early part of the last deglaciation (19-15ka) was performed by forcing LOVECLIM with changes in orbital parameters (Berger, 1978) as well as Northern Hemispheric ice-sheet geometry and albedo (Abe-Ouchi et al., 2007), and starting from a LGM simulation that best fit oceanic carbon isotopic ( $^{13}\text{C}$  and  $^{14}\text{C}$ ) records (Menviel et al., 2017). The simulation we analyzed for this study is “LH1-SO-SHW” from Menviel et al. (2018). We briefly describe the relevant deglacial forcing here. Firstly, a freshwater flux of 0.07 Sv is added into the North Atlantic between 17.6 ka and 16.2 ka, resulting in an AMOC shut down. Secondly, a salt flux is added into the Southern Ocean between 17.2 ka and 16.0 ka to enhance Antarctic Bottom Water (AABW) formation. Enhanced AABW could have occurred due to changes in buoyancy forcing at the surface of the Southern Ocean, or opening of polynyas, processes which could be mis-represented in the model due to its relatively coarse resolution. Lastly, two stages of enhanced Southern Ocean westerlies are prescribed in the simulation at 17.2 ka and at 16.2 ka; this timing generally corresponds to Southern Ocean warming associated with two phases of NADW weakening during Heinrich Stadial 1 (Hodell et al., 2017). For more detail about this experiment, see Menviel et al. (2018).

## 2.2 cGENIE Sensitivity experiments

The cGENIE model is also based on a 3-D dynamical ocean model plus dynamic and thermodynamic sea ice components but run at a lower resolution (36x36 horizontal grid with 16 vertical layers.) than LOVECLIM. In addition, cGENIE lacks a dynamical atmosphere. Climate feedback is instead provided by a 2-D energy-moisture balance atmosphere (Edwards & Marsh, 2005), making it much less computationally expensive than LOVECLIM. cGENIE includes a representation of marine biogeochemical cycling (Ridgwell et al., 2007). Preformed dissolved inorganic carbon ( $\text{DIC}_{\text{pref}}$ ) and  $\delta^{13}\text{C}$  ( $\delta^{13}\text{C}_{\text{pref}}$ ) tracers are explicitly simulated in cGENIE (Ödalen et al., 2018). These are created by resetting the preformed tracer value at the ocean surface to the equivalent full tracer value at each model time-step, and then allowing ocean circulation

100 to transport the preformed tracers conservatively – i.e. no remineralization or other interior ocean geochemical processes are allowed to modify the preformed tracer value.

A series of cGENIE simulations were run based on the pre-industrial configuration of Cao et al., (2009) (Table 1). The spin-up includes two stages: the first stage was run for 10,000 years, with prescribed atmospheric  $p\text{CO}_2 = 278$  ppm,  $\delta^{13}\text{C} = -6.5\text{‰}$ ; the second stage was run for 3,000 years, with a 0.1 Sv of freshwater input into the North Atlantic to weaken the  
105 Atlantic Meridional Overturning Circulation (AMOC). The atmosphere is fixed at the first stage. We then performed 2 idealized simulations to investigate the role of air-sea exchange in upper ocean  $\delta^{13}\text{C}$ , each integrated for 2000 years. In these sensitivity experiments, in addition to a continuous freshwater flux into the North Atlantic, we applied a -0.3 Sv freshwater flux (i.e. salt flux) into the Pacific sector of the surface Southern Ocean to enhance AABW formation and ventilation rate. In the experiment ‘fix’, the atmosphere is held constant as in the spin up. In the experiment ‘free’, the atmosphere is allowed to  
110 evolve freely. The radiative forcing for both experiments is fixed at the pre-industrial level so that the two experiments have an identical climate even though the  $\text{CO}_2$  concentrations will differ. Note also that by holding the atmospheric  $\text{CO}_2$  and  $\delta^{13}\text{C}$  constant in the experiment ‘fix’, the atmosphere-ocean inventories of carbon and  $\delta^{13}\text{C}$  are slightly different from those in the experiment ‘free’.

### 115 2.3 Carbon pool partitioning

To diagnose the mechanisms responsible for the carbon isotope perturbation, the DIC pool is separated into remineralized and preformed components:  $\text{DIC} = \text{DIC}_{\text{reg}} + \text{DIC}_{\text{pref}}$  (Ito & Follows, 2005).  $\text{DIC}_{\text{reg}}$  consists of remineralized organic matter ( $\text{DIC}_{\text{org}}$ ) and remineralized calcium carbonate ( $\text{DIC}_{\text{CaCO}_3}$ ). In LOVECLIM,  $\text{DIC}_{\text{org}}$  is estimated by the Apparent Oxygen Utilization (AOU); AOU is the difference between saturation concentration for oxygen at the ambient temperature  
120 and salinity and in situ oxygen.  $\text{DIC}_{\text{org}} = -R_{\text{C/O}} * \text{AOU}$ , where  $R_{\text{C/O}} = 117\text{--}170$  (Anderson & Sarmiento, 1994).  $\text{DIC}_{\text{org}}$  is highly depleted in  $\delta^{13}\text{C}$  and changes in  $\text{DIC}_{\text{org}}$  has a strong impact on the  $\delta^{13}\text{C}$  budget.  $\text{DIC}_{\text{CaCO}_3}$ , on the other hand, has an isotopic composition close to seawater and does not have a strong influence on oceanic  $\delta^{13}\text{C}$  variability.  $\text{DIC}_{\text{CaCO}_3}$  and its impact on  $\delta^{13}\text{C}$  is therefore not considered in this study. Changes in  $\delta^{13}\text{C}$  ( $\Delta\delta^{13}\text{C}$ ) due to remineralization of organic matter is estimated by  $\Delta\delta^{13}\text{C}_{\text{reg}} = \delta^{13}\text{C}_{\text{org}} * \Delta(^{12}\text{C}_{\text{org}} / ^{12}\text{C}) = \delta^{13}\text{C}_{\text{org}} * \Delta(^{12}\text{C}_{\text{org}}/\text{DIC})$ ;  $\Delta\delta^{13}\text{C}$  in response to perturbations of the preformed pool

125  $(\Delta\delta^{13}\text{C}_{\text{pref}})$  is estimated by  $\Delta\delta^{13}\text{C} - \Delta\delta^{13}\text{C}_{\text{reg}}$ .

In cGENIE,  $\delta^{13}\text{C}_{\text{pref}}$  is explicitly simulated and the remineralization effect is estimated by  $\Delta\delta^{13}\text{C}_{\text{reg}} = \Delta\delta^{13}\text{C} - \Delta\delta^{13}\text{C}_{\text{pref}}$ .

## 2.4 Stable Isotope Analyses and Age Model for Piston Core GeoB17402

The WEP piston core GeoB17402 (8°N, 126°34'E, 556m) was recovered from the expedition SO-228. The planktic foraminiferal samples for  $^{14}\text{C}$  age dating were typically between 2 and 5mg. All new radiocarbon ages were measured at the University of California Irvine Accelerator laboratory. An age model was developed for this core by converting the *Trilobatus sacculifer* (*T. sacculifer*)  $^{14}\text{C}$  ages to calendar age using BChron and the Marine13 calibration database. There is no evidence that surface reservoir ages were significantly different during the glacial or deglacial period. We therefore did not apply any adjustment to Delta R. Once the calendar ages were established the results were plotted vs depth. Between each adjacent *T. sacculifer* age, linear interpolation was applied to develop an age model for the core. For benthic foraminiferal  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  measurements approximately 4-8 *Cibicidoides mundulus* (*C. mundulus*) were picked. These samples were cleaned by first cracking the tests open and then sonicating them in deionized water after which they were dried at low temperature. The isotope measurements were conducted at the University of Southern California on a GV Instruments Isoprime mass spectrometer equipped with an autocarb device. An in-house calcite standard (ultissima marble) was run in conjunction with foraminiferal samples to monitor analytical precision. The  $1\sigma$  standard deviation for standards measured during the study was less than 0.1‰ for both  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$ . The stable isotope data are reported in per mil with respect to VPDB and will be archived on Pangaea.

## 3 Results

In the LOVECLIM transient simulation, freshwater input into the North Atlantic leads to reduced North Atlantic Deep Water (NADW) formation. Atlantic Meridional Overturning Circulation (AMOC) is significantly weaker than its glacial condition by ~18 ka (Figure 1a), but this only has a minor effect on the atmospheric  $\text{CO}_2$  (Figure 1b) and  $\delta^{13}\text{C}$  (Figure 1c). On the other hand, enhanced ventilation of Antarctic bottom water (AABW) and Antarctic intermediate water (AAIW) between 17.2-15 ka leads to an atmospheric  $\text{CO}_2$  increase of ~25 ppm and  $\delta^{13}\text{C}$  decline of -0.35‰ (Figure 1b, 1c). Below, our analyses center around the Pacific basin between 17.2 - 15.0 ka. The Atlantic basin will be discussed in Sect. 4.3.

The model simulates a global negative sea surface  $\delta^{13}\text{C}$  anomaly (here defined as 15-17.2 ka) (Figure 2a). The  
150 strongest negative anomaly occurs at the surface of the Southern Ocean and North Atlantic. We separate the simulated sea  
surface  $\delta^{13}\text{C}$  signal (Figure 2a) into 2 components: 1) air-sea thermodynamic component due to atmospheric  $\delta^{13}\text{C}$  and sea  
surface temperature (SST) changes ( $\Delta\delta^{13}\text{C}_{\text{thermo}}$ , Figure 2b) (Zhang et al., 1995) (Note the SST effect ( $\Delta\delta^{13}\text{C}_{\text{sst}}$ ) alone is shown  
in figure S2.) and 2) the residual component ( $\Delta\delta^{13}\text{C}_{\text{res}}$ ) (Figure 2c) that mainly reflects enhanced primary productivity in  
response to increased nutrient supply upwelled from the deep ocean (Figure S3). The surface  $\Delta\delta^{13}\text{C}$  (Figure 2a) is then  
155 propagated into the ocean interior as a preformed signal when surface waters subduct. To the North of 50°S in the Pacific,  $\delta^{13}\text{C}$   
in the upper 1000m (Figure 3a) is dominated by a preformed signal of  $\sim -0.3\text{‰}$  (Figure 3c), with minor contribution from  
respired carbon transport within the ocean interior (Figure 3b).

In the Pacific,  $\Delta\delta^{13}\text{C}_{\text{pref}}$  of -0.2 to -0.3‰ can be traced to  $\sim 1000$  m in the LOVECLIM simulation (Figure 3c). Since  
there is a minor change in  $\Delta\delta^{13}\text{C}_{\text{reg}}$  above 1000m in the tropical Pacific, this preformed signal would have been recorded by  
160 benthic foraminifera from this region. Indeed, our new record from 556 m depth in the WEP (Figure 4b) documents a -0.3 to  
-0.4‰ decline during the early deglaciation (Figure 4b), consistent with records from the EEP at similar depths (Stott et al.,  
2019). We acknowledge that the magnitude of increasing  $\delta^{13}\text{C}$  between 15-13 ka is much larger in our benthic  $\delta^{13}\text{C}$  record,  
which might be caused by other factors. Nonetheless, our new shallow benthic  $\delta^{13}\text{C}$  records share a similar ‘W’ shape as the  
atmospheric record over the last 20ka, suggesting a sustained influence from the atmosphere.

165 Our results support the ‘top down’ transport scenario and challenges the ‘bottom up’ transport scenario as the primary  
mechanism for the  $\delta^{13}\text{C}$  decline seen in upper ocean proxy reconstructions. The ‘top down’ scenario is also compatible with  
the idea of a nutrient teleconnection between the Southern Ocean and low latitudes (Palter et al., 2010; Pasquier & Holzer,  
2016; Sarmiento et al., 2004). Figure 3d illustrates that stronger upwelling brings excess nutrients to the surface of the Southern  
Ocean. Unused nutrients are then transported to low latitudes within the upper ocean circulation (e.g. through mode waters  
170 and thermocline waters). However, a nutrient teleconnection does not, in itself, reflect enhanced flux of  $\delta^{13}\text{C}$ -depleted DIC  
from the deep ocean to low latitudes in a ‘tunnel-like’ fashion. The  $\delta^{13}\text{C}$  signal that is transported in the upper ocean has been  
strongly affected by air-sea gas exchange at the surface of Southern Ocean and therefore its pathway is different from the  
nutrient signal in the LOVECLIM simulation.

To be clear, the stronger negative  $\Delta\delta^{13}\text{C}_{\text{pref}}$  compared to  $\Delta\delta^{13}\text{C}_{\text{reg}}$  in the upper ocean does not mean respired carbon is  
175 not important in the simulation. In fact, the ultimate  $\delta^{13}\text{C}$ -depleted carbon source in LOVECLIM is the simulated respired  
carbon that accumulated in the deep and intermediate waters during the glacial period as a consequence of the imposed  
weakened deep water formation. Our results suggest that when deep ocean stratification breaks down in the model, the  $\delta^{13}\text{C}$ -  
depleted deep waters upwell; the signal is transmitted to the atmosphere through strong outgassing in the Southern Ocean  
(Figure 5). Subsequently, equilibrium thermodynamic exchange between the atmosphere and the surface ocean dominates the  
180  $\delta^{13}\text{C}$  decline in the global upper ocean.

Our approach to partitioning carbon in LOVECLIM is not perfect and subject to errors. For example, AOU likely  
over estimates the true Oxygen Utilization, and thus  $\text{DIC}_{\text{org}}$ , particularly in water masses formed in regions with sea ice  
(Bernardello et al., 2014; Ito et al., 2004; Khatiwala et al., 2019). To confirm the results obtained from the LOVECLIM  
simulation are robust, we conducted experiments with another Earth System model – cGENIE. In cGENIE, similar  
185 freshwater/salt forcing as in the LOVECLIM simulation were applied. Unlike LOVECLIM, in cGENIE carbon partitioning  
can be performed in a traceable and more accurate manner (see Methods). In the cGENIE ‘free’ experiment, enhanced deep  
ocean ventilation is associated with a rapid decrease in upper ocean  $\delta^{13}\text{C}$  during the first 1000 years and then stabilizes between  
model year 1000 and 2000 (not shown). The  $\delta^{13}\text{C}$  decline in the upper 1000m is also dominated by the preformed signal (Figure  
6), consistent with the LOVECLIM simulation. When atmospheric  $p\text{CO}_2$  and atmospheric  $\delta^{13}\text{C}$  are held constant in experiment  
190 ‘fix’, the  $\Delta\delta^{13}\text{C}_{\text{pref}}$  in the upper 500m is very small (Figure 6d). These sensitivity experiments with cGENIE further reinforce  
the fact that it is the atmospheric signal that dominates the upper ocean  $\delta^{13}\text{C}$  response.

We acknowledge that LOVECLIM and cGENIE are two distinct models and initial conditions, boundary conditions,  
prescribed forcing in the simulations are all quite different. For example, the LOVECLIM simulation starts with a glacial like  
climate and a strong stratified deep ocean; atmospheric  $p\text{CO}_2$  increases from 190 ppm to 207 ppm between 17.2 ka and 15 ka.  
195 The cGENIE simulations begin with a pre-industrial like climate; atmospheric  $p\text{CO}_2$  increases from 278 ppm to 310 ppm.  
Thus, direct comparisons between the model simulations are not our focus. Nonetheless, both models suggest upper ocean  
 $\delta^{13}\text{C}$  cannot be used as a direct tracer of respired carbon transport during the deglaciation, due to the influence of air-sea  
exchange.

## 200 4 Discussion :

### 4.1 Atmospheric $\delta^{13}\text{C}$ Bridge

Our simulations imply that the wide-spread deglacial  $\delta^{13}\text{C}$  minimum observed in marine planktic records can be explained, to the first order, by air-sea gas exchange (Lynch-Stieglitz et al., 2019) originating from the atmosphere. The atmosphere seems to act as a bridge in transmitting a lower  $\delta^{13}\text{C}$  signal from sites where  $\delta^{13}\text{C}$ -depleted carbon is released to  
205 the atmosphere (i.e. high latitude Southern Ocean in the LOVECLIM and cGENIE simulation) into the global surface and subsurface ocean. A good example is the simulated transient  $\delta^{13}\text{C}$  minimum event between 16.2 -15.8 ka in LOVECLIM (Figure 1c), which clearly originates from the Southern Hemisphere and particularly from enhanced ventilation of AAIW (Figure 1a). If the ‘top down’ scenario is true, the upper water masses away from the Southern Hemisphere would show similar magnitude of  $\delta^{13}\text{C}$  changes as the atmosphere, while water masses in the mid or high latitude Southern Hemisphere may show  
210 different  $\delta^{13}\text{C}$  responses due to dynamical circulation and productivity changes induced by Southern Ocean processes. On the other hand, if the ‘bottom up’ scenario is true, a large depleted  $\delta^{13}\text{C}$  signal should first appear in the South Pacific subtropical gyre (STGSP), then progressively spread to the tropics and finally reach the North Pacific; the depleted  $\delta^{13}\text{C}$  anomaly is also likely to be diluted along its pathway from the South Pacific to the North Pacific. In the LOVECLIM simulation, there is no  $\delta^{13}\text{C}$  minimum in the upstream STGSP, while the atmosphere-like negative  $\delta^{13}\text{C}$  anomaly appears in the EEP thermocline, the  
215 North Pacific subtropical gyre (STGNP) and North Pacific Intermediate Water (NPIW) simultaneously (Figure 7). In addition, millennial-scale  $\delta^{13}\text{C}$  evolution in these upper ocean water masses to the north of the equator all show pattern similar to the atmosphere. The synchronized  $\delta^{13}\text{C}$  anomaly clearly points to the dominant role of atmospheric communication rather than time-progressive oceanic transport of a low  $\delta^{13}\text{C}$  signal in LOVECLIM.

In the LOVECLIM simulation, both millennial- and centennial-scale atmospheric  $\delta^{13}\text{C}$  declines are the result of  
220 enhanced deep ocean and/or intermediate ocean ventilation through the Southern Ocean. Using the UVic Earth-System model, Schmittner and Lund (2015) showed that a slow-down of AMOC alone is able to weaken the global biological pump and lead to light carbon accumulation in the upper ocean and the atmosphere, without invoking any Southern Ocean processes. Despite the different prescribed forcing,  $\Delta\delta^{13}\text{C}_{\text{pref}}$  also dominates the total  $\Delta\delta^{13}\text{C}$  in the upper 1000m of the global ocean in the UVic

experiment (See fig. 6 in Schmittner & Lund, 2015). Taken together, simulations by all three models suggest that any process  
225 that lowers the atmospheric  $\delta^{13}\text{C}$  would have an influence on the global upper ocean  $\delta^{13}\text{C}$ . This limits the use of planktic  $\delta^{13}\text{C}$   
records alone for identifying source(s) and locations of light carbon released to the atmosphere during the last deglaciation,  
consistent with what Lynch-Stieglitz et al., (2019) proposed. In section 4.2 and 4.3, we provide two examples over the last  
deglaciation to illustrate how recognizing the role of ‘atmospheric bridge’ in transmitting  $\delta^{13}\text{C}$  anomaly could lead to critical  
re-evaluation of what marine  $\delta^{13}\text{C}$  records actually reveal. Ice core records have documented multiple atmospheric  $\delta^{13}\text{C}$   
230 excursions during the last glacial period (Eggleston et al., 2016), our findings thus have important implications for interpreting  
marine  $\delta^{13}\text{C}$  records over glacial cycles.

#### 4.2 Revisiting EEP Thermocline $\delta^{13}\text{C}$

Waters at eastern equatorial Pacific (EEP) thermocline depths are thought to be connected to the deep ocean through  
AAIW from the south and NPIW from the north. The EEP is therefore a potential conduit for deep ocean carbon release to the  
235 atmosphere. As illustrated in the result section, the LOVECLIM simulated  $\delta^{13}\text{C}$  changes in the thermocline of the EEP mainly  
reflects a preformed signal. In the cGENIE experiment ‘free’,  $\Delta\delta^{13}\text{C}_{\text{pref}}$  also plays a dominant role in the total  $\Delta\delta^{13}\text{C}$  signal in  
the thermocline EEP. In contrast, in the experiment ‘fix’, there is almost no change in  $\delta^{13}\text{C}$  (Table 2). Thus, the release of  
isotopically-light carbon through the surface Southern Ocean (in both exp ‘fix’ and ‘free’) and the consequential air-sea re-  
equilibration of  $\delta^{13}\text{C}$  through gas exchange (in exp ‘free’ only) are both necessary to obtain the observed magnitude of  $\delta^{13}\text{C}$   
240 decline within the EEP thermocline.

The EEP is a dynamical region and observed  $\delta^{13}\text{C}$  variability in its upper waters likely reflects local processes that  
are not accounted for by the LOVECLIM simulation. However, we would like to highlight two planktic  $\delta^{13}\text{C}$  records that show  
strikingly similar evolution to the model simulation (Figure 8, Figure S4). Site GGC17/JPC30 is close to the coast and the  
wood-constrained constant surface reservoir ages over the last 20ka suggest this site was not influenced by old respired carbon  
245 from high latitudes (Zhao & Keigwin, 2018). Site ODP1238 is located in the main upwelling region where strengthened  $\text{CO}_2$   
outgassing inferred from boron isotope data has been interpreted to reflect respired carbon transported from the Southern  
Ocean (Martínez-Botí et al., 2015). If the deglacial history of subsurface influence was indeed distinctively different at the two  
sites, the remarkably similar planktic  $\delta^{13}\text{C}$  evolution provides strong evidence that thermocline  $\delta^{13}\text{C}$  in the EEP is dominantly

controlled by the ‘top down’ mechanism rather than the ‘bottom up’ mechanism as previously suggested (Martínez-Botí et al.,  
250 2015; Spero & Lea, 2002), consistent with the LOVECLIM simulation (Figure 8). At the same time, if there was significant  
outgassing in the EEP as expressed in the Boron isotope results (Martínez-Botí et al., 2015), the EEP itself could have partially  
contributed to the overall deglacial atmospheric  $\delta^{13}\text{C}$  evolution that dominates upper ocean  $\delta^{13}\text{C}$  response.

Collectively, our results show that even in strong upwelling regions, where atmospheric  $\delta^{13}\text{C}$  signal from above are  
likely to be erased by outcropping subsurface waters from below, thermocline  $\delta^{13}\text{C}$  is still subjected to strong atmosphere  
255 influences. This implies that the upper few hundred meters of the water column can be influenced by the atmosphere, consistent  
with our interpretation of the new benthic  $\delta^{13}\text{C}$  record presented in this study.

#### 4.3 How deep can the low preformed $\delta^{13}\text{C}$ signal reach during the early deglaciation?

We have shown that given the dominant negative  $\delta^{13}\text{C}_{\text{pref}}$  anomaly in the upper ocean, some interpretation of planktic  
260  $\delta^{13}\text{C}$  records might need to be re-evaluated. Our simulations also reveal that an atmospheric influence can reach deeper than  
thermocline depths, which is supported by the fact that some benthic  $\delta^{13}\text{C}$  records from upper 1000m resemble the atmospheric  
 $\delta^{13}\text{C}$  evolution. It is plausible that below 1000m, a  $\Delta\delta^{13}\text{C}_{\text{pref}}$  signal from the atmosphere still exists, but no longer dominates  
the total  $\Delta\delta^{13}\text{C}$  as  $\Delta\delta^{13}\text{C}_{\text{reg}}$  becomes increasingly important at depth.

It has been suggested that deglacial  $\delta^{13}\text{C}$  variability in the waters above 2000m depth in the Atlantic could be driven  
265 by air-sea exchange (Lynch-Stieglitz et al., 2019). However, mid-depth (1800-2100m) benthic  $\delta^{13}\text{C}$  records from the Brazil  
margin ( $\sim 27^\circ\text{S}$ ) document a  $\delta^{13}\text{C}$  decline of  $-0.4\text{‰}$  between 18.3 and 17 ka, earlier than the atmospheric  $\delta^{13}\text{C}$  signal, which  
decreases between 17 and 15 ka (Lund et al., 2019). Lund et al., (2019) suggest these observations seem at odds with the idea  
that  $\delta^{13}\text{C}_{\text{pref}}$  contributed to  $\delta^{13}\text{C}$  variability at their site.

The observed benthic  $\delta^{13}\text{C}$  anomaly at these Brazil margin sites are well simulated by LOVECLIM (Figure 9). Prior  
270 to 17.2 ka,  $\delta^{13}\text{C}$  variability at  $\sim 2000\text{m}$  depth at the Brazil Margin in the LOVECLIM simulation is dominantly controlled by  
accumulation of respired carbon (Figure S5b) and there is only a minor contribution from  $\delta^{13}\text{C}_{\text{pref}}$  (Figure S5c), as previous  
studies suggested (Lacerra et al., 2017; Lund et al., 2019; Schmittner & Lund, 2015). Interestingly, LOVECLIM also reveals  
a strong negative  $\Delta\delta^{13}\text{C}_{\text{pref}}$  signal between 17-15ka when the atmospheric  $\delta^{13}\text{C}$  declines (Figure 10c). But a positive  $\Delta\delta^{13}\text{C}_{\text{reg}}$

(Figure 10b) signal originating from a loss of respired carbon due to enhanced ventilation at those depths completely  
275 compensates for the negative  $\Delta\delta^{13}\text{C}_{\text{pref}}$ . As a result, there is only a minor  $\Delta\delta^{13}\text{C}$  (Figure 10a) signal, which is consistent with  
the proxy observations.

It is not clear why the simulated  $\Delta\delta^{13}\text{C}_{\text{pref}}$  values are more negative in the Atlantic than in the Pacific in LOVECLIM  
simulation (compare figure 3c and Figure 10c). It could be due to different circulation and/or subduction of different water  
masses in the two basins. Nonetheless, these results suggest that, between 17.2 and 15ka, a negative preformed  $\delta^{13}\text{C}$  signal  
280 from the atmosphere needs to be considered when interpreting benthic  $\delta^{13}\text{C}$  records shallower than 2000m depth.

## 5 Conclusions:

The LOVECLIM transient simulation is used as a tool to investigate the pathway of low  $\delta^{13}\text{C}$  signal transport under  
a prevailing deglacial scenario that involves Southern Ocean processes. We have shown that ocean-atmosphere gas exchange  
285 likely dominates the negative  $\delta^{13}\text{C}$  anomalies documented in surface and upper ocean proxy reconstructions between 17.2 ka  
and 15 ka. Numerical simulations suggest that enhanced Southern Ocean upwelling leads to a transfer of  $\delta^{13}\text{C}$ -depleted respired  
carbon from the Southern Ocean directly to the atmosphere. Consequently, atmospheric  $\delta^{13}\text{C}$  declines and this leaves its imprint  
on the global upper ocean through air-sea equilibration. This preformed signal could account for a marine  $\delta^{13}\text{C}$  decline up to  
0.3-0.4‰ at the surface and down to 2000m depth during the early deglaciation. At the same time, the amount of upwelling in  
290 the Southern Ocean is a forcing imposed on the model and therefore it is not directly constrained. It is therefore possible there  
were other sites where excess carbon was ventilated to the atmosphere during the deglaciation, which would have also affected  
atmospheric  $\delta^{13}\text{C}$ . Our findings therefore imply that planktic  $\delta^{13}\text{C}$  records do not provide strong constraints on the site or the  
mechanisms through which  $\text{CO}_2$  was released from the ocean to the atmosphere. Interpretation of early deglacial benthic  $\delta^{13}\text{C}$   
records shallower than 2000m depth needs to take into account an atmospheric influence. Whereas in the model simulations  
295 the source of the atmospheric signal is a direct response to enhanced Southern Ocean upwelling, our results underscore the  
need to find a way to fingerprint the actual source(s) of  $^{13}\text{C}$ -depleted carbon that caused the atmospheric  $\delta^{13}\text{C}$  decline.

470 **Figure 4. a): Atmospheric  $\delta^{13}\text{C}$  records (Bauska et al., 2016; Schmitt et al., 2012) b): *C. mundulus*  $\delta^{13}\text{C}$  record for upper intermediate and mode waters in the western equatorial Pacific. The negative  $\delta^{13}\text{C}$  decline in the atmospheric and our benthic record are highlighted in a grey bar.**

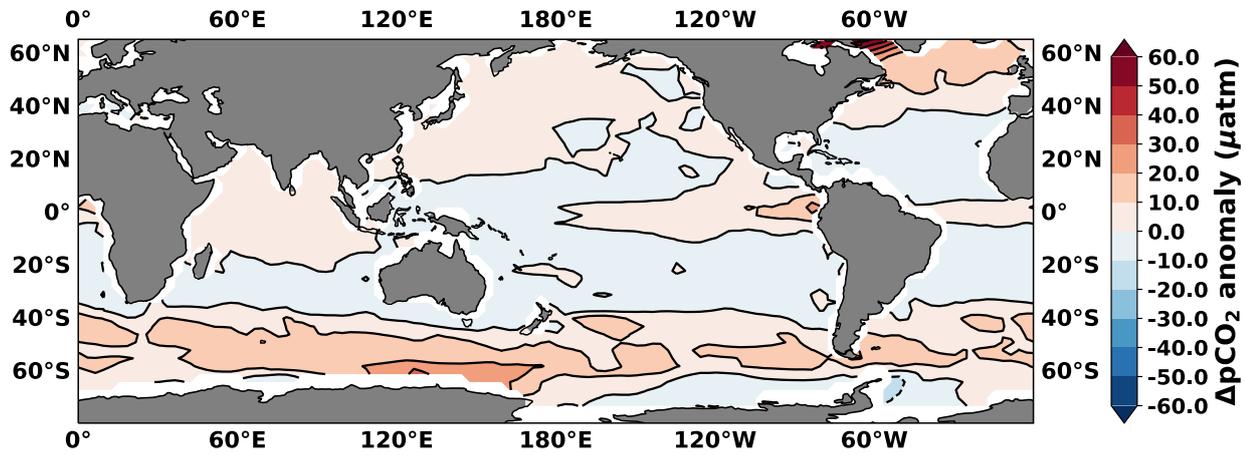

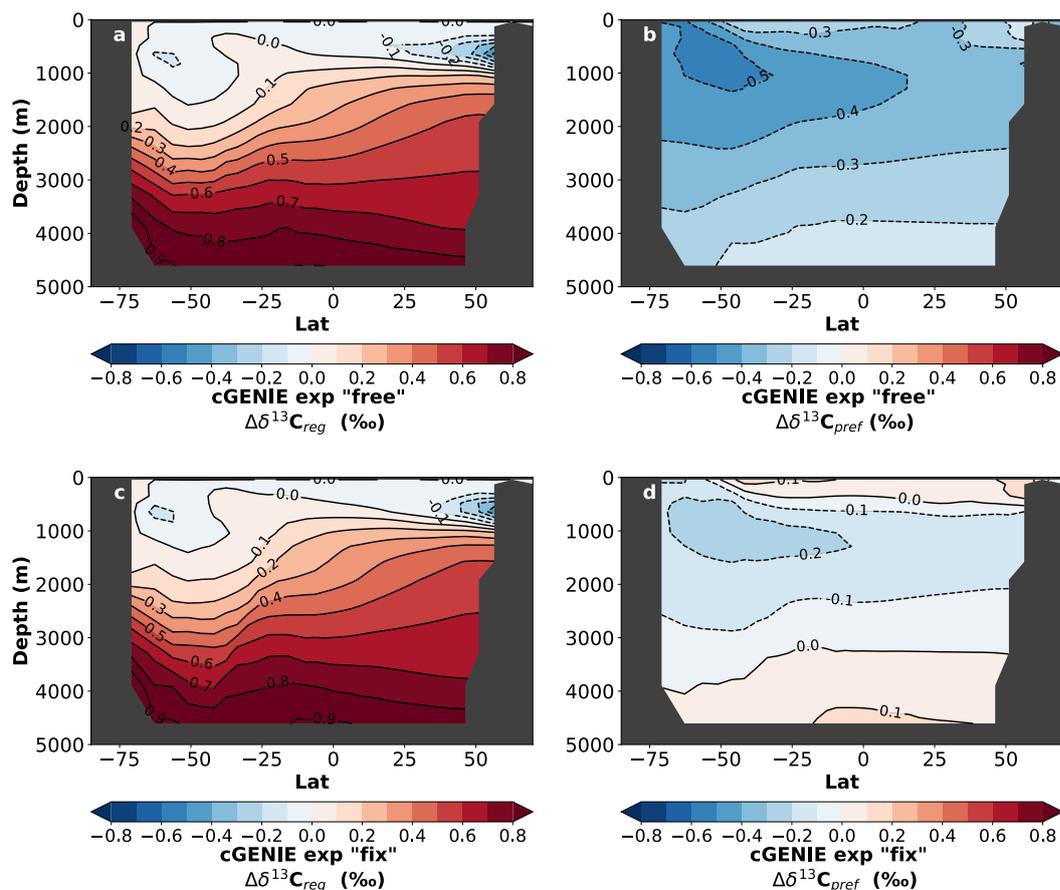

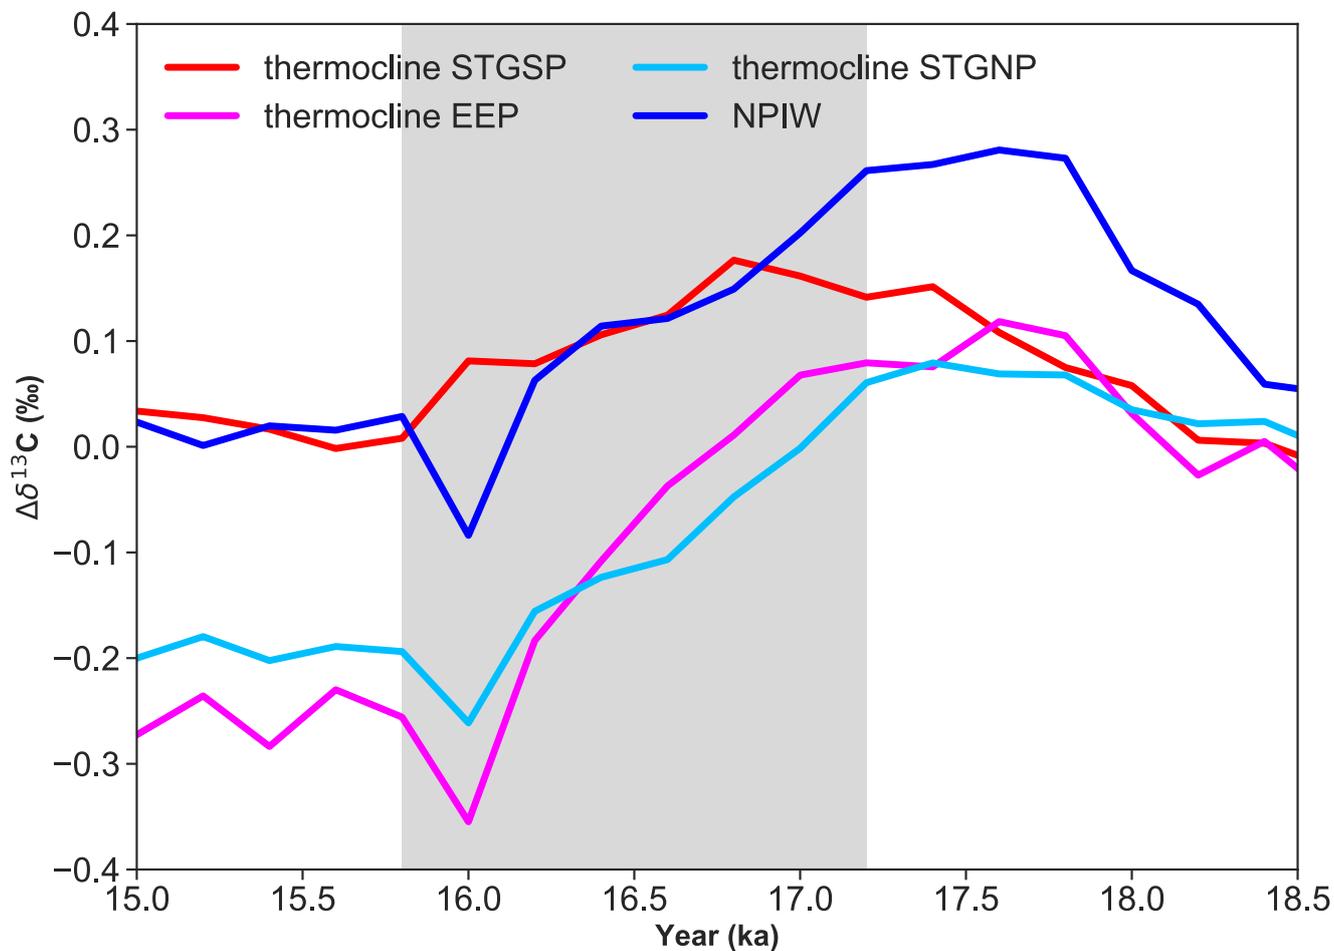

Figure 5. Changes in air-sea surface  $p\text{CO}_2$  gradient (15-17.2 ka)

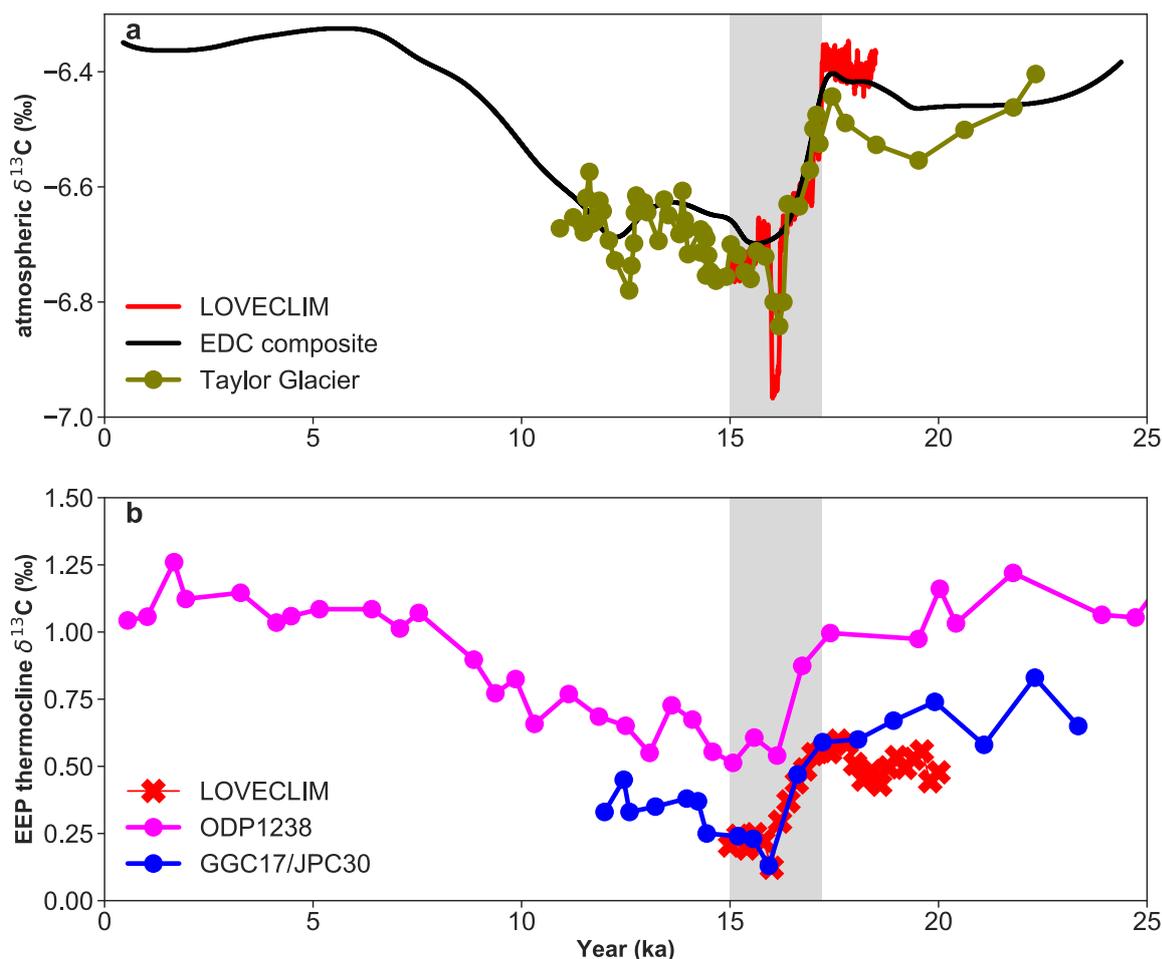

475

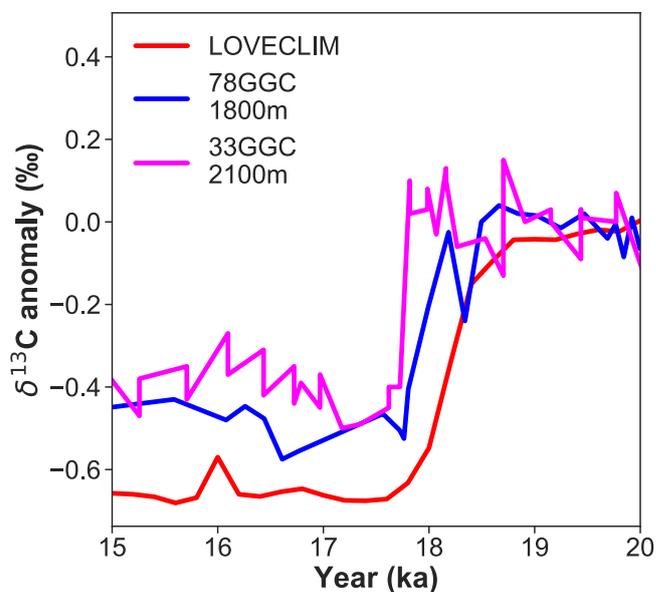

**Figure 6.** cGENIE simulated a)  $\Delta\delta^{13}\text{C}_{\text{reg}}$  b)  $\Delta\delta^{13}\text{C}_{\text{pref}}$  in experiment ‘free’ and simulated c)  $\Delta\delta^{13}\text{C}_{\text{reg}}$  d)  $\Delta\delta^{13}\text{C}_{\text{pref}}$  in experiment ‘fix’. Anomaly are calculated as the difference between model year 2000 and 0.

480 **Figure 7.** LOVECLIM simulated  $\Delta\delta^{13}\text{C}$  in thermocline EEP (90-82°W, 5°S-5°N, 77-105m), South Pacific subtropical gyre (STGSP, 160°E- 100°W, 40-22°S, 187-400m), North Pacific subtropical gyre (STGNP, 110°E- 140°W, 22-40°N, 187-400m), NPIW (167-170°E, 54-57°N, 660m). The average of 23.8-20 ka (i.e. LGM) is used as a reference level for the  $\Delta\delta^{13}\text{C}$  calculations.  $\delta^{13}\text{C}$  decline between 17.2-15.8 ka is highlighted with a grey bar.

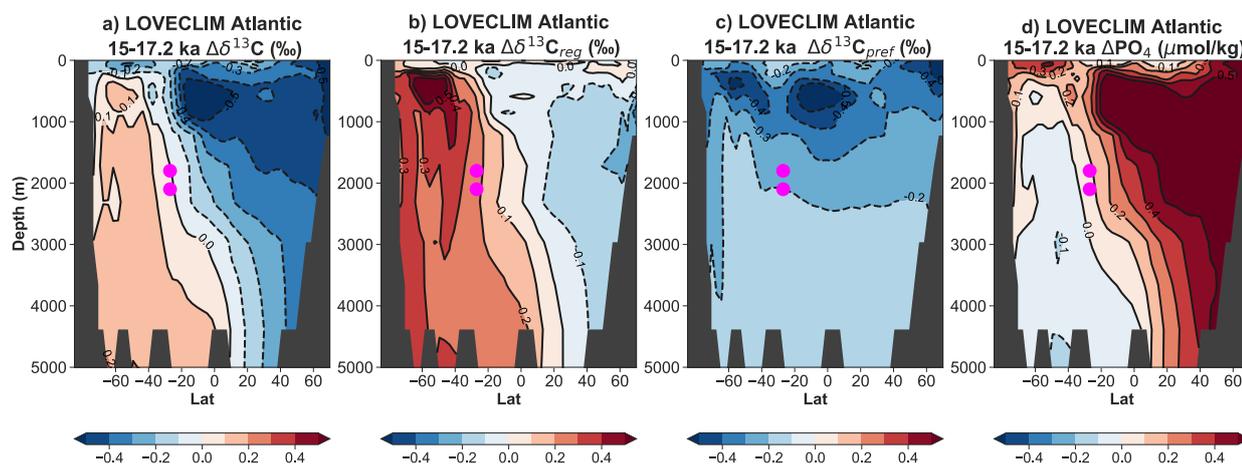

485 **Figure 8. a): Atmospheric  $\delta^{13}\text{C}$  records (Bauska et al., 2016; Schmitt et al., 2012), simulated atmospheric  $\delta^{13}\text{C}$  (21-year running average) in LOVECLIM (Menviel et al., 2018) b): *Neogloboquadrina. dutertrei* (*N. dutertrei*, a shallow thermocline species)  $\delta^{13}\text{C}$  data from ODP 1238 (Martínez-Boti et al., 2015), GGC17/JPC30 (Zhao & Keigwin, 2018), and LOVECLIM simulated  $\delta^{13}\text{C}$  of DIC at 100m (average of 82-90°W, 5°S-5°N). The *N. dutertrei* data are corrected by -0.5‰ to normalize to  $\delta^{13}\text{C}$  of DIC (Spero et al., 2003). The grey shaded bars highlight the time period we focus in this study.**
