## 11 Abstract

12 Environmental conditions during Marine Isotope Stage (MIS) 5e (130-116 ka) represent an important  
13 ‘process analogue’ for understanding the climatic responses to present and future anthropogenic  
14 warming. The response of Antarctic sea ice to global warming is particularly uncertain due to the short  
15 length of the observational record. Reconstructing Antarctic winter sea-ice extent during MIS 5e  
16 therefore provides insights into the temporal and spatial patterns of sea-ice change under warmer  
17 than present climate. This study presents new MIS 5e records from nine marine sediment cores  
18 located south of the Antarctic Polar Front, between 55 and 70 °S. Winter sea-ice extent and sea-  
19 surface temperatures are reconstructed using marine diatom assemblages and a Modern Analog  
20 Technique transfer function, and changes in these environmental variables between the three  
21 Southern Ocean sectors are investigated. The Atlantic and East Indian sector records show much more  
22 variable MIS 5e winter sea-ice extent and sea-surface temperatures than the Pacific sector records.  
23 High variability in the Atlantic sector winter sea-ice extent is attributed to high glacial meltwater flux  
24 in the Weddell Sea, indicated by increased abundances of the diatom species *Eucampia antarctica* and  
25 *Fragilariopsis cylindrus*. The high variability in the East Indian sector winter sea-ice extent is conversely  
26 believed to result from large latitudinal migrations of the flow bands of the Antarctic Circumpolar  
27 Current, inferred from latitudinal shifts in the sea-surface temperature isotherms. Overall, these  
28 findings suggest that Pacific sector winter sea ice displays a low sensitivity to warmer climates. The  
29 different variability and sensitivity of Antarctic winter sea-ice extent in the three Southern Ocean  
30 sectors during MIS 5e may have significant implications for the Southern Hemisphere climatic system  
31 under future warming.

## 32 **1. Introduction**

33 Antarctic sea ice is a critical part of the Southern Ocean (SO) and global climate system (Maksym,  
34 2019). The vast extent of Antarctic sea ice and its huge seasonal variability (from  $\sim 4 \times 10^6 \text{ km}^2$  in  
35 summer to  $\sim 18 \times 10^6 \text{ km}^2$  in winter in the present day) have a strong albedo-radiation feedback (Hall,  
36 2004). Brine rejection during sea-ice formation contributes to the production of dense shelf and  
37 bottom water masses, which, in turn, influence the strength of global overturning ocean circulation  
38 (Abernathey et al., 2016; Rintoul, 2018). Sea-ice cover also regulates heat and gas exchange between  
39 the SO and the atmosphere as well as phytoplankton productivity by acting as a physical barrier  
40 (Rysgaard et al., 2011) and barrier to sunlight and, when melting, causing stratification of the upper  
41 part of the water column (Goosse and Zunz, 2014).

42 Modern Antarctic sea-ice extent has shown a rapid decline since 2014 after four decades of gradual  
43 expansion (Parkinson, 2019). Within this overall trend there is substantial spatial heterogeneity in  
44 regional sea-ice trends, with decreases in the Bellingshausen and Amundsen seas concurrent with  
45 increases in the Weddell Sea and Ross Sea sectors (Hobbs et al., 2016; King, 2014; Parkinson, 2019).  
46 Alongside the inter-annual Antarctic sea-ice trends (Parkinson, 2019), there are also trends in seasonal  
47 variability, with the Amundsen Sea showing a substantial decrease in summer and autumn sea-ice  
48 concentrations but a slight increase in winter and spring sea-ice concentrations (Hobbs et al., 2016).  
49 Model simulations are unable to replicate the modern sea-ice changes without reduced regional  
50 warming trends (Rosenblum and Eisenman, 2017). Difficulties in reproducing modern sea-ice trends  
51 indicate the complexities of the climate dynamics that influence sea-ice extent in the SO today at  
52 different timescales (Ferreira et al., 2015; Hobbs et al., 2016; King, 2014; Purich et al., 2016;  
53 Stammerjohn et al., 2008).

54 Rising greenhouse gas concentrations are driving current global warming, with polar regions warming  
55 twice as fast ( $0.5 \text{ }^\circ\text{C}$  per decade) as the global average (IPCC, 2019) and Antarctic winter sea-ice extent  
56 (WSIE) predicted to shrink by 24-34 % by C.E. 2100 (Meredith et al., 2019). However, the very short  
57 length of observational records in high latitudes together with the complexity of the climate system,  
58 as mentioned above, limit our understanding of the underlying processes and ability to accurately  
59 predict future changes. Past warm periods can help document the amplitude of sea-ice extent  
60 reduction and, therefore, help guide our understanding of the impacts of future climate change in  
61 polar regions.

62 Interglacial Marine Isotope Stage (MIS) 5e (130-116 ka; Lisiecki and Raymo (2005)) is the latest period  
63 when global mean annual atmospheric temperatures were warmer than present ( $\sim 1 \text{ }^\circ\text{C}$ ; Fischer et al.  
64 (2018)) and global sea levels were higher than present ( $\sim 6\text{-}9 \text{ m}$ ; Kopp et al. (2009)). Summer sea-

65 surface temperatures (SSSTs) in the SO peaked at an average of  $1.6 \pm 1.4$  °C warmer than present at  
 66 and north of the modern Antarctic Polar Front during this period (Capron et al., 2014; Shukla et al.,  
 67 2021). MIS 5e warming is primarily orbitally forced, unlike current and future anthropogenic warming  
 68 which is driven by rising greenhouse gas concentrations. Whilst MIS 5e cannot be considered a direct  
 69 analogue for greenhouse gas induced global warming, it still represents an important ‘process  
 70 analogue’ for understanding climate mechanisms and responses that are active under warmer-than-  
 71 present climate conditions (Stone et al., 2016).

**Figure 1:** Map of core locations (black stars – this study, white star – Bianchi and Gersonde (2002)) with the modern (1981-2010) mean annual SSTs (COBE-SST2 dataset provided by the NOAA PSL, Boulder, Colorado, USA (<https://psl.noaa.gov/>)) and modern (1981-2010) median September and February sea-ice extents (data from Fetterer et al. (2017)). **White dots mark the locations of surface sediment samples (located south of 50°S) used as a modern reference dataset for the Modern Analog Technique transfer function.** The black solid line is the September sea-ice extent (15 % cover) and the blue solid line is the February sea-ice extent (15 % cover). The grey solid line is the position of the modern Antarctic Polar Front (Trathan et al., 2000). The black dashed lines mark the boundaries between the three SO sectors (Atlantic, Indian and Pacific). AP – Antarctic Peninsula, BS – Bellingshausen Sea, AS – Amundsen Sea.

72 Diatoms preserved in SO marine sediments have been used for over 40 years to reconstruct past  
 73 changes in Antarctic sea-ice extent and sea-surface temperatures (SSTs) (Armand and Leventer, 2010;  
 74 Burckle et al., 1982; Thomas et al., 2019) due to the close relationship between their biogeographic

75 distribution patterns and surface water environmental conditions (Armand et al., 2005; Crosta et al.,  
76 2005; Esper et al., 2010; Gersonde and Zielinski, 2000; Romero et al., 2005; Zielinski and Gersonde,  
77 1997). Several previous studies have used model simulations, alongside limited data constraints from  
78 marine sediment cores, to reconstruct SO WSIE and SSTs during MIS 5e (Capron et al., 2017; Holloway  
79 et al., 2017; Holloway et al., 2018). However, there are currently no marine core records located far  
80 enough south to constrain the predicted WSIE during MIS 5e (Chadwick et al., 2020; Holloway et al.,  
81 2017). Due to chronological uncertainties in SO proxy records (Govin et al., 2015), previous studies  
82 have assumed the minimum WSIE occurred synchronously around Antarctica and was coincident with  
83 peak atmospheric temperatures in Antarctic ice cores at 128 ka (Holloway et al., 2017).

84 This study presents new reconstructions of SO winter sea ice (WSI) during MIS 5e from the diatom  
85 assemblages preserved in nine marine sediment cores located south of 55 °S and south of the modern  
86 Antarctic Polar Front (Figure 1). Qualitative reconstructions are based on the occurrence of sea-ice  
87 related diatoms (Gersonde and Zielinski, 2000). Quantitative estimates are produced through a  
88 diatom-based Modern Analog Technique transfer function, based on numerous core-top sediment  
89 samples (Figure 1) and originally detailed in Crosta et al. (1998). Quantitative and qualitative  
90 reconstructions of WSIE in the three SO sectors; the Atlantic sector (70 °W – 20 °E), the Indian sector  
91 (20 °E – 150 °E) and the Pacific sector (150 °E – 70 °W), are compared to answer the following  
92 questions:

- 93 - Did the minimum WSIE occur synchronously throughout the SO during MIS 5e?
- 94 - Was the WSIE minimum concurrent with the peak Antarctic air temperatures at 128 ka?
- 95 - Were the patterns in MIS 5e sea-ice change consistent between SO sectors?

## 96 **2. Materials and methods**

### 97 *2.1. Core sites*

98 The nine sediment cores used in this study are shown in Figure 1 alongside modern SSTs and sea-ice  
99 extents. Details for each core are listed in Table 1. These cores were chosen as they contain >20 cm  
100 thick intervals of diatom-rich sediments deposited during MIS 5e (including Termination II) and are  
101 located further south than almost all previously published MIS 5e sea ice records (Chadwick et al.,  
102 2020). Due to the locations of core sites MD03-2603 and U1361A, our SST and sea-ice reconstructions  
103 for the Indian Ocean sector of the SO may reflect conditions only representative for the eastern Indian  
104 sector.

105 2.2. Diatom counts

106 For the diatom assemblage data, microscope slides were produced using a method adapted from  
 107 Scherer (1994). Samples of 7-28 mg were exposed to 10% Hydrochloric acid to remove any carbonate,  
 108 30% Hydrogen peroxide to break down organic material and a 4% Sodium Hexametaphosphate  
 109 solution to promote disaggregation and placed in a warm water bath for a minimum of 12 hours. The  
 110 material was homogenised, transferred into a ~10 cm high water column and allowed to settle  
 111 randomly onto coverslips over a minimum of 4 hours. The water was drained away and coverslips  
 112 were mounted on microscope slides with Norland Optical Adhesive (NOA 61). Slides were examined  
 113 using a light microscope (Olympus BH-2 at x1000 magnification) and a minimum of 300 diatom valves  
 114 were counted in each sample.

Core	Latitude (°), Longitude (°)	Water depth (m)	Cruise, Year	Ship	Core length (cm)
TPC290	-55.55, -45.02	3826	JR48, 2000	<i>RRS James Clark Ross</i>	1179*
TPC288	-59.14, -37.96	2864	JR48, 2000	<i>RRS James Clark Ross</i>	940*
TPC287	-60.31, -36.65	1998	JR48, 2000	<i>RRS James Clark Ross</i>	615*
MD03-2603	-64.28, 139.38	3320	MD130, 2003	<i>R/V Marion DuFresne II</i>	3033
U1361A	-64.41, 143.89	3459	IODP Exp. 318, 2010	<i>R/V JOIDES Resolution</i>	38800
ELT17-9	-63.08, -135.12	4935	ELT17, 1965	<i>R/V Eltanin</i>	2018
NBP9802-04	-64.20, -170.08	2696	PA9802, 1998	<i>R/V Nathaniel B. Palmer</i>	740
PC509	-68.31, -86.03	3559	JR179, 2008	<i>RRS James Clark Ross</i>	989
ANTA91-8	-70.78, 172.83	2383	ANTA91, 1990	<i>R/V Cariboo</i>	511

**Table 1:** Details of the location and recovery information for the nine marine sediment cores analysed in this study. Cores are ordered by sector (Atlantic - East Indian - Pacific) and then latitude. \* For each of the three TPC cores (TPC290, TPC288 and TPC287), the trigger core (TC) and piston core (PC) were spliced together to produce a composite record.

115 The combined relative abundance of *Fragilariopsis curta* and *F. cylindrus* (FCC) is used as a qualitative  
 116 indicator of WSI presence (Gersonde and Zielinski, 2000), with abundances >3 % associated with  
 117 locations south of the mean WSI edge, abundances 1-3 % found between the mean and maximum  
 118 WSI edge and abundances <1 % indicative of conditions north of the maximum WSI edge (Gersonde  
 119 et al., 2005; Gersonde and Zielinski, 2000). The relative abundance of the diatom species *Azpeitia*  
 120 *tabularis* is used as a comparison with reconstructed SSSTs. *Azpeitia tabularis* is a warm water species  
 121 restricted to the region north of the maximum WSIE (Zielinski and Gersonde, 1997), with abundances  
 122 <5 % in surface sediments south of the modern Antarctic Polar Front (Esper et al., 2010; Romero et

123 al., 2005). Increasing abundances of this species in high latitude SO sediments therefore indicate  
124 warmer SSTs and ice-free conditions.

### 125 2.3. Modern Analog Technique (MAT)

126 September sea-ice concentrations (SIC) and SSSTs (January to March) are estimated by applying a MAT  
127 transfer function to the MIS 5e diatom assemblages. The MAT compares the relative abundances of  
128 33 diatom species in each MIS 5e sample to the abundances of the same species in a modern reference  
129 dataset composed of 257 surface sediment samples (modern analogs) from the SO. Modern  
130 conditions for each surface sediment sample are interpolated on a 1° x 1° grid, with SSSTs from the  
131 World Ocean Atlas 2013 (Locarnini et al., 2013) and September SIC from the numerical atlas of  
132 Schweitzer (1995). The MAT was implemented using the “bioindic” R-package (Guiot and de Vernal,  
133 2011), with chord distance used to select the 5 most similar modern analogs to each MIS 5e  
134 assemblage. A cut-off threshold, above which any analogs are deemed too dissimilar to the MIS 5e  
135 sample, is fixed as the first quartile of random distances determined by a Monte Carlo simulation of  
136 the reference dataset (Simpson, 2007). The MAT257-33-5 (based on 257 reference samples, 33 taxa  
137 and up to 5 analogs) utilised in this study is an evolution of the MAT195-33-5 detailed in Crosta et al.  
138 (1998), with the addition of a further 62 surface sediment samples (Figure 1). The incremental  
139 evolutions of this transfer function over the last 20 years have yielded robust SST and sea-ice  
140 reconstructions when compared alongside other proxies within the same cores (e.g. Civel-Mazens et  
141 al., 2021; Crosta et al., 2004; Ghadi et al., 2020; Nair et al., 2019; Shemesh et al., 2002).

142 Quantitative estimates of September SIC and SSSTs are produced for each MIS 5e sample from a  
143 distance-weighted average of the climate values associated with the selected analogs. The  
144 reconstructed SSSTs have a Root Mean Square Error of Prediction (RMSEP) of 1.09 °C and an R<sup>2</sup> of  
145 0.96, and the reconstructed September SIC have a RMSEP of 9 % and an R<sup>2</sup> of 0.93. The reconstructed  
146 September SIC and SSST for each MIS 5e sample only use analogs below the dissimilarity threshold  
147 and therefore could be reconstructed from less than 5 analogs in some samples. It is also possible to  
148 get no-analog conditions, where none of the reference surface sediment samples are similar enough  
149 to a MIS 5e sample, and it is therefore not possible to reconstruct September SIC and SSST for this MIS  
150 5e sample.

### 151 2.4. Diatom preservation

152 For both the MAT and the FCC proxy, it is important that the diatom assemblage is well preserved, as  
153 high dissolution causes preferential loss of the more lightly silicified diatom species, generally sea-ice  
154 related species, and would therefore bias reconstructions towards warmer SSTs and lower sea-ice

155 conditions. The samples used in this study were investigated for signs of dissolution following the  
 156 procedure detailed in Warnock et al. (2015), whereby the areolae in *F. kerguelensis* valves were  
 157 checked to ensure there was little, or no, expansion and conjoining, as would occur under a high  
 158 degree of dissolution. Diatom assemblages in the analysed samples were also checked for a mixture  
 159 of both heavily and weakly silicified diatoms across the whole size range, which was suggested by  
 160 Zielinski (1993) as an indicator of good preservation. Poor preservation of diatoms in sediments  
 161 located beneath heavy winter sea ice (SIC >75 %) has likely limited most previous attempts to  
 162 reconstruct MIS 5e conditions from core sites located south of the modern mean WSIE, and thus the  
 163 preservation of samples analysed in this study was carefully considered to avoid introducing a warm  
 164 (low sea ice) bias into our reconstructions.

Core	SO sector	Chronology for MIS 5e	Chronological uncertainty (ka)
TPC290	Atlantic	Correlating MS from TPC290 to EDC ice core dust record combined with <i>C. davisiana</i> abundances (Pugh et al., 2009)*	± 2.6
TPC288	Atlantic	Correlating MS from TPC288 to EDC ice core dust record combined with <i>C. davisiana</i> abundances (Pugh et al., 2009)	± 2.5
TPC287	Atlantic	Correlating MS from TPC287 to MS in core TPC288 (Chadwick et al., 2022)	± 2.6-2.7
MD03-2603	East Indian	Correlating Ba/Al and Ba/Ti ratios from MD03-2603 to LR04 benthic oxygen isotope stack combined with diatom biostratigraphy (Presti et al., 2011)	± 2.6
U1361A	East Indian	Correlating Ba/Al ratios and lithological changes to the LR04 benthic oxygen isotope stack combined with LOD <i>H. karstenii</i> (Wilson et al., 2018)	± 2.6-2.7
ELT17-9	Pacific	Combined abundance stratigraphies of <i>E. antarctica</i> and <i>C. davisiana</i> on SPECMAP age scale (Chase et al., 2003)	± 2.5
NBP9802-04	Pacific	Correlating MS from NBP9802-04 to EDC ice core dust record combined with LOD <i>H. karstenii</i> (Williams, 2018)	± 2.7
PC509	Pacific	Correlating wet bulk density (= proxy mirroring biogenic opal content) from PC509 to the LR04 benthic oxygen isotope stack (Chadwick et al., 2022)	± 2.6-2.7
ANTA91-8	Pacific	Correlating MS from ANTA91-8 to the LR04 benthic oxygen isotope stack combined with LCO <i>Rouxia</i> spp. (this study; Figure 2)	± 2.6

**Table 2:** Summary of the location and chronologies for the nine sediment cores analysed in this study. Cores are ordered by sector (Atlantic – East Indian - Pacific) and then latitude. LOD: Last Occurrence datum, LCO: Last Common Occurrence \*For core TPC290 the chronology has been slightly adjusted from the published record of Pugh et al. (2009) by shifting the Termination II tiepoint to better align the magnetic susceptibility (MS) record with the dust record of the EPICA Dome C (EDC) ice core in East Antarctica (Chadwick et al., 2022).

165 **3. Age models**

166 **3.1. Published chronologies**

167 Eight of the sediment cores presented in this study have previously published age models, summarised  
168 in Table 2. Cores TPC290, TPC288, TPC287 and NBP9802-04 are published on the EDC3 chronology,  
169 cores MD03-2603, U1361A and PC509 are published on the LR04 chronology and core ELT17-9 is  
170 published on the SPECMAP chronology. These published chronologies are further constrained by  
171 checking the abundance of the diatom species *Rouxia leventerae* in all MIS 5e samples. All diatom  
172 assemblages analysed in this study have *R. leventerae* abundances <1 %, which suggest that the  
173 considered sediments are younger than the ~135 ka Last Occurrence Datum identified by Zielinski et  
174 al. (2002). To allow for consistent comparison of timings between cores, all cores are translated across  
175 onto the AICC2012 chronology (Bazin et al., 2013; Veres et al., 2013) using the alignment strategy of  
176 Govin et al. (2012) and the conversion tables of Lisiecki and Raymo (2005) and Parrenin et al. (2013b).  
177 Chronological uncertainties for the MIS 5e ages of samples in this study (Table 2) vary between 2.5  
178 and 2.7 ka. The AICC2012 chronology has an uncertainty of ±1.5 ka during MIS 5e, with an additional  
179 uncertainty of ±1 ka arising from the translation between chronologies (Capron et al., 2014). Each core  
180 sample comprises a 0.5 cm thick slice of sediment, and therefore additional age uncertainty due to  
181 integrating over the corresponding time interval in each core needs to be taken into account (see  
182 Table 2).

183 **3.2. ANTA91-8 chronology**

184 The chronology for core ANTA91-8 was constructed by aligning the magnetic susceptibility (MS) to the  
185 LR04 benthic foraminifera  $\delta^{18}\text{O}$  stack (Lisiecki and Raymo, 2005) using the AnalySeries software  
186 (Paillard et al., 1996). Increased supply of terrigenous glacial detritus from the Antarctic continent  
187 to its margin and increased dust input from Patagonia and Australia to the pelagic SO during glacial  
188 periods resulted in higher MS values during glacial periods than interglacial periods (Bareille et al.,  
189 1994; Pugh et al., 2009; Walter et al., 2000). Tie points were selected in the MS record at the  
190 boundaries of MIS stages and sub-stages (Figure 2 & Table 3). Ages for the MIS 5 sub-stage boundaries  
191 are from Govin et al. (2009), and the ages are translated from the LR04 chronology onto the AICC2012  
192 chronology.

193 The chronology for core ANTA91-8 presented in this study differs from chronologies previously  
 194 published by Ceccaroni et al. (1998) and Brambati et al. (2002), who – on the basis of <sup>230</sup>Thorium  
 195 measurements, subsequently adjusted by matching maxima in palaeo-productivity proxies to peak  
 196 interglacials – placed MIS 5e ~50 cm higher than in our age model (Supplementary Figure 1). Our new  
 197 chronology assigns the MS minimum from 2.65-3.05 metres below seafloor (mbsf), which comprises  
 198 a peak in organic carbon content (Ceccaroni et al., 1998), to MIS 5e. In contrast, both the Ceccaroni et  
 199 al. (1998) and Brambati et al. (2002) age models placed this MS minimum within MIS 6 (Supplementary  
 200 Figure 1), resulting in inexplicably high accumulation rates of productivity proxies during this glacial  
 201 period (Ceccaroni et al., 1998). Our new chronology is corroborated by *R. leventerae*, which occurs in  
 202 abundances <1 % in ANTA91-8 samples between 2.72 and 3.14 mbsf (Chadwick and Allen, 2021a). If  
 203 the sediments in this depth interval were deposited during MIS 6, as suggested by the Ceccaroni et al.  
 204 (1998) and Brambati et al. (2002) age models, then the *R. leventerae* abundances in the corresponding  
 205 samples should be >1 % (Zielinski et al., 2002).

ANTA91-8 depth (mbsf)	LR04 Age (ka)	MIS stage/sub-stage boundary
0.65	14	1-2
2.09	71	4-5a
2.39	83	5a-b
2.55	105	5c-d
2.65	116	5d-e
3.05	131.5	5e-6
3.17	136	-

**Table 3:** Tiepoints for ANTA91-8 chronology. The MS record for ANTA91-8 is aligned to the LR04 benthic stack using the AnalySeries software (Paillard et al., 1996).

**Figure 2:** Alignment between the MS from core ANTA91-8 (red) and the LR04 benthic  $\delta^{18}\text{O}$  stack (black) using the AnalySeries software (Paillard et al., 1996). Blue squares and connecting lines mark the tiepoints between records.

#### 206 4. Results

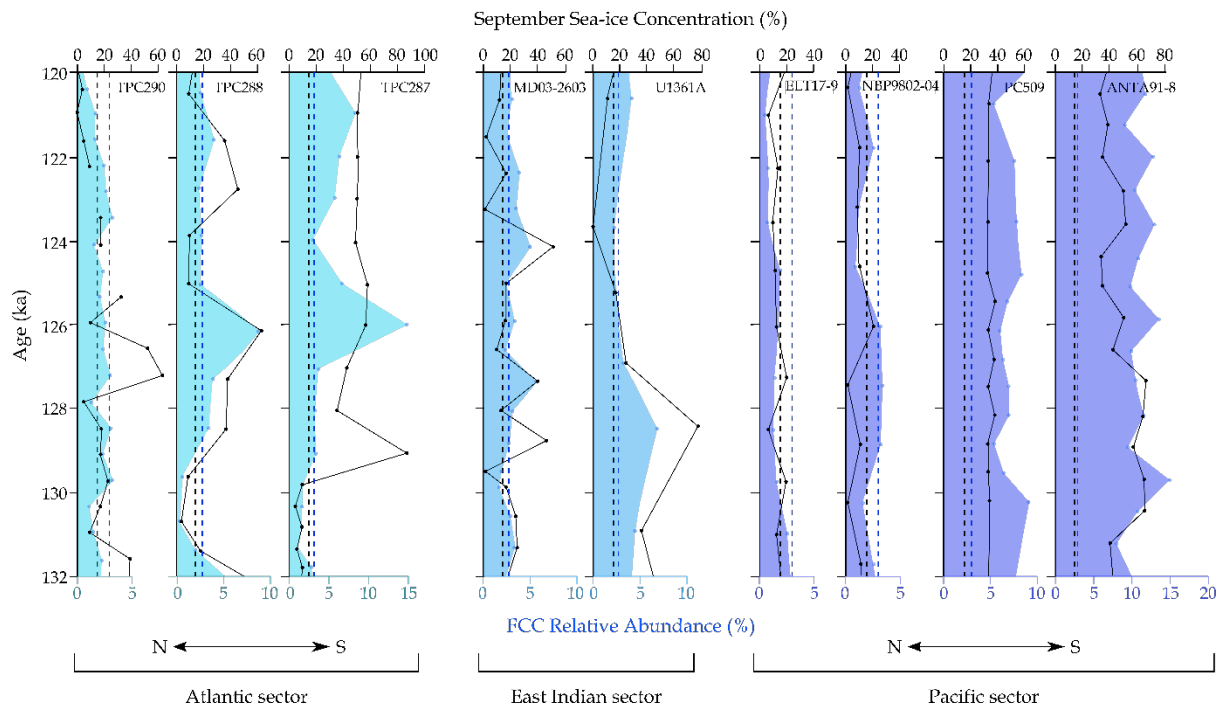

207 The September SIC values, reconstructed using the MAT, and the FCC relative abundances are  
 208 presented for the 132-120 ka interval in all nine sediment cores (Figure 3). This interval is chosen to  
 209 capture the sea-ice signature from both the end of glacial Termination II and during ‘peak’ MIS 5e.

210 SSST data, also reconstructed using MAT, is presented over the same time interval alongside the  
211 relative abundance of *A. tabularis*.

#### 212 4.1. *Sea ice*

213 **The three** Atlantic sector cores (TPC290, TPC288 and TPC287) display a N-S increasing trend in mean  
214 FCC relative abundances ( $2.1 \pm 0.7\%$ ,  $3.1 \pm 2.2\%$  and  $4.7 \pm 3.6\%$ ) and Sept. SICs ( $19 \pm 17\%$ ,  $25 \pm 18\%$   
215 and  $33 \pm 20\%$ ). All three cores have low FCC relative abundances ( $1.2 \pm 0.5\%$ ) and Sept. SICs ( $8.8 \pm$   
216  $4.6\%$ ) during the 131-130 ka interval, with cores TPC288 and TPC287 both reaching their minimum  
217 Sept. SIC and FCC values at this time (Figure 3). Following this interval of low Sept. SIC and FCC values,  
218 all three cores show an increase to their maximum Sept. SICs ( $58 \pm 5\%$ ) and FCC relative abundances  
219 ( $9 \pm 5\%$ ) at 127-126 ka (Figure 3). After  $126 \pm 2.6$  ka core TPC290 displays a gradual decline in both  
220 FCC relative abundance and Sept. SIC to minimum values at 121-120 ka (Figure 3). In contrast, core  
221 TPC287 maintains high Sept. SICs ( $51 \pm 3\%$ , multiple samples) throughout the 126-120 ka period as  
222 well as high ( $6.2 \pm 1.8\%$ , multiple samples) FCC relative abundances, although they are lower than the  
223  $126 \pm 2.6$  ka peak of  $\sim 15\%$  (single sample) (Figure 3). Core TPC288 maintains, relative to the  $\sim 130 \pm$   
224  $2.5$  ka minimum and  $\sim 126 \pm 2.5$  ka maximum, intermediate FCC ( $2.9 \pm 0.6\%$ , multiple samples) and  
225 Sept. SIC ( $22 \pm 15\%$ , multiple samples) values throughout the 126-120 ka interval, **but** the Sept. SICs  
226 are much more variable than in TPC287 (Figure 3).

227 All three Atlantic sector cores (TPC290, TPC288 and TPC287) have a strong match between the FCC  
228 and Sept. SIC variations ( $p = 0.05$ ,  $p < 0.01$  and  $p < 0.01$  respectively), with the notable exception of the  
229 TPC287 sample at  $\sim 129 \pm 2.6$  ka, which has a very high Sept. SIC (86 %) but a relatively low FCC relative  
230 abundance (3.4 %). **For this sample, only a single modern analog could be identified, indicating that**  
231 **the fossil diatom assemblage is different from almost everything in the modern reference database.**  
232 **The single selected analog is not chosen by the transfer function for any of the other MIS 5e samples**  
233 **from core TPC287, indicating that it is unlikely to be a truly representative modern analog for the MIS**  
234 **5e condition at this core site. The location of this single selected analog, which is further south than**  
235 **any of the analogs chosen for the other MIS 5e samples from core TPC287, suggests that the fossil**  
236 **assemblage has been biased towards colder, heavier sea-ice conditions, probably due to dissolution**  
237 **or transport of the preserved assemblage.** Thus, the reconstructed Sept. SIC for this sample is  
238 disregarded from the analysis. There are two MIS 5e samples in TPC290 (at  $124.7 \pm 2.6$  ka and  $122.8 \pm$   
239  $2.6$  ka), for which none of the reference surface sediment samples were below the dissimilarity  
240 threshold (see section 2.3 for details) and thus no MAT estimate of Sept. SIC (or SSST) is given for those  
241 samples.

242

**Figure 3:** Down-core September SICs, determined using the MAT, and FCC relative abundances for the 132-120 ka interval in nine marine sediment cores. The blue shading indicates the FCC relative abundance, with the colour saturation varying between SO sectors. The solid black lines indicate the September SICs with the gaps in the TPC290 record caused by two samples being too dissimilar from all modern reference samples, so that the latter cannot be considered as analogs. Dashed lines mark the mean WSIE thresholds of 3 % FCC abundance (blue lines) and 15 % Sept. SIC (black lines). Within each SO sector cores are arranged from north to south.

243 To check for other potentially anomalous palaeo-reconstructions, the number of times each modern  
 244 reference sample was selected as an analog were considered (Supplementary Figure 2). Fossil samples  
 245 were separated into three MIS 5e-Termination II time intervals (following the approach of Chadwick  
 246 et al. (2022)) and modern reference samples that are only selected as analogs for a small number (<5)  
 247 of fossil samples were identified (Supplementary Figure 2). None of these less-selected reference  
 248 samples are the primary or sole analog for an MIS 5e fossil sample and are therefore unlikely to result  
 249 in an unrepresentative Sept. SIC (or SSST) reconstruction.

250 The two East Indian sector cores (MD03-2603 and U1361A) have similar average MIS 5e FCC relative  
 251 abundances ( $3.2 \pm 1\%$  and  $3.9 \pm 1.5\%$ ) to each other but the average Sept. SIC ( $19 \pm 15\%$  and  $27 \pm 25$   
 252 %) is nearly 10 % higher in U1361A. However, the MIS 5e variability in Sept. SIC within each core is  
 253 greater than this difference between the two cores. Core MD03-2603 has three Sept. SIC maxima of  
 254 >40 % (single samples) during MIS 5e, at  $124.1 \pm 2.6$  ka,  $127.3 \pm 2.6$  ka and  $128.8 \pm 2.6$  ka, as well as  
 255 three minima of <5 % (single samples) at  $121.5 \pm 2.6$  ka,  $123.3 \pm 2.6$  ka and  $129.5 \pm 2.6$  ka (Figure 3).  
 256 Contrastingly, the nearby core from Hole U1361A (Figure 1) has a maximum in MIS 5e Sept. SIC (76.4  
 257 %, single sample) at  $128.4 \pm 2.7$  ka and a minimum (0 %, single sample) at  $123.7 \pm 2.7$  ka (Figure 3).

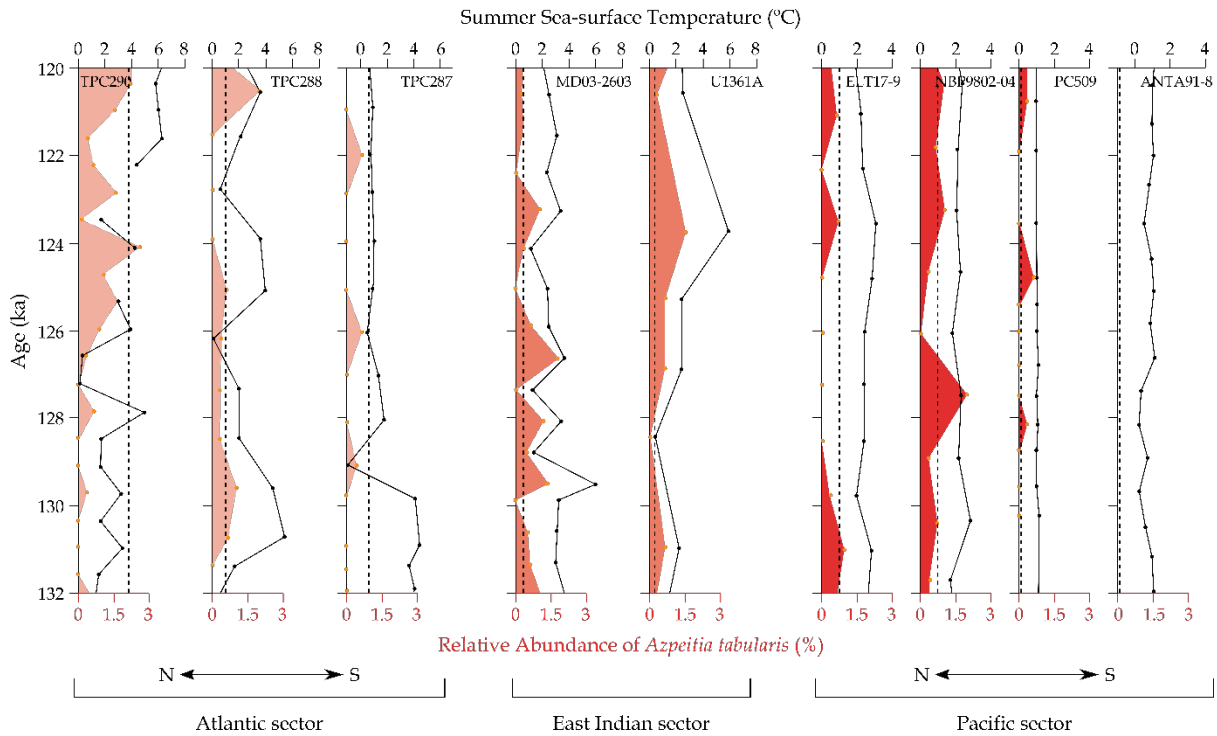

258 Together these two records suggest that the greatest MIS 5e Sept. SICs in the East Indian sector  
259 occurred during the 129-127 ka interval and the minimum was at 123.5-121 ka (Figure 3).

260 Unlike the Atlantic and East Indian sectors, the four cores from the Pacific sector (ELT17-9, NBP9802-  
261 04, PC509 and ANTA91-8) have low variability in their FCC relative abundances ( $1.4 \pm 0.6 \%$ ,  $2.3 \pm 1 \%$ ,  
262  $5.8 \pm 0.9 \%$  and  $11 \pm 1.9 \%$ ) and Sept. SICs ( $13 \pm 4 \%$ ,  $8.4 \pm 5.7 \%$ ,  $34 \pm 2 \%$  and  $48 \pm 11 \%$ ) throughout  
263 MIS 5e, with no pronounced maxima or minima (Figure 3). The northernmost Pacific sector core  
264 ELT17-9 has the lowest average MIS 5e FCC relative abundance ( $1.4 \pm 0.6 \%$ ) but the more southerly  
265 core NBP9802-04 has the lowest average MIS 5e Sept. SIC ( $8.4 \pm 5.7 \%$ ). The two most southerly Pacific  
266 sector cores (PC509 and ANTA91-8) have the highest average MIS 5e Sept. SICs and FCC relative  
267 abundances of all the cores analysed for this study.

#### 268 4.2. *Sea-surface temperatures*

269 For the Atlantic sector cores the average MIS 5e SSSTs ( $3.2 \pm 1.9 \text{ }^\circ\text{C}$ ,  $2.7 \pm 1.6 \text{ }^\circ\text{C}$  and  $2.2 \pm 1.5 \text{ }^\circ\text{C}$ ) show  
270 an inverse trend to Sept. SICs with higher values in more northerly cores. Both TPC288 and TPC287  
271 have their highest MIS 5e SSSTs during the 131-129 ka interval ( $5 \text{ }^\circ\text{C}$  and  $4.3 \text{ }^\circ\text{C}$ , respectively, multiple  
272 samples) followed by a SSST minimum at  $\sim 126 \pm 2.6 \text{ ka}$  ( $0.1 \text{ }^\circ\text{C}$  and  $0.6 \text{ }^\circ\text{C}$ , respectively, single samples)  
273 (Figure 4). In contrast, the warmest MIS 5e SSSTs for TPC290 occur in the youngest part of the record,  
274 with an average of  $6 \text{ }^\circ\text{C}$  in the 122-120 ka period (Figure 4). The relative abundance of *A. tabularis* in  
275 core TPC290 shows a good consistency ( $p = 0.01$ ,  $R^2 = 0.34$ ) with the SSST pattern during MIS 5e, with  
276 the highest relative abundances ( $1.3 \pm 0.8 \%$ , multiple samples) observed after  $126 \pm 2.6 \text{ ka}$  (Figure 4).  
277 The southernmost core TPC287 from the Atlantic sector shows a very poor match between MIS 5e  
278 SSSTs and *A. tabularis* relative abundances ( $p = 0.3$ ,  $R^2 = 0.09$ ). This lack of correlation is likely due to  
279 the scarcity of *A. tabularis* at this site throughout MIS 5e, as can be seen in modern surface sediments  
280 (Chadwick, 2020), and thus a single valve can create a relative abundance peak that may be largely  
281 unrelated to the SSST trends.

282 The East Indian sector cores have similar average SSSTs ( $2.8 \pm 1.1 \text{ }^\circ\text{C}$  and  $2.4 \pm 1.7 \text{ }^\circ\text{C}$ ). However, unlike  
283 for the Sept. SICs (Figure 3), the MIS 5e SSST minima and maxima in cores MD03-2603 and U1361A  
284 occur at different times (Figure 4). SSSTs in core U1361A fall to a minimum of  $0.7 \text{ }^\circ\text{C}$  (single sample) at  
285  $\sim 128 \pm 2.7 \text{ ka}$  before rising to a maximum of  $5.9 \text{ }^\circ\text{C}$  (single sample) at  $\sim 124 \pm 2.7 \text{ ka}$ . In contrast, SSSTs  
286 in core MD03-2603 reach an early peak of  $5.9 \text{ }^\circ\text{C}$  (single sample) at  $\sim 129.5 \pm 2.6 \text{ ka}$  and have minima  
287 of  $\sim 1 \text{ }^\circ\text{C}$  (single samples) at  $124.1 \pm 2.6 \text{ ka}$ ,  $127.3 \pm 2.6 \text{ ka}$  and  $128.8 \pm 2.6 \text{ ka}$  (Figure 4). Both MD03-  
288 2603 and U1361A show a strong coherence between the MIS 5e SSSTs and the *A. tabularis* abundance  
289 ( $p = 0.01$ ,  $R^2 = 0.4$  and  $p < 0.01$ ,  $R^2 = 0.92$  respectively).

290

**Figure 4:** Down-core summer (January to March) SSTs, determined using the MAT, and the relative abundance of *Azpeitia tabularis* for the 132-120 ka interval in nine marine sediment cores. The red shading indicates the relative abundance of *A. tabularis*, with the colour saturation varying between SO sectors. The solid black lines indicate the SSSTs with the gaps in the TPC290 record caused by two samples being too dissimilar from all modern reference samples, so that the latter cannot be considered as analogs. Black dashed lines mark the modern (Jan-Mar, 1980-2019) SSSTs at each core site (Hersbach et al., 2019). Within each SO sector cores are arranged from north to south.

291 In the Pacific sector cores, SSSTs are largely consistent throughout MIS 5e, with averages of  $2.5 \pm 0.3$   
 292 %,  $2.2 \pm 0.3$  %,  $1.03 \pm 0.03$  % and  $0.8 \pm 0.3$  % (Figure 4). Although there is very little variation in MIS 5e  
 293 SSSTs in all four records, both core NBP9802-04 and core PC509 reveal maximum SSSTs ( $2.8$  °C and  $1.1$   
 294 °C, respectively, single samples) at  $\sim 130 \pm 2.7$  ka (Figure 4). None of the Pacific sector cores show a  
 295 strong match between MIS 5e SSSTs and the relative abundance of *A. tabularis*. For the more southerly  
 296 core PC509 this poor correlation ( $p = 0.65$ ,  $R^2 = 0.02$ ) is likely caused by the same scarcity of *A. tabularis*  
 297 as for core TPC287 in the Atlantic sector.

## 298 5. Discussion

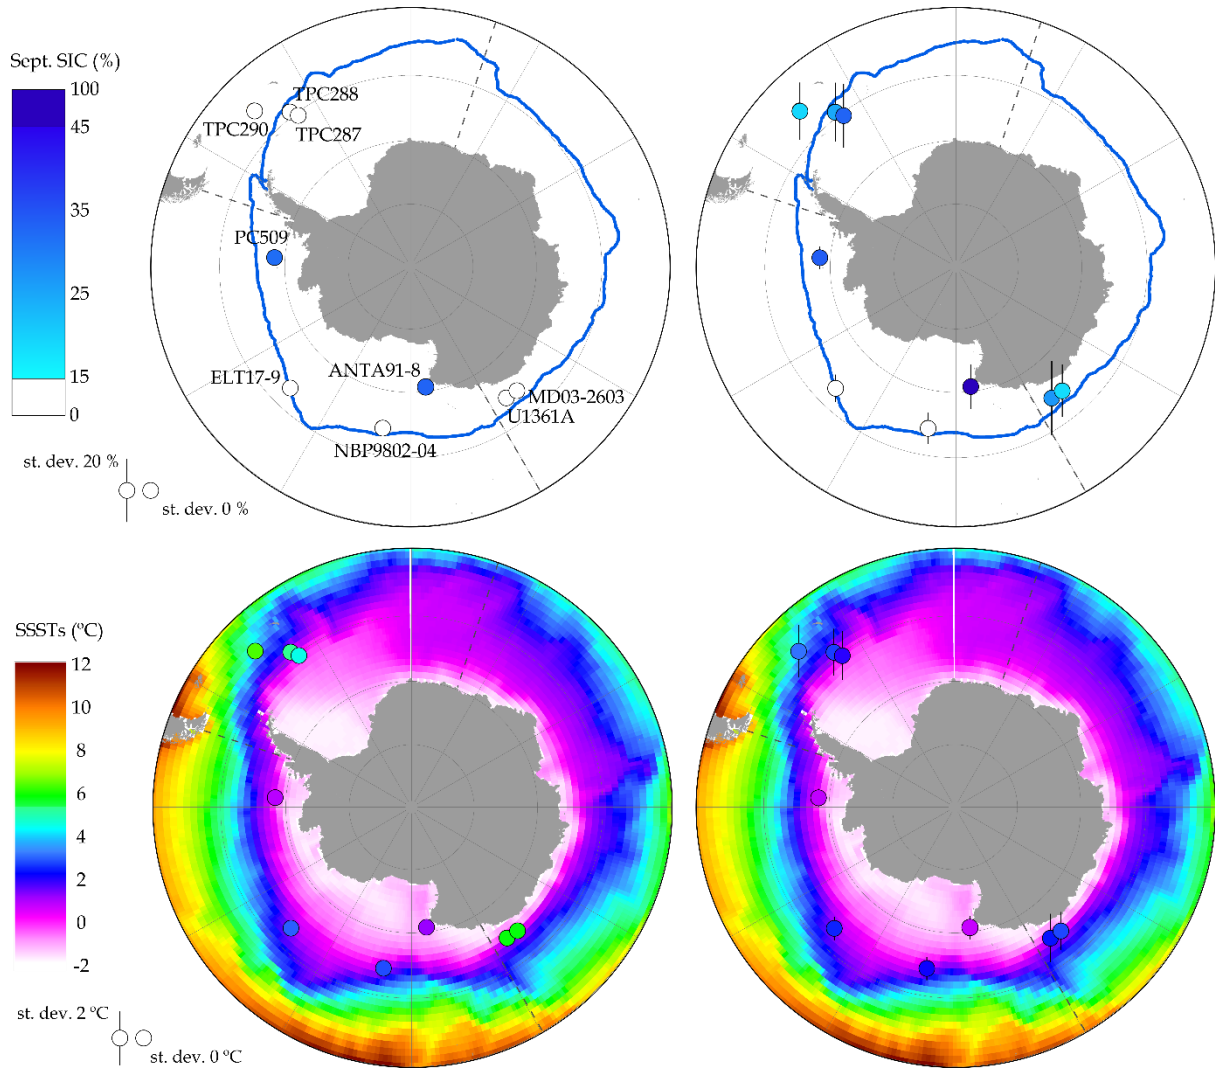

299 Both the Sept. SICs and FCC relative abundances indicate substantial differences in the pattern of MIS  
 300 5e WSIE change between the three SO sectors, most notably between the Atlantic and Pacific sectors.  
 301 In all three Atlantic sector records, the FCC relative abundances and Sept. SICs indicate year-round  
 302 open marine conditions and thus a poleward contraction of the mean WSIE (FCC <3 % (Gersonde and  
 303 Zielinski, 2000) and Sept. SIC <15 % (Zwally et al., 2002)) during the 131-130 ka interval. This minimum  
 304 is succeeded by a re-expansion of sea ice to a maximum extent in the 127-126 ka interval when all

305 three core sites were covered by WSI. An early minimum in MIS 5e WSIE succeeded by a maximum ~4  
306 ka later is a consistent, but offset, pattern as the FCC relative abundance in nearby core PS2305-6  
307 (Figure 1; 58.72 °S, 33.04 °W) (Bianchi and Gersonde, 2002; Chadwick et al., 2020).

308 We cannot rule out that the apparent retreat in Atlantic sector sea ice to a minimum during  
309 Termination II followed by a sea-ice expansion coincident with peak Antarctic air temperatures is an  
310 artefact caused by chronological uncertainties, with the WSIE minimum actually occurring alongside  
311 the peak Antarctic air temperatures at  $\sim 128 \pm 1.5$  ka (Holloway et al., 2017; Parrenin et al., 2013a).  
312 However, a genuine early (i.e., before 130 ka) retreat in Atlantic sector sea ice would also be consistent  
313 with most of the Termination II and MIS 5e records from this sector analysed by Bianchi and Gersonde  
314 (2002). Model experiments by Menviel et al. (2010) have demonstrated that during early MIS 5e the  
315 release of vast quantities of glacial meltwater into the surface waters of the Antarctic Zone (i.e., the  
316 region south of the Antarctic Polar Front) caused by Antarctic ice sheet deglaciation, especially the  
317 potential partial or total loss of the West Antarctic Ice Sheet (WAIS), would have led to SST reduction  
318 and equatorward sea-ice expansion. Importantly, this meltwater injection into the SO, which is  
319 supported by the observation of meltwater “spikes” characterizing planktic foraminifera  $\delta^{18}\text{O}$  data in  
320 cores from the Weddell Sea continental margin during glacial-interglacial transitions (Grobe et al.,  
321 1990), would also have resulted in a warming of subsurface waters that, in turn, would have triggered  
322 further ocean-forced melting of the ice-sheet grounding zones, especially of the predominantly  
323 marine-based WAIS, thus kick starting a positive feedback loop (Bronsele et al., 2018; Menviel et al.,  
324 2010). Because of their location within “Iceberg Alley”, a main pathway of Antarctic icebergs travelling  
325 with the clockwise Weddell Gyre from the southern Weddell Sea Embayment into the Scotia Sea  
326 (Weber et al., 2014), core TPC290 and especially cores TPC287 and TPC288 can be expected to be  
327 particularly sensitive for recording such meltwater supply.

328 In fact, the MIS 5e WSIE maximum in the Atlantic sector records coincides, within chronological  
329 uncertainty, with higher global sea level (Kopp et al., 2013) and evidence for increased meltwater flux  
330 in the Weddell Sea (Chadwick et al., 2022), which both indicate substantial mass loss from the  
331 Antarctic ice sheets, consistent with findings of major ice loss in the Weddell Sea sector during MIS 5e  
332 (Turney et al., 2020). Higher glacial meltwater fluxes associated with increased ice-sheet loss could  
333 therefore be a major driver of the WSIE expansion in the Atlantic sector records as less saline surface  
334 waters freeze more easily (Bintanja et al., 2013; Merino et al., 2018). The peak in FCC abundance in  
335 core TPC287 at  $126 \pm 2.6$  ka is primarily a peak in the abundance of *F. cylindrus* (Chadwick and Allen,  
336 2021f). *Fragilariopsis cylindrus* generally dominates water column diatom assemblages in both ice-  
337 covered (Burckle et al., 1987) and marginal sea-ice zones (Kang and Fryxell, 1992, 1993; Kang et al.,  
338 1993). The occurrence of high modern *F. cylindrus* abundances in marginal sea-ice zones indicates that

339 this species is not purely associated with sea-ice, from which it might have been seeded when  
 340 retreating, but also strongly affiliated with sea-ice melt and strong surface stratification (Cremer et al.,  
 341 2003; Kang and Fryxell, 1993; von Quillfeldt, 2004). The peak in *F. cylindrus* abundances at  $126 \pm 2.6$   
 342 ka in core TPC287, separate from any notable increase in *F. curta* abundance, therefore supports an  
 343 increased glacial meltwater signal at this time.

**Figure 5:** Maps of MIS 5e SSSTs and Sept. SICs for the nine core sites compared with the modern conditions. On all maps the SO sector boundaries are marked with dashed lines. **Top left:** Minimum MIS 5e Sept. SIC for each core site (coloured circles) compared to the modern (1981-2010) 15 % September sea-ice extent (blue line) (Fetterer et al., 2017). **Top right:** Average MIS 5e Sept. SICs (coloured circles) and standard deviations (vertical bars) at each core site compared to the modern (1981-2010) 15 % September sea-ice extent (blue line) (Fetterer et al., 2017). **Bottom left:** Maximum MIS 5e SSSTs for each core site (coloured circles) compared to modern (Jan-Mar, 1980-2019) SSSTs (Hersbach et al., 2019). **Bottom right:** Average MIS 5e SSSTs (coloured circles) and standard deviations (vertical bars) for each core site compared to modern (Jan-Mar, 1980-2019) SSSTs (Hersbach et al., 2019). Core data are given in Supplementary Table 1.

344 The discrepancy between Sept. SICs and FCC relative abundances at  $\sim 127 \pm 2.6$  ka in core TPC290  
345 (Figure 3) is likely due to increased *Chaetoceros* resting spore (rs.) abundance at this time (Chadwick  
346 and Allen, 2021h). This *Chaetoceros* rs. abundance increase is also observed in the nearby core  
347 PS2305-6 (Bianchi and Gersonde, 2002) and is inferred to be caused by higher meltwater and iceberg  
348 flux at this time (Bianchi and Gersonde, 2002; Crosta et al., 1997). For core TPC290, there is a scarcity  
349 of modern analogs from the Scotia Sea region (Figure 1) and thus, the high *Chaetoceros* rs. abundances  
350 in MIS 5e samples are associated with modern analogs from sites along the Antarctic Peninsula, where  
351 SICs are greater than in the Scotia Sea.

352 Atlantic sector SSSTs reach their maxima during Termination II before a substantial drop coincident  
353 with the peak Antarctic air temperatures in ice cores (Parrenin et al., 2013a). As with the down-core  
354 Sept. SIC profiles, this offset may result from chronological uncertainties, with the highest SSSTs  
355 actually occurring alongside peak Antarctic air temperatures at  $\sim 128 \pm 1.5$  ka. However, air  
356 temperature and SST reconstructions from the Antarctic Peninsula and Scotia Sea have shown that  
357 during Termination I temperatures peaked at higher values than during the Holocene (Mulvaney et  
358 al., 2012; Xiao et al., 2016), thus, our records could indicate an equivalent early warming during  
359 Termination II for this region. Also, if the high air temperatures at  $\sim 128 \pm 1.5$  ka caused substantial  
360 Antarctic ice sheet loss, then the cold SSSTs in our ice-sheet proximal records at this time could, as  
361 discussed above, actually reflect major input of cold and fresh meltwater not recorded in cores further  
362 north.

363 In the East Indian sector, core MD03-2603 has an average MIS 5e Sept. SIC ( $25 \pm 18$  %) and FCC relative  
364 abundance ( $3.2 \pm 1$  %) indicative of a location just south of the mean WSIE (Figures 3 & 5) but with  
365 multiple maxima and minima contributing to the high variability. MIS 5e Sept. SICs and FCC relative  
366 abundances in the nearby core U1361A indicate that it was located within the seasonal sea-ice zone  
367 from 132-126 ka before the mean WSIE retreated to the south of this location (Figure 3 &  
368 Supplementary Figure 3). The different patterns in MIS 5e Sept. SIC and SSSTs between cores MD03-  
369 2603 and U1361A are likely due to the different age resolution of the samples, with two of the Sept.  
370 SIC maxima in MD03-2603 occurring in the 129-127 ka interval coincident with the U1361A Sept. SIC  
371 maximum, and likewise, two of the Sept. SIC minima in MD03-2603 occurring in the 124-121 ka period  
372 concurrent with the minimum Sept. SIC in core U1361A (Figure 3). The different age resolution of  
373 samples in MD03-2603 and U1361A is primarily due to the lower sedimentation rate (Table 2) at site  
374 U1361A, and thus a sample from this core spans more time than in core MD03-2603.

375 None of the Pacific sector cores show pronounced minima or maxima in their MIS 5e FCC and Sept.  
376 SIC records (Figure 3), indicating a less variable WSIE in this sector compared to the Atlantic and Indian

377 sectors (Figure 3). The Pacific sector cores PC509 and ANTA91-8 are also the only cores in this study  
378 which are covered by WSI for the entirety of MIS 5e (Figure 3 & 5). The position of these cores south  
379 of the mean WSIE throughout MIS 5e is significant as they are the first published marine records from  
380 within the seasonal sea-ice zone and able to constrain the poleward limit of the MIS 5e minimum WSIE  
381 (Chadwick et al., 2020). Cores ELT17-9 and NBP9802-04 are the only records in this study with average  
382 MIS 5e Sept. SICs <15 % (Figure 5), indicating they were located north of the mean WSIE for the  
383 majority of the 132-120 ka period, with core ELT17-9 having been located closer to the MIS 5e mean  
384 WSIE. The FCC relative abundances for cores ELT17-9 and NBP9802-04 also indicate that both sites  
385 were predominantly positioned north of the mean WSIE during MIS 5e (Figure 3) but suggest that core  
386 NBP9802-04 was located closer to the MIS 5e mean WSIE.

387 The reconstructed MIS 5e Sept. SICs for site ELT17-9 are higher than for site NBP9802-04 (Figure 3)  
388 which is likely related to the higher abundance of *Chaetoceros* rs. in core ELT17-9 when compared to  
389 core NBP9802-04 (Chadwick and Allen, 2021b, d). The *Chaetoceros* rs. group is associated with both  
390 WSI (Armand et al., 2005) and meltwater stratification (Crosta et al., 1997), and high abundances of  
391 *Chaetoceros* rs. in Ross Sea sediments deposited during past interglacial periods have been linked to  
392 increased upwelling and subsequent meltwater stratification within the Ross Sea Gyre (Kim et al.,  
393 2020). The high *Chaetoceros* rs. abundance in core ELT17-9 during MIS 5e could therefore indicate an  
394 north-eastward shift of the Ross Sea Gyre from its modern day position (Dotto et al., 2018) and an  
395 accompanying displacement of meltwater circulation (Merino et al., 2016) and the WSI edge in the  
396 Pacific sector. It is also possible that the reduced Pacific sector WSIE during MIS 5e is associated with  
397 earlier seasonal sea-ice retreat during the austral spring and a longer open-ocean season, promoting  
398 a stronger spring bloom signal, of which the *Chaetoceros* group is a major component (Leventer,  
399 1991).

400 The average MIS 5e SSSTs in the nine cores are ~1-2 °C warmer than the modern SSSTs (Figure 5),  
401 consistent with the SST anomalies presented in Chadwick et al. (2020) and Capron et al. (2014).  
402 However, the SSST records in the Atlantic and East Indian sectors have large variability with maximum  
403 SSSTs that are 2-4 °C higher than the MIS 5e average SSSTs (Figure 5). Maximum MIS 5e SSSTs in the  
404 Atlantic and East Indian sectors were therefore ~3-5 °C warmer than modern SSSTs (Figure 5), which  
405 is a much larger SSST anomaly than in the Antarctic Zone records presented in Chadwick et al. (2020),  
406 and marks a ~5 degrees latitude poleward shift in SSST isotherms relative to the present. Unlike the  
407 Atlantic and East Indian sectors, the Pacific sector core records indicate low variability in MIS 5e SSSTs  
408 with peak values 0-2 °C warmer than present (Figure 5) marking a poleward shift in SSST isotherms of  
409 <3° latitude.

410 Within their chronological uncertainties (Table 2), cores TPC288, TPC287, MD03-2603, ELT17-9,  
411 NBP9802-04 and PC509 all reach minimum MIS 5e Sept. SICs synchronously (Supplementary Table 1)  
412 and coincident with the peak in Antarctic air temperatures and minimum in EPICA Dome C (EDC) sea-  
413 salt sodium flux ( $Na_{ss}$ ) at  $\sim 128 \pm 1.5$  ka (Holloway et al., 2017; Wolff et al., 2006). The two East Indian  
414 sector core records reach a minimum MIS 5e WSIE (and maximum SSST in core U1361A)  $\sim 4.5$  ka after  
415 the  $Na_{ss}$  minimum in Antarctic ice cores, outside of the combined chronological uncertainties of the  
416 sediment cores (Table 2) and AICC2012 ice core chronology (Bazin et al., 2013). Although the duration  
417 of the SSST maximum, and accompanying WSIE minimum, in core MD03-2603 is short, it occurs within  
418 chronological error of the maximum air temperatures in Antarctic ice cores (Figures 3 & 4).

419 Satellite era trends in Antarctic winter SIC (Hobbs et al., 2016) are largely consistent with the patterns  
420 observed during MIS 5e. Northern Weddell Sea winter SIC has declined by 5-10 % per decade in the  
421 satellite era (Hobbs et al., 2016) indicating a sensitivity to warming consistent with the early retreat  
422 of MIS 5e sea ice in this region. Similarly, winter SICs in the Pacific sector have remained stable, or  
423 even slightly increased, during the satellite era (Hobbs et al., 2016) which is in agreement with the  
424 stability of the Pacific sector WSIE throughout MIS 5e. In recent decades, Bellingshausen Sea summer  
425 sea ice has decreased, whilst WSIE has stayed stable (Hobbs et al., 2016; Parkinson, 2019). The MIS 5e  
426 Sept. SICs and SSSTs (as a proxy for summer sea ice) imply that the MIS 5e WSIE in the Bellingshausen  
427 Sea is similar to the modern but the summer sea-ice extent was reduced. The northern part of the  
428 Ross Sea is a region in which the modern and MIS 5e trends differ, with recent winter SIC increases of  
429 10-15 % per decade contrasting with the MIS 5e WSIE reduction observed at site NBP9802-04.

## 430 **6. Wider implications**

431 During MIS 5e the three SO sectors display heterogeneous responses in WSIE and SSSTs, which may  
432 guide our predictions of the impact of future warming on the Antarctic region. The prominent early  
433 (131-130 ka) minimum in WSIE and coinciding maximum in SSSTs for the two southerly Atlantic sector  
434 cores (TPC288 and TPC287, Figure 3) is associated with a mean WSI edge located at least 3-5 ° south  
435 of its modern position. This substantial reduction in WSIE and seasonal sea-ice cover would have  
436 reduced brine rejection and likely decreased the rates of deep and bottom water formation in the  
437 Weddell Sea, causing a warming of the abyssal waters (Bouttes et al., 2010; Marzocchi and Jansen,  
438 2019). Deep water warming would have promoted the basal melting and retreat of Weddell Sea ice  
439 shelves and marine terminating ice streams and caused substantial Antarctic ice sheet mass loss  
440 (Hellmer et al., 2012; Rignot et al., 2019; Wahlin et al., 2021). We hypothesise that substantial mass  
441 loss from the Weddell Sea sector of the WAIS (Turney et al., 2020) drove the Atlantic sector WSI

442 resurgence at  $\sim 126 \pm 2.6$  ka, as suggested by the model experiments of Menviel et al. (2010), and  
443 contributed to the global sea-level rise at this time (Kopp et al., 2013; Sime et al., 2019).

444 Variations in the WSIE and SSST records between the East Indian sector cores MD03-2603 and U1361A  
445 are due to the differences in sampling resolution, with the MD03-2603 record indicating multiple  
446 relatively short duration WSIE and SSST oscillations during MIS 5e. The U1361A record seems to  
447 present an averaged signal of these oscillations with a greater frequency of warm periods with  
448 reduced WSIE after  $125 \pm 2.7$  ka. Along the modern Wilkes Land margin the Antarctic Circumpolar  
449 Current (ACC) flows much closer to the continent than in other regions (Tamsitt et al., 2017) and the  
450 MIS 5e record in core MD03-2603 could therefore suggest multiple intervals when the ACC was  
451 displaced to the south of its modern position. A more southerly ACC in this region would have caused  
452 a poleward shift in precipitation fields and resulted in drier conditions across Southern Australia (Liu  
453 and Curry, 2010; Saunders et al., 2012), a trend that can already be observed under a modern warming  
454 climate (CSIRO, 2018). A southerly shift of the ACC would also increase the advection of warmer  
455 Circumpolar Deep Water onto the Antarctic continental shelf (Fogwill et al., 2014), promoting periods  
456 of high basal melting and ice sheet retreat in Wilkes Land during MIS 5e, as supported by Wilson et al.  
457 (2018).

458 In contrast to the Atlantic and East Indian sectors, the Pacific sector records indicate a more stable  
459 WSIE throughout MIS 5e. The MIS 5e Sept. SIC records of cores ELT17-9 and NBP9802-04 indicate a  
460 poleward shift in the mean WSI edge by at least  $2^\circ$  of latitude relative to the modern. The PC509  
461 record indicates a southerly shift in the mean WSI edge by  $<2^\circ$  latitude. This highlights a seemingly  
462 greater resilience of sea ice in the Bellingshausen Sea, with the WSI edge remaining north of  $68^\circ\text{S}$   
463 throughout MIS 5e, possibly in response to major glacial meltwater release from the Bellingshausen  
464 Sea drainage basin of the WAIS. In the modern Pacific sector the WSIE is strongly constrained by the  
465 southern extent of the ACC and the configuration of the Ross Sea Gyre (Benz et al., 2016; Nghiem et  
466 al., 2016). An uneven poleward constriction of the ACC across the Pacific sector during MIS 5e could  
467 therefore help explain the differing WSI retreat in this sector, with greater poleward migration of the  
468 ACC and reduction in the Ross Sea Gyre northward extent in the western Pacific sector than in the  
469 eastern Pacific sector. However, unlike in the East Indian sector, there is no evidence for millennial-  
470 scale migration of the ACC across the Pacific sector. The stable and persistent WSIE in the Pacific sector  
471 during MIS 5e may have resulted from major WAIS deglaciation (Menviel et al., 2010), but then  
472 protected further melting of ice shelves in the Ross, Amundsen and Bellingshausen seas which  
473 buttressed ice grounded further upstream (Massom et al., 2018). This buttressing may have acted as  
474 a stabilising factor preventing total loss of the WAIS during MIS 5e, with the majority of its deep  
475 subglacial basins terminating in the Ross, Amundsen and Bellingshausen Seas (Gardner et al., 2018).

476 The sensitivity of Weddell Sea WSI to warmer climates could have substantial implications for the SO  
477 biosphere given the high rates of primary productivity in this region today (Vernet et al., 2019). Whilst  
478 a future reduction in WSIE and increase in glacial meltwater flux would be expected to promote  
479 primary productivity in the western part of the Weddell Sea (de Jong et al., 2012), the higher SSTs  
480 would not favour key trophic intermediaries, e.g. Antarctic krill (*Euphausia superba*) (Atkinson et al.,  
481 2017; Siegel and Watkins, 2016), and would therefore negatively affect megafauna at higher trophic  
482 levels (Hill et al., 2013). The impacts of warming and reduced WSIE on the SO food web are seen along  
483 the Antarctic Peninsula in the present day, with a recent shift in phytoplankton community structure  
484 from diatoms to smaller cryophytes, which are less efficiently grazed by Antarctic krill (Mendes et al.,  
485 2018; Moline et al., 2004). Future WSI edge retreat, at equivalent levels to MIS 5e, would also  
486 negatively impact upon modern sea-ice obligate species, such as Emperor and Adélie Penguins (Cimino  
487 et al., 2013; Jenouvrier et al., 2005).

## 488 **7. Conclusions**

489 Similarly to the modern SO (Parkinson, 2019), WSIE trends during MIS 5e show both spatial and  
490 temporal heterogeneity. The Atlantic and East Indian sectors display more variable WSIE and SSTs  
491 during MIS 5e than the Pacific sector. High Atlantic sector environmental variability during MIS 5e is  
492 attributed to high glacial meltwater release from the Weddell Sea drainage sector of the WAIS,  
493 whereas the high variability in the East Indian sector is attributed to large latitudinal migrations of the  
494 ACC flow bands occurring on a millennial timescale. In contrast, the stability of the Pacific sector WSIE  
495 may be due to the local bathymetric pinning of the ACC limiting the possible poleward displacement  
496 of the ACC during MIS 5e.

497 The greater MIS 5e WSIE reduction in the Atlantic sector compared to the Pacific sector is consistent  
498 with recent model simulations (Holloway et al., 2017). Most of the core records in this study reach  
499 their minimum WSIE at the same time, i.e., within chronological uncertainties, as the  $128 \pm 1.5$  ka  
500 minimum in Antarctic ice core  $\text{Na}_{ss}$  flux (Wolff et al., 2006), with only cores TPC290 and U1361A  
501 indicating a later WSIE minimum (Figure 3 & Supplementary Figure 3). The apparent high sensitivity  
502 of Weddell Sea WSIE, and apparent resilience of Bellingshausen Sea WSIE, to warmer than present  
503 climates is unexpected from the recent observational trends (Hobbs et al., 2016; Parkinson, 2019), but  
504 may be related to regionally variable influx of glacial meltwater and its advection around the Antarctic  
505 continent. Our study highlights the importance of reconstructing palaeoenvironmental conditions  
506 around Antarctica during past warm periods, such as MIS 5e, for understanding how the Antarctic and  
507 SO regions respond to warmer climates on longer than decadal timescales.

508 **Data availability**

509 Full diatom count data for all samples are available from the NERC EDS UK Polar Data Centre (Chadwick  
510 and Allen, 2021a, b, c, d, e, f, g, h, i). Sept. SIC and SSST data for all samples, produced using the MAT  
511 transfer function, are available from PANGAEA (*in press*).

519 **Acknowledgements**

520 Funding for this work was provided by The Natural Environmental Research Council [grant number  
521 NE/L002531/1]. The British Ocean Sediment Core Research Facility (BOSCORF) is thanked for supplying  
522 sediment samples for core TPC287 and multi-sensor core logging of core PC509. We thank the Lamont-  
523 Doherty Core Repository of Lamont-Doherty Earth Observatory for providing sediment sample  
524 material for core NBP9802-04 (IGSN – DSR0003YW). The International Ocean Discovery Program  
525 (IODP) is thanked for providing the sample material for core U1361A. We also thank the Oregon State  
526 University Marine and Geology Repository for providing sediment samples for core ELT17-9, the  
527 Sorting Centre of MNA-Trieste (Italy) for providing sediment samples for core ANTA91-8 and S.J.  
528 Crowhurst from the Department of Earth Sciences, University of Cambridge (UK), for X-ray  
529 fluorescence scanning of core PC509.
