11 **Abstract**

12 Environmental conditions during Marine Isotope Stage (MIS) 5e (130-116 ka) represent an important
13 ‘process analogue’ for understanding the climatic responses to present and future anthropogenic
14 warming. The response of Antarctic sea ice to global warming is particularly uncertain due to the short
15 length of the observational record. Reconstructing Antarctic winter sea-ice extent during MIS 5e
16 therefore provides insights into the temporal and spatial patterns of sea-ice change under warmer
17 than present climate. This study presents new MIS 5e records from nine marine sediment cores
18 located south of the Antarctic Polar Front, between 55 and 70 °S. We investigate changes in winter
19 sea-ice extent and sea-surface temperatures between the three Southern Ocean sectors. The Atlantic
20 and Indian sector records have much more variable MIS 5e winter sea-ice extent and sea-surface
21 temperatures than the Pacific sector records. High variability in the Atlantic sector winter sea-ice
22 extent is attributed to high glacial meltwater flux in the Weddell Sea while high variability in the Indian
23 sector winter sea-ice extent results from large latitudinal migrations of the flow bands of the Antarctic
24 Circumpolar Current. Overall, these findings suggest that Pacific sector winter sea ice displays a low
25 sensitivity to warmer climates. The different variability and sensitivity of Antarctic winter sea-ice
26 extent in the three Southern Ocean sectors during MIS 5e may have significant implications for the
27 Southern Hemisphere climatic system under future warming.

28 **1. Introduction**

29 Antarctic sea ice is a critical part of the Southern Ocean (SO) and global climate system (Maksym,
30 2019). The vast extent of Antarctic sea ice and its huge seasonal variability (~4-18 x 10⁶ km² in the
31 present day) have a strong albedo-radiation feedback (Hall, 2004). Brine rejection during sea-ice
32 formation contributes to the production of dense shelf and bottom water masses, which, in turn,

33 influence the strength of global overturning ocean circulation (Abernathey et al., 2016; Rintoul, 2018).
34 Sea-ice cover also regulates heat and gas exchange between the SO and the atmosphere as well as
35 phytoplankton productivity by causing stratification of the upper part of the water column (Goosse
36 and Zunz, 2014) and acting as a physical barrier (Rysgaard et al., 2011) and barrier to sunlight.

37 Modern Antarctic sea-ice extent has shown a rapid decline since 2014 after four decades of gradual
38 expansion (Parkinson, 2019). Within this overall trend there is substantial spatial heterogeneity in
39 regional sea-ice trends, with decreases in the Bellingshausen and Amundsen seas concurrent with
40 increases in the Weddell Sea and Ross Sea sectors (Hobbs et al., 2016; King, 2014; Parkinson, 2019).
41 Alongside the interannual Antarctic sea-ice trends (Parkinson, 2019), there are also trends in seasonal
42 variability, with the Amundsen Sea showing a substantial decrease in summer and autumn sea-ice
43 concentrations but a slight increase in winter and spring sea-ice concentrations (Hobbs et al., 2016).
44 Model simulations are unable to replicate the modern sea-ice changes without reduced regional
45 warming trends (Rosenblum and Eisenman, 2017). Difficulties in reproducing modern sea-ice trends
46 indicate the complexities of the climate dynamics that influence sea-ice extent in the SO today at
47 different timescales (Ferreira et al., 2015; Hobbs et al., 2016; King, 2014; Purich et al., 2016;
48 Stammerjohn et al., 2008).

49 Rising greenhouse gas concentrations are driving current global warming, with polar regions warming
50 twice as fast (0.5 °C per decade) as the global average (IPCC, 2019) and Antarctic winter sea-ice extent
51 (WSIE) predicted to shrink by 24-34 % by C.E. 2100 (Meredith et al., 2019). However, the very short
52 length of observational records in high latitudes and together with the complexity of the climate
53 system, as mentioned above, limit our understanding of the underlying processes and ability to
54 accurately predict future changes. Past warm periods can help document the amplitude of sea-ice
55 extent reduction and, therefore, help guide our understanding of the impacts of future climate change
56 in polar regions.

57 Interglacial Marine Isotope Stage (MIS) 5e (130-116 ka) is the latest period when global mean annual
58 atmospheric temperatures were warmer than present (~1 °C; Fischer et al. (2018)) and global sea
59 levels were higher than present (~6-9 m; Kopp et al. (2009)). Summer sea-surface temperatures
60 (SSSTs) in the SO peaked at an average of 1.6 ± 1.4 °C warmer than present at and north of the modern
61 Antarctic Polar Front during this period (Capron et al., 2014; Shukla et al., 2021). MIS 5e warming is
62 primarily orbitally forced, unlike current and future anthropogenic warming which is driven by rising
63 greenhouse gas concentrations. Whilst MIS 5e cannot be considered a direct analogue for greenhouse
64 gas induced global warming it still represents an important 'process analogue' for understanding

65 climate mechanisms and responses that are active under warmer-than-present climate conditions
66 (Stone et al., 2016).

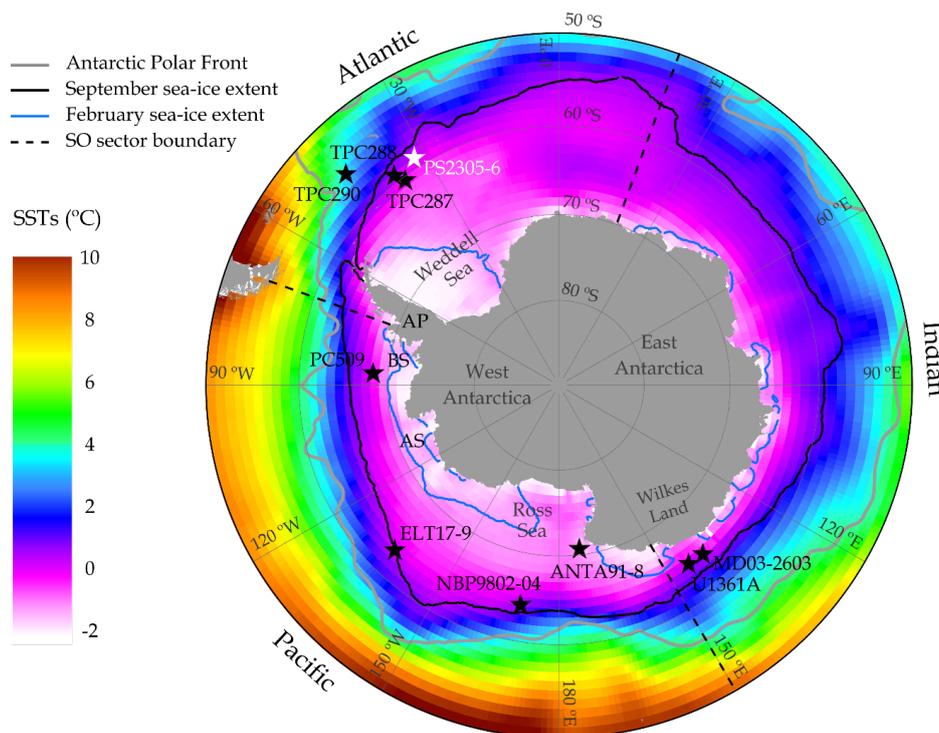

Figure 1: Map of core locations (black stars – this study, white star – Bianchi and Gersonde (2002)) with the modern (1981-2010) mean annual SSTs (COBE-SST2 dataset provided by the NOAA PSL, Boulder, Colorado, USA (<https://psl.noaa.gov/>)) and modern (1981-2010) median September and February sea-ice extents (data from Fetterer et al. (2017)). The black solid line is the September sea-ice extent (15 % cover) and the blue solid line is the February sea-ice extent (15 % cover). The grey solid line is the position of the modern Antarctic Polar Front (Trathan et al., 2000). The black dashed lines mark the boundaries between the three SO sectors (Atlantic, Indian and Pacific). AP – Antarctic Peninsula, BS – Bellingshausen Sea, AS – Amundsen Sea.

67 Diatoms preserved in SO marine sediments have been used for over 40 years to reconstruct past
68 changes in Antarctic sea-ice extent and sea-surface temperatures (SSTs) (Armand and Leventer, 2010;
69 Burckle et al., 1982; Thomas et al., 2019) due to the close relationship between their biogeographic
70 distribution patterns and surface water environmental conditions (Armand et al., 2005; Crosta et al.,
71 2005; Esper et al., 2010; Gersonde and Zielinski, 2000; Romero et al., 2005; Zielinski and Gersonde,
72 1997). Several previous studies have used model simulations, alongside limited data constraints from
73 marine sediment cores, to reconstruct SO WSIE and SSTs during MIS 5e (Capron et al., 2017; Holloway
74 et al., 2017; Holloway et al., 2018). However, there are currently no marine core records located far

75 enough south to constrain the predicted WSIE during MIS 5e (Chadwick et al., 2020; Holloway et al.,
76 2017). Due to chronological uncertainties in SO proxy records (Govin et al., 2015), previous studies
77 have assumed the minimum WSIE occurred synchronously around Antarctica and was coincident with
78 peak atmospheric temperatures in Antarctic ice cores at 128 ka (Holloway et al., 2017).

79 This study presents new reconstructions of SO winter sea ice (WSI) during MIS 5e from the diatom
80 assemblages preserved in nine marine sediment cores located south of 55 °S and south of the modern
81 Antarctic Polar Front (Figure 1). Quantitative and qualitative reconstructions of WSIE in the three SO
82 sectors; the Atlantic sector (70 °W – 20 °E), the Indian sector (20 °E – 150 °E) and the Pacific sector
83 (150 °E – 70 °W), are compared to answer the following questions:

- 84 - Did the minimum WSIE occur synchronously throughout the SO during MIS 5e?
- 85 - Was the WSIE minimum concurrent with the peak Antarctic air temperatures at 128 ka?
- 86 - Were the patterns in MIS 5e sea-ice change consistent between SO sectors?

87 **2. Materials and methods**

88 **2.1. Core sites**

89 The nine sediment cores used in this study are shown in Figure 1 alongside modern SSTs and sea-ice
90 extents. Details for each core are listed in Table 1. These cores were chosen as they contain >20 cm of

Core	Latitude (°), Longitude (°)	Water depth (m)	Cruise, Year	Ship	Core length (cm)
TPC290	-55.55, -45.02	3826	JR48, 2000	<i>RRS James Clark Ross</i>	1179*
TPC288	-59.14, -37.96	2864	JR48, 2000	<i>RRS James Clark Ross</i>	940*
TPC287	-60.31, -36.65	1998	JR48, 2000	<i>RRS James Clark Ross</i>	615*
MD03-2603	-64.28, 139.38	3320	MD130, 2003	<i>R/V Marion DuFresne II</i>	3033
U1361A	-64.41, 143.89	3459	IODP Exp. 318, 2010	<i>R/V JOIDES Resolution</i>	38800
ELT17-9	-63.08, -135.12	4935	ELT17, 1965	<i>R/V Eltanin</i>	2018
NBP9802-04	-64.20, -170.08	2696	PA9802, 1998	<i>R/V Nathaniel B. Palmer</i>	740
PC509	-68.31, -86.03	3559	JR179, 2008	<i>RRS James Clark Ross</i>	989
ANTA91-8	-70.78, 172.83	2383	ANTA91, 1990	<i>R/V Cariboo</i>	511

Table 1: Details of the location and recovery information for the nine marine sediment cores analysed in this study. Cores are ordered by sector (Atlantic-Indian-Pacific) and then latitude. * For each of the three TPC cores (TPC290, TPC288 and TPC287), the trigger core (TC) and piston core (PC) were spliced together to produce a composite record.

91 diatom rich MIS 5e sediments and are located further south than almost all existing MIS 5e sea ice
92 records (Chadwick et al., 2020).

93 2.2. Diatom counts

94 For the diatom assemblage data, microscope slides were produced using a method adapted from
95 Scherer (1994). Samples of 7-28 mg were exposed to 10% Hydrochloric acid to remove any carbonate,
96 30% Hydrogen peroxide to break down organic material and a 4% Sodium Hexametaphosphate
97 solution to promote disaggregation and placed in a warm water bath for a minimum of 12 hours. The
98 material was homogenised, transferred into a ~10 cm water column and allowed to settle randomly
99 onto coverslips over a minimum of 4 hours. The water was drained away and coverslips were mounted
100 on microscope slides with Norland Optical Adhesive (NOA 61). Slides were examined using a light
101 microscope (Olympus BH-2 at x1000 magnification) and a minimum of 300 diatom valves were
102 counted for each sample.

103 The combined relative abundance of *Fragilariopsis curta* and *F. cylindrus* (FCC) is used as a qualitative
104 indicator of WSI presence (Gersonde and Zielinski, 2000), with abundances >3 % associated with
105 locations south of the mean WSI edge, abundances 1-3 % found between the mean and maximum
106 WSI edge and abundances <1 % indicative of conditions north of the maximum WSI edge (Gersonde
107 et al., 2005; Gersonde and Zielinski, 2000).

108 2.3. Modern Analog Technique (MAT)

109 September sea-ice concentrations (SIC) and SSTs (January to March) are estimated by applying the
110 MAT transfer function, detailed in Crosta et al. (2020) , to the MIS 5e diatom assemblages. The MAT
111 compares the relative abundances of 33 diatom species in each MIS 5e sample to the abundances of
112 the same species in a modern reference dataset composed of 257 surface sediment samples (modern
113 analogs) from the SO. Modern conditions for each surface sediment sample are interpolated on a 1° x
114 1° grid, with SSTs from the World Ocean Atlas 2013 (Locarnini et al., 2013) and September SIC from
115 the numerical atlas of Schweitzer (1995). The MAT was implemented using the “bioindic” R-package
116 (Guiot and de Vernal, 2011), with chord distance used to select the 5 most similar modern analogs to
117 each MIS 5e assemblage. A cut-off threshold, above which any analogs are deemed too dissimilar to
118 the MIS 5e sample, is fixed as the first quartile of random distances determined by a Monte Carlo
119 simulation of the reference dataset (Simpson, 2007).

120 Quantitative estimates of September SIC and SSTs are produced for each MIS 5e sample from a
121 distance-weighted average of the climate values associated with the selected analogs. The
122 reconstructed SSTs have a Root Mean Square Error of Prediction (RMSEP) of 1.09 °C and an R² of

123 0.96, and the reconstructed September SIC have a RMSEP of 9 % and an R^2 of 0.93. It is also possible
 124 to get no-analog conditions, where none of the reference surface sediment samples are similar
 125 enough to a MIS 5e sample, and it is therefore not possible to reconstruct September SIC and SSST for
 126 this MIS 5e sample. The reconstructed September SIC and SSST for each MIS 5e sample only use
 127 analogs below the dissimilarity threshold and therefore could be reconstructed from less than 5
 128 analogs in some samples.

Core	SO sector	Chronology for MIS 5e	Chronological uncertainty (ka)
TPC290	Atlantic	Correlating MS from TPC290 to EDC ice core dust record combined with <i>C. davisiana</i> abundances (Pugh et al., 2009)*	± 2.58
TPC288	Atlantic	Correlating MS from TPC288 to EDC ice core dust record combined with <i>C. davisiana</i> abundances (Pugh et al., 2009)	± 2.59-2.64
TPC287	Atlantic	Correlating MS from TPC287 to MS in core TPC288 (Chadwick et al., <i>in review</i>)	± 2.57-2.65
MD03-2603	Indian	Correlating Ba/Al and Ba/Ti ratios from MD03-2603 to LR04 benthic oxygen isotope stack combined with diatom biostratigraphy (Presti et al., 2011)	± 2.55-2.56
U1361A	Indian	Correlating Ba/Al ratios and lithological changes to the LR04 benthic oxygen isotope stack combined with LOD <i>H. karstenii</i> (Wilson et al., 2018)	± 2.62-2.70
ELT17-9	Pacific	Combined abundance stratigraphies of <i>E. antarctica</i> and <i>C. davisiana</i> on SPECMAP age scale (Chase et al., 2003)	± 2.51
NBP9802-04	Pacific	Correlating MS from NBP9802-04 to EDC ice core dust record combined with LOD <i>H. karstenii</i> (Williams, 2017)	± 2.68
PC509	Pacific	Correlating wet bulk density (= proxy mirroring biogenic opal content) from PC509 to the LR04 benthic oxygen isotope stack (Chadwick et al., <i>in review</i>)	± 2.59-2.65
ANTA91-8	Pacific	Correlating MS from ANTA91-8 to the LR04 benthic oxygen isotope stack combined with LCO <i>Rouxia</i> spp. (this study; Figure 2)	± 2.60

Table 2: Summary of the location and chronologies for the nine sediment cores analysed in this study. Cores are ordered by sector (Atlantic-Indian-Pacific) and then latitude. LOD: Last Occurrence datum, LCO: Last Common Occurrence *For core TPC290 the chronology has been slightly adjusted from the published record of Pugh et al. (2009) by shifting the Termination II tiepoint to better align the magnetic susceptibility (MS) record with the dust record of the EPICA Dome C (EDC) ice core in East Antarctica (Chadwick et al. *in review*).

129 3. Age models

130 3.1. Published chronologies

131 Eight of the sediment cores presented in this study have previously published age models, summarised
 132 in Table 2. Cores TPC290, TPC288, TPC287 and NBP9802-04 are published on the EDC3 chronology,
 133 cores MD03-2603, U1361A and PC509 are published on the LR04 chronology and core ELT17-9 is
 134 published on the SPECMAP chronology. To allow for consistent comparison of timings between cores,

135 all cores are translated across onto the AICC2012 chronology (Bazin et al., 2013; Veres et al., 2013)
 136 using the alignment strategy in Govin et al. (2012) and the conversion tables in Lisiecki and Raymo
 137 (2005) and Parrenin et al. (2013).

138 Chronological uncertainties for the MIS 5e ages of samples in this study (Table 2) vary between 2.5
 139 and 2.7 ka. The AICC2012 chronology has an uncertainty of ± 1.5 ka during MIS 5e, with an additional
 140 uncertainty of ± 1 ka arising from the translation between chronologies (Capron et al., 2014). Each core
 141 sample comprises a 0.5 cm thick slice of sediment, and therefore additional age uncertainty due to
 142 integrating over the corresponding time interval in each core needs to be taken into account (see
 143 Table 2).

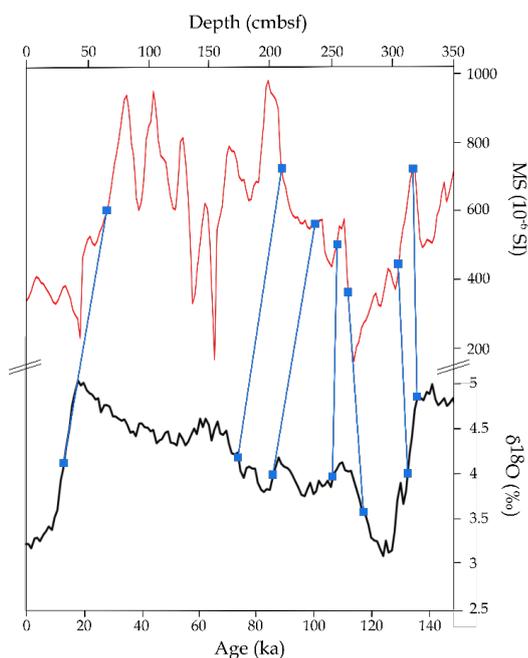

144 3.2. ANTA91-8 chronology

145 The chronology for core ANTA91-8 was constructed by aligning the magnetic susceptibility (MS) to the
 146 LR04 benthic foraminifera $\delta^{18}\text{O}$ stack (Lisiecki and Raymo, 2005) using the AnalySeries software
 147 (Paillard et al., 1996). Increased supply of terrigenous glacial detritus from the Antarctic continent
 148 to its margin and increased dust input from Patagonia and Australia to the pelagic SO during glacial
 149 periods resulted in higher MS values during glacial periods than interglacial periods (Bareille et al.,
 150 1994; Pugh et al., 2009; Walter et al., 2000). Tie points were selected in the MS record at the
 151 boundaries of MIS stages and sub-stages (Figure 2 & Table 3). Ages for the MIS 5 sub-stage boundaries

ANTA91-8 depth (mbsf)	LR04 Age (ka)	MIS stage/sub- stage boundary
0.65	14	1-2
2.09	71	4-5a
2.39	83	5a-b
2.55	105	5c-d
2.65	116	5d-e
3.05	131.5	5e-6
3.17	136	-

Table 3: Tiepoints for ANTA91-8 chronology. The MS record for ANTA91-8 is aligned to the LR04 benthic stack using the AnalySeries software (Paillard et al., 1996).

Figure 2: Alignment between the MS from core ANTA91-8 (red) and the LR04 benthic $\delta^{18}\text{O}$ stack (black) using the AnalySeries software (Paillard et al., 1996). Blue squares and connecting lines mark the tiepoints between records.

152 are from Govin et al. (2009), and the ages are translated from the LR04 chronology onto the AICC2012
153 chronology.

154 The chronology for core ANTA91-8 presented in this study differs from chronologies previously
155 published by Ceccaroni et al. (1998) and Brambati et al. (2002), who – on the basis of ²³⁰Thorium
156 measurements, subsequently adjusted by matching maxima in palaeo-productivity proxies to peak
157 interglacials – placed MIS 5e ~50 cm higher than in our age model (Supplementary Figure 1). Our new
158 chronology assigns the broad MS minimum from 2.65-3.05 mbsf, which comprises a peak in organic
159 carbon content (Ceccaroni et al., 1998), to MIS 5e. In contrast, both the Ceccaroni et al. (1998) and
160 Brambati et al. (2002) age models placed this MS minimum within MIS 6 (Supplementary Figure 1),
161 resulting in inexplicably high accumulation rates of productivity proxies during this glacial period
162 (Ceccaroni et al., 1998). Our new chronology is corroborated by the diatom group *Rouxia* spp., which
163 occurs in abundances <1 % in ANTA91-8 samples between 2.72 and 3.14 mbsf (Chadwick and Allen,
164 2021a). If the samples in this depth interval were deposited during MIS 6, as suggested by the
165 Ceccaroni et al. (1998) and Brambati et al. (2002) age models, then the *Rouxia* spp. abundances should
166 be >1 % (Zielinski et al., 2002).

167 **4. Results**

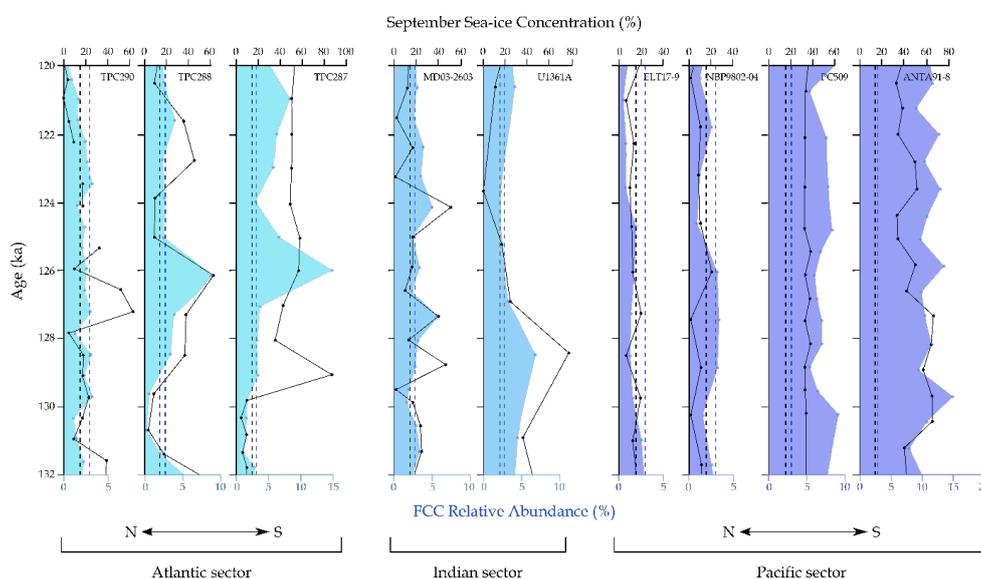

168 The September SIC values, reconstructed using the MAT, and the FCC relative abundances are
169 presented for the 132-120 ka interval in all nine sediment cores (Figure 3). This interval is chosen to
170 capture the sea-ice signature from both the end of glacial Termination II and during ‘peak’ MIS 5e.
171 SSST data, also reconstructed using MAT, is presented over the same time interval alongside the
172 cumulative relative abundance of the eight tropical/subtropical diatom species and groups according
173 to Romero et al. (2005).

174 **4.1. Sea ice**

175 In the Atlantic sector, the three cores (TPC290, TPC288 and TPC287) display a N-S increasing trend in
176 mean FCC relative abundances (2.1 ± 0.7 %, 3.1 ± 2.2 % and 4.7 ± 3.6 %) and Sept. SICs (19 ± 17 %, 25
177 ± 18 % and 33 ± 20 %). All three cores have low FCC relative abundances (1.2 ± 0.5 %) and Sept. SICs
178 (8.8 ± 4.6 %) during the 131-130 ka interval, with cores TPC288 and TPC287 both reaching their
179 minimum MIS 5e Sept. SIC and FCC values at this time (Figure 3). Following this interval of low Sept.
180 SIC and FCC values, all three cores show an increase to their maximum Sept. SICs (58 ± 5 %) and FCC
181 relative abundances (9 ± 5 %) at 127-126 ka (Figure 3). After 126 ± 2.6 ka core TPC290 displays a
182 gradual decline in both FCC relative abundance and Sept. SIC to minimum values at 121-120 ka (Figure
183 3). In contrast, core TPC287 maintains high Sept. SICs (51 ± 3 %, multiple samples) throughout the 126-

184 120 ka period as well as high (6.2 ± 1.8 %, multiple samples) FCC relative abundances, although they
185 are lower than the 126 ± 2.6 ka peak of ~ 15 % (single sample) (Figure 3). Core TPC288 maintains,
186 relative to the $\sim 130 \pm 2.6$ ka minimum and $\sim 126 \pm 2.6$ ka maximum, intermediate FCC (2.9 ± 0.6 %,
187 multiple samples) and Sept. SIC (22 ± 15 %, multiple samples) values throughout the 126-120 ka
188 interval, however the Sept. SICs are much more variable than in TPC287 (Figure 3).

189

Figure 3: Downcore September SICs, determined using the MAT, and FCC relative abundances for the 132-120 ka interval in nine marine sediment cores. The blue shading indicates the FCC relative abundance, with the colour saturation varying between SO sectors. The solid black lines indicate the September SICs with the gaps in the TPC290 record caused by two samples being too dissimilar from all modern reference samples, so that the latter cannot be considered as analogs. Dashed lines mark the mean WSIE thresholds of 3 % FCC abundance (blue lines) and 15 % Sept. SIC (black lines). Within each SO sector cores are arranged from north to south.

190 All three Atlantic sector cores (TPC290, TPC288 and TPC287) have a strong match ($p = 0.05$, $p < 0.01$
191 and $p < 0.01$ respectively) between the FCC and Sept. SIC variations, with the notable exception of the
192 TPC287 sample at $\sim 129 \pm 2.6$ ka which has a very high Sept. SIC (86 %) but a relatively low FCC relative
193 abundance (3.4 %). The only pronounced difference between the diatom species assemblage in this
194 sample compared to neighbouring depths is a substantially higher relative abundance of *F. separanda*
195 (Chadwick and Allen, 2021f), a species known to achieve highest abundances in modern sediments
196 overlain by winter SICs above 60 % (Armand et al., 2005). There was also only a single modern analog
197 identified for this sample and so it is likely that the high *F. separanda* relative abundance (~ 9 %) has
198 biased the MAT reconstruction towards colder conditions with a greater SIC than the conditions
199 reflected by the rest of the diatom species assemblage for that sample. Thus, the reconstructed Sept.

200 SIC for this sample is disregarded from the analysis. There are two MIS 5e samples in TPC290 (at 124.7
201 ± 2.6 ka and 122.8 ± 2.6 ka) for which none of the reference surface sediment samples were below
202 the dissimilarity threshold (see section 2.3 for details) and thus no MAT estimate of Sept. SIC (or SSST)
203 is given for those samples.

204 The two Indian sector cores (MD03-2603 and U1361A) have similar average MIS 5e FCC relative
205 abundances ($3.2 \pm 1\%$ and $3.9 \pm 1.5\%$) to each other but the average Sept. SIC ($19 \pm 15\%$ and 27 ± 25
206 $\%$) is nearly 10% higher in U1361A. However, the MIS 5e variability in Sept. SIC within each core is
207 greater than this difference between the two cores. Core MD03-2603 has three Sept. SIC maxima of
208 $>40\%$ (single samples) during MIS 5e, at 124.1 ± 2.6 ka, 127.3 ± 2.6 ka and 128.8 ± 2.6 ka, as well as
209 three minima of $<5\%$ (single samples) at 121.5 ± 2.6 ka, 123.3 ± 2.6 ka and 129.5 ± 2.6 ka (Figure 3).
210 Contrastingly, the nearby core U1361A (Figure 1) has a maximum in MIS 5e Sept. SIC (76.4%, single
211 sample) at 128.4 ± 2.7 ka and a minimum (0%, single sample) at 123.7 ± 2.7 ka (Figure 3). Together
212 these two records suggest that the greatest MIS 5e Sept. SICs in the Indian sector occurred during the
213 129-127 ka interval and the minimum was at 123.5-121 ka (Figure 3).

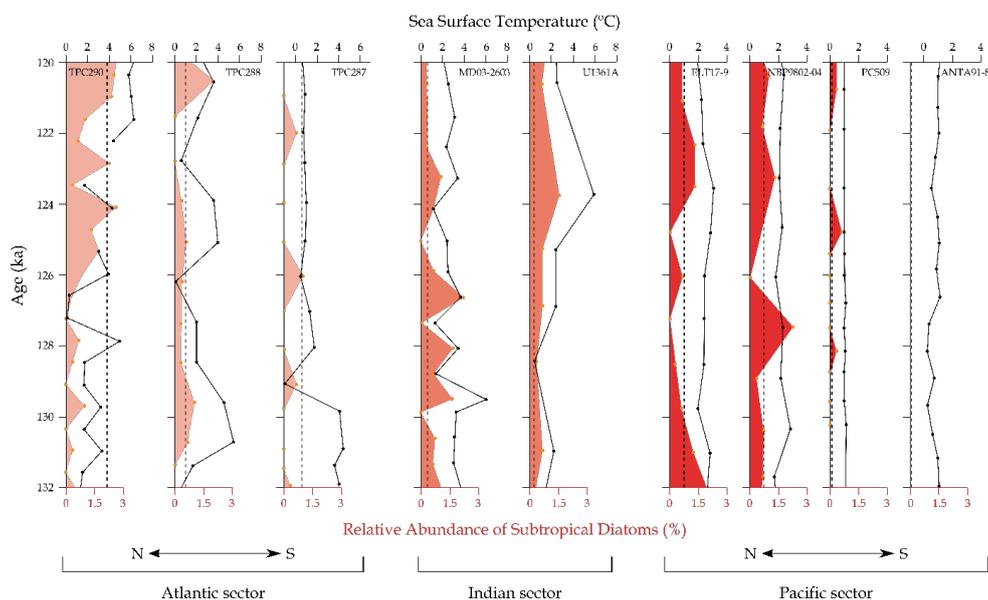

214 Unlike the Atlantic and Indian sectors, the four cores from the Pacific sector (ELT17-9, NBP9802-04,
215 PC509 and ANTA91-8) have low variability in their FCC relative abundances ($1.4 \pm 0.6\%$, $2.3 \pm 1\%$, 5.8
216 $\pm 0.9\%$ and $11 \pm 1.9\%$) and Sept. SICs ($13 \pm 4\%$, $8.4 \pm 5.7\%$, $34 \pm 2\%$ and $48 \pm 11\%$) throughout MIS
217 5e, with no pronounced maxima or minima (Figure 3). The northernmost Pacific sector core ELT17-9
218 has the lowest average MIS 5e FCC relative abundance ($1.4 \pm 0.6\%$) but the more southerly core
219 NBP9802-04 has the lowest average MIS 5e Sept. SIC ($8.4 \pm 5.7\%$). The two most southerly Pacific
220 sector cores (PC509 and ANTA91-8) have the highest average MIS 5e Sept. SICs and FCC relative
221 abundances of all the cores analysed for this study.

222 4.2. Sea-surface temperatures

223 For the Atlantic sector cores the average MIS 5e SSSTs ($3.2 \pm 1.9^\circ\text{C}$, $2.7 \pm 1.6^\circ\text{C}$ and $2.2 \pm 1.5^\circ\text{C}$) show
224 an inverse trend to Sept. SICs with higher values in more northerly cores. Both TPC288 and TPC287
225 have their highest MIS 5e SSSTs during the 131-129 ka interval (5°C and 4.3°C , respectively, multiple
226 samples) followed by a SSST minimum at $\sim 126 \pm 2.6$ ka (0.1°C and 0.6°C , respectively, single samples)
227 (Figure 4). In contrast, the warmest MIS 5e SSSTs for TPC290 occur in the youngest part of the record,
228 with an average of 6°C in the 122-120 ka period (Figure 4). The relative abundance of subtropical
229 diatoms in core TPC290 shows a good consistency ($p < 0.01$, $R^2 = 0.51$) with the SSST pattern during
230 MIS 5e, with the highest relative abundances ($1.6 \pm 0.8\%$, multiple samples) after 126 ± 2.6 ka (Figure
231 4). In the southernmost Atlantic sector core TPC287 there is a very poor match between MIS 5e SSSTs
232 and subtropical diatom relative abundances ($p = 0.3$, $R^2 = 0.11$). This lack of correlation is likely due to

233 the scarcity of subtropical diatoms at this site throughout MIS 5e, as can be seen in modern surface
234 sediments (Chadwick, 2020), and thus a single valve can create a relative abundance peak that may
235 be largely unrelated to the SSST trends.

236

Figure 4: Downcore summer (January to March) SSTs, determined using the MAT, and the relative abundance of all tropical/subtropical diatom species (Romero et al., 2005) for the 132-120 ka interval in nine marine sediment cores. The red shading indicates the relative abundance of subtropical diatom species, with the colour saturation varying between SO sectors. The solid black lines indicate the SSSTs with the gaps in the TPC290 record caused by two samples being too dissimilar from all modern reference samples, so that the latter cannot be considered as analogs. Black dashed lines mark the modern (Jan-Mar, 1980-2019) SSSTs at each core site (Hersbach et al., 2019). Within each SO sector cores are arranged from north to south.

237 The Indian sector cores have similar average SSSTs (2.8 ± 1.1 °C and 2.4 ± 1.7 °C). However, unlike for
238 the Sept. SICs (Figure 3), the MIS 5e SSST minima and maxima in cores MD03-2603 and U1361A occur
239 at different times (Figure 4). SSSTs in core U1361A fall to a minimum of 0.7 °C (single sample) at ~ 128
240 ± 2.7 ka before rising to a maximum of 5.9 °C (single sample) at $\sim 124 \pm 2.7$ ka. In contrast, SSSTs in
241 core MD03-2603 reach an early peak of 5.9 °C (single sample) at $\sim 129.5 \pm 2.6$ ka and have minima of
242 ~ 1 °C (single samples) at 124.1 ± 2.6 ka, 127.3 ± 2.6 ka and 128.8 ± 2.6 ka (Figure 4). Both MD03-2603
243 and U1361A show a strong coherence between the MIS 5e SSSTs and the subtropical diatom
244 abundance ($p = 0.02$, $R^2 = 0.34$ and $p < 0.01$, $R^2 = 0.98$ respectively).

245 In the Pacific sector cores, SSSTs are largely consistent throughout MIS 5e, with averages of 2.5 ± 0.3
246 %, 2.2 ± 0.3 %, 1.03 ± 0.03 % and 0.8 ± 0.3 % (Figure 4). Although there is very little variation in MIS 5e
247 SSSTs in all four records, both core NBP9802-04 and core PC509 reveal maximum SSSTs (2.8 °C and 1.1

248 °C, respectively, single samples) at $\sim 130 \pm 2.7$ ka (Figure 4). None of the Pacific sector cores show a
249 strong match between MIS 5e SSSTs and the relative abundance of subtropical diatom species. For
250 the more southerly core PC509 this poor correlation ($p = 0.65$, $R^2 = 0.02$) is likely caused by the same
251 scarcity of subtropical diatoms as for core TPC287 in the Atlantic sector.

252 **5. Discussion**

253 Both the Sept. SICs and FCC relative abundances indicate substantial differences in the pattern of MIS
254 5e WSIE change between the three SO sectors, most notably between the Atlantic and Pacific sectors.
255 In all three Atlantic sector records, the FCC relative abundances and Sept. SICs indicate year-round
256 open marine conditions and thus a poleward contraction of the mean WSIE (FCC <3 % (Gersonde and
257 Zielinski, 2000) and Sept. SIC <15 % (Zwally et al., 2002)) during the 131-130 ka interval. This minimum
258 is succeeded by a re-expansion of sea ice to a maximum extent in the 127-126 ka interval when all
259 three core sites were covered by WSI. An early minimum in MIS 5e WSIE succeeded by a maximum ~ 4
260 ka later is consistent with the FCC relative abundance in nearby core PS2305-6 (Figure 1; 58.72 °S,
261 33.04 °W) (Bianchi and Gersonde, 2002; Chadwick et al., 2020). The MIS 5e WSIE maximum in the
262 Atlantic sector records coincides, within chronological uncertainty, with higher global sea level (Kopp
263 et al., 2013) and evidence for increased meltwater flux in the Weddell Sea (Chadwick et al., *in review*),
264 which both indicate substantial mass loss from the Antarctic ice sheets, consistent with findings of
265 major ice loss in the Weddell Sea sector during MIS 5e (Turney et al., 2020). Higher glacial meltwater
266 fluxes associated with increased ice-sheet loss could therefore be a major driver of the WSIE expansion
267 in the Atlantic sector records as less saline surface waters freeze more easily (Bintanja et al., 2013;
268 Merino et al., 2018). The peak in FCC abundance in core TPC287 at 126 ± 2.6 ka is primarily a peak in
269 the abundance of *F. cylindrus* (Chadwick and Allen, 2021f) which is affiliated with sea-ice melt and
270 strong surface stratification (Cremer et al., 2003; von Quillfeldt, 2004) and further supports an
271 increased glacial meltwater signal at this time.

272 The discrepancy between Sept. SICs and FCC relative abundances at $\sim 127 \pm 2.6$ ka in core TPC290
273 (Figure 3) is likely due to increased *Chaetoceros* resting spore (rs.) abundance at this time (Chadwick
274 and Allen, 2021h). For core TPC290, there is a scarcity of modern analogs from the Scotia Sea region
275 (Gersonde et al., 2005) and thus, the high *Chaetoceros* rs. abundances in MIS 5e samples are
276 associated with modern analogs from sites along the Antarctic Peninsula, where SICs are greater than
277 in the Scotia Sea.

278 In the Indian sector, core MD03-2603 has an average MIS 5e Sept. SIC (25 ± 18 %) and FCC relative
279 abundance (3.2 ± 1 %) indicative of a location just south of the mean WSIE (Figures 3 & 5) but with

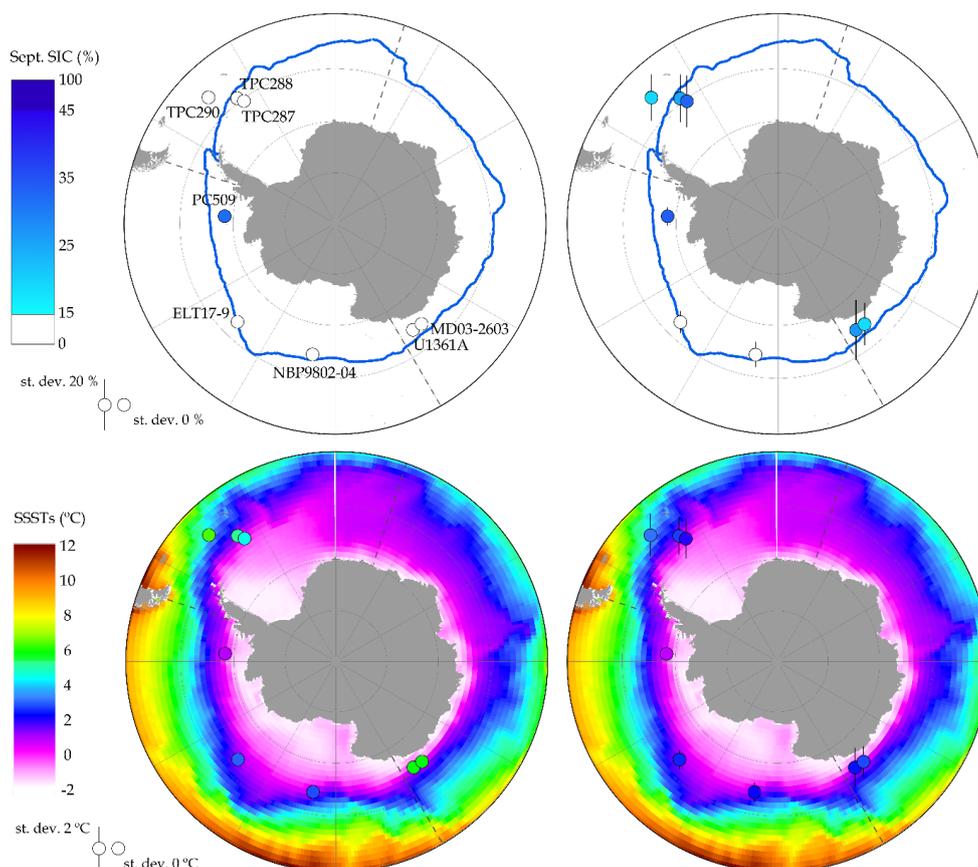

Figure 5: Maps of MIS 5e SSSTs and Sept. SICs for the nine core sites compared with the modern conditions. On all maps the SO sector boundaries are marked with dashed lines. **Top left:** Minimum MIS 5e Sept. SIC for each core site (coloured circles) compared to the modern (1981-2010) 15 % September sea-ice extent (blue line) (Fetterer et al., 2017). **Top right:** Average MIS 5e Sept. SICs (coloured circles) and standard deviations (vertical bars) at each core site compared to the modern (1981-2010) 15 % September sea-ice extent (blue line) (Fetterer et al., 2017). **Bottom left:** Maximum MIS 5e SSSTs for each core site (coloured circles) compared to modern (Jan-Mar, 1980-2019) SSSTs (Hersbach et al., 2019). **Bottom right:** Average MIS 5e SSSTs (coloured circles) and standard deviations (vertical bars) for each core site compared to modern (Jan-Mar, 1980-2019) SSSTs (Hersbach et al., 2019). Core data are given in Supplementary Table 1.

280 multiple maxima and minima contributing to the high variability. MIS 5e Sept. SICs and FCC relative
281 abundances in the nearby core U1361A indicate that it was located within the seasonal sea-ice zone
282 from 132-126 ka before the mean WSIE retreated to the south of this location (Figure 3 &
283 Supplementary Figure 2). The different patterns in MIS 5e Sept. SIC and SSSTs between cores MD03-
284 2603 and U1361A are likely due to the different age resolution of the samples, with two of the Sept.
285 SIC maxima in MD03-2603 occurring in the 129-127 ka interval coincident with the U1361A Sept. SIC
286 maximum, and likewise, two of the Sept. SIC minima in MD03-2603 occurring in the 124-121 ka period

287 concurrent with the minimum Sept. SIC in core U1361A (Figure 3). The different age resolution of
288 samples in MD03-2603 and U1361A is primarily due to the lower sedimentation rate (Table 2) at site
289 U1361A, and thus a sample from this core spans more time than in core MD03-2603.

290 None of the Pacific sector cores show pronounced minima or maxima in their MIS 5e FCC and Sept.
291 SIC records (Figure 3), indicating a less variable WSIE in this sector compared to the Atlantic and Indian
292 sectors (Figure 3). The Pacific sector cores PC509 and ANTA91-8 are also the only cores in this study
293 which are covered by WSI for the entirety of MIS 5e (Figure 3 & 5). The position of these cores south
294 of the mean WSIE throughout MIS 5e is significant as they are the first published marine records from
295 within the seasonal sea ice zone and able to constrain the poleward limit of the MIS 5e minimum WSIE
296 (Chadwick et al., 2020). Cores ELT17-9 and NBP9802-04 are the only records in this study with average
297 MIS 5e Sept. SICs <15 % (Figure 5), indicating they were located north of the mean WSIE for the
298 majority of the 132-120 ka period, with core ELT17-9 having been located closer to the MIS 5e mean
299 WSIE. The FCC relative abundances for cores ELT17-9 and NBP9802-04 also indicate that both were
300 located on average north of the mean WSIE during MIS 5e (Figure 3) but suggest that core NBP9802-
301 04 was located closer to the MIS 5e mean WSIE.

302 The reconstructed MIS 5e Sept. SICs for site ELT17-9 are higher than for site NBP9802-04 (Figure 3)
303 which is likely related to the higher abundance of *Chaetoceros* rs. in core ELT17-9 when compared to
304 core NBP9802-04 (Chadwick and Allen, 2021b, d). The *Chaetoceros* rs. group is associated with both
305 WSI (Armand et al., 2005) and meltwater stratification (Crosta et al., 1997), and it reached high
306 abundances in the Ross Sea during past interglacials (Kim et al., 2020). The high *Chaetoceros* rs.
307 abundance in core ELT17-9 during MIS 5e could therefore indicate a north-eastward shift of the Ross
308 Sea gyre from its modern day position (Dotto et al., 2018) and an accompanying displacement of
309 meltwater circulation (Merino et al., 2016) and the WSI edge in the Pacific sector.

310 The average MIS 5e SSSTs in the nine cores are ~1-2 °C warmer than the modern SSSTs (Figure 5),
311 consistent with the SST anomalies presented in Chadwick et al. (2020) and Capron et al. (2014).
312 However, the SSST records in the Atlantic and Indian sectors have large variability with maximum
313 SSSTs that are 2-4 °C higher than the MIS 5e average SSSTs (Figure 5). Maximum MIS 5e SSSTs in the
314 Atlantic and Indian sectors were therefore ~3-5 °C warmer than modern SSSTs (Figure 5), which is a
315 much larger SSST anomaly than the Antarctic Zone (south of the Antarctic Polar Front) records
316 presented in Chadwick et al. (2020), and marks a ~5 degrees latitude poleward shift in SSST isotherms
317 relative to the present. Unlike the Atlantic and Indian sectors, the Pacific sector core records indicate
318 low variability in MIS 5e SSSTs with peak values 0-2 °C warmer than present (Figure 5) marking a
319 poleward shift in SSST isotherms of <3 degrees latitude.

320 Within their chronological uncertainties (Table 2), cores TPC288, TPC287, MD03-2603, ELT17-9,
321 NBP9802-04 and PC509 all reach minimum MIS 5e Sept. SICs synchronously (Supplementary Table 1)
322 and coincident with the peak in Antarctic air temperatures and minimum in EPICA Dome C (EDC) sea-
323 salt sodium flux (Na_{ss}) at $\sim 128 \pm 1.5$ ka (Holloway et al., 2017; Wolff et al., 2006). The two Indian sector
324 core records reach a minimum MIS 5e WSIE (and maximum SSST in core U1361A) ~ 4.5 ka after the
325 Na_{ss} minimum in Antarctic ice cores, outside of the combined chronological uncertainties of the
326 sediment cores (Table 2) and AICC2012 ice core chronology (Bazin et al., 2013). Although the duration
327 of the SSST maximum, and accompanying WSIE minimum, in core MD03-2603 is short, it occurs within
328 chronological error of the maximum air temperatures in Antarctic ice cores (Figures 3 & 4).

329 Satellite era trends in Antarctic winter SIC (Hobbs et al., 2016) are largely consistent with the patterns
330 observed during MIS 5e. Northern Weddell Sea winter SIC has declined by 5-10 % per decade in the
331 satellite era (Hobbs et al., 2016) indicating a sensitivity to warming consistent with the early retreat
332 of MIS 5e sea ice in this region. Similarly, winter SICs in the Pacific sector have remained stable, or
333 even slightly increased, during the satellite era (Hobbs et al., 2016) which is in agreement with the
334 stability of the Pacific sector WSIE throughout MIS 5e. In recent decades, Bellingshausen Sea summer
335 sea ice has decreased, whilst WSIE has stayed stable (Hobbs et al., 2016; Parkinson, 2019). The MIS 5e
336 Sept. SICs and SSSTs (as a proxy for summer sea ice) imply that the MIS 5e WSIE in the Bellingshausen
337 Sea is similar to the modern but the summer sea-ice extent was reduced. The western Ross Sea is a
338 region in which the modern and MIS 5e trends differ, with recent winter SIC increases of 10-15 % per
339 decade contrasting with the MIS 5e WSIE reduction observed at site NBP9802-04.

340 **6. Conclusions & wider implications**

341 During MIS 5e the three SO sectors display heterogeneous responses in WSIE and SSSTs, which may
342 guide our predictions of the impact of future warming on the Antarctic region. The prominent early
343 (131-130 ka) minimum in WSIE and coinciding maximum in SSSTs for the two southerly Atlantic sector
344 cores (TPC288 and TPC287, Figure 3) is associated with a mean WSI edge located at least 3-5 ° south
345 of its modern position. This substantial reduction in WSIE and seasonal sea-ice cover would have
346 reduced brine rejection and likely decreased the rates of deep and bottom water formation in the
347 Weddell Sea, causing a warming of the abyssal waters (Bouttes et al., 2010; Marzocchi and Jansen,
348 2019). Deep water warming would have promoted the basal melting and retreat of Weddell Sea ice
349 shelves and marine terminating ice streams and caused substantial Antarctic ice sheet mass loss
350 (Hellmer et al., 2012; Rignot et al., 2019; Wahlin et al., 2021). We hypothesise that substantial mass
351 loss from the Weddell Sea sector drove the Atlantic sector WSI resurgence at $\sim 126 \pm 2.6$ ka and
352 contributed to the global sea-level rise at this time (Kopp et al., 2013; Sime et al., 2019).

353 Variations in the WSIE and SSST records between the Indian sector cores MD03-2603 and U1361A are
354 due to the differences in sampling resolution, with the MD03-2603 record indicating multiple
355 relatively short duration WSIE and SSST oscillations during MIS 5e. The U1361A record seems to
356 present an averaged signal of these oscillations with a greater frequency of warm periods with
357 reduced WSIE after 125 ± 2.7 ka. Along the modern Wilkes Land margin the Antarctic Circumpolar
358 Current (ACC) flows much closer to the continent than in other regions (Tamsitt et al., 2017) and the
359 MIS 5e record in core MD03-2603 could therefore suggest multiple intervals when the ACC was
360 displaced to the south of its modern position. A more southerly ACC in this region would have caused
361 a poleward shift in precipitation fields and resulted in drier conditions across Southern Australia (Liu
362 and Curry, 2010; Saunders et al., 2012), a trend that can already be observed under a modern warming
363 climate (CSIRO, 2018). A southerly shift of the ACC would also increase the advection of warmer
364 Circumpolar Deep Water onto the Antarctic continental shelf (Fogwill et al., 2014), promoting periods
365 of high basal melting and ice sheet retreat in Wilkes Land during MIS 5e, as supported by Wilson et al.
366 (2018).

367 In contrast to the Atlantic and Indian sectors, the Pacific sector records indicate a more stable WSIE
368 throughout MIS 5e. The MIS 5e Sept. SIC records of cores ELT17-9 and NBP9802-04 indicate a
369 poleward shift in the mean WSI edge by at least 2° of latitude relative to the modern. The PC509
370 record indicates a southerly shift in the mean WSI edge by $<2^\circ$ latitude, highlighting a seemingly
371 greater resilience of sea ice in the Bellingshausen Sea with the WSI edge having remained north of 68
372 $^\circ$ S throughout MIS 5e. In the modern Pacific sector the WSIE is strongly constrained by the southern
373 extent of the ACC and the shape of the Ross Sea gyre (Benz et al., 2016; Nghiem et al., 2016). An
374 uneven poleward constriction of the ACC across the Pacific sector during MIS 5e could therefore help
375 explain the differing WSI retreat in this region, with greater poleward migration of the ACC and
376 reduction in the Ross Sea gyre extent in the western Pacific sector than in the eastern Pacific sector.
377 However, unlike in the Indian sector, there is no evidence for millennial-scale migration of the ACC
378 across the Pacific sector. The stable and persistent WSIE in the Pacific sector during MIS 5e may have
379 protected ice shelves in the Ross, Amundsen and Bellingshausen seas which buttressed ice grounded
380 further upstream (Massom et al., 2018). This buttressing may have acted as a stabilising factor for the
381 West Antarctic Ice Sheet during MIS 5e, with the majority of its deep subglacial basins terminating in
382 the Ross, Amundsen and Bellingshausen Seas (Gardner et al., 2018).

383 The sensitivity of Weddell Sea WSI to warmer climates could have substantial implications for the SO
384 biosphere given the high rates of primary productivity in this region today (Vernet et al., 2019). Whilst
385 a future reduction in WSIE and increase in glacial meltwater flux would be expected to promote
386 primary productivity in the western part of the Weddell Sea (de Jong et al., 2012), the higher SSTs

387 would not favour key trophic intermediaries, e.g. Antarctic krill (*Euphausia superba*) (Atkinson et al.,
388 2017; Siegel and Watkins, 2016), and would therefore negatively affect megafauna at higher trophic
389 levels (Hill et al., 2013). Future WSI edge retreat, at equivalent levels to MIS 5e, would also negatively
390 impact upon modern sea-ice obligate species, such as Emperor and Adélie Penguins (Cimino et al.,
391 2013; Jenouvrier et al., 2005).

392 Similarly to the modern SO (Parkinson, 2019), WSIE trends during MIS 5e show both spatial and
393 temporal heterogeneity. The greater MIS 5e WSIE reduction in the Atlantic sector compared to the
394 Pacific sector is consistent with recent model simulations (Holloway et al., 2017). Most of the core
395 records in this study reach their minimum WSIE synchronously (within chronological uncertainties)
396 with the 128 ± 1.5 ka minimum in Antarctic ice core Na_{ss} flux (Wolff et al., 2006), with only cores
397 TPC290 and U1361A indicating a later WSIE minimum (Figure 3 & Supplementary Figure 1). The
398 stability of the Pacific sector WSIE is likely due to the bathymetric pinning of the ACC limiting the
399 possible poleward displacement of the ACC during MIS 5e. The apparent high sensitivity of Weddell
400 Sea WSIE, and seeming resilience of Bellingshausen Sea WSIE, to warmer than present climates is
401 unexpected from the recent observational trends (Hobbs et al., 2016; Parkinson, 2019) and highlights
402 the importance of reconstructing palaeoenvironmental conditions around Antarctica during past
403 warm periods, such as MIS 5e, for understanding how the Antarctic and SO regions respond to warmer
404 climates on longer than decadal timescales.

405 **Data availability**

406 Full diatom count data for all samples are available from the NERC EDS UK Polar Data Centre (Chadwick
407 and Allen, 2021a, b, c, d, e, f, g, h, i). Sept. SIC and SSST data for all samples, produced using the MAT
408 transfer function, are available from PANGAEA (submitted, doi pending).
