**Abstract.** Wildfire is the most common disturbance type in boreal forests and can trigger significant changes in forest composition. Waterlogging in peatlands determines the degree of tree cover and the depth of the burning horizon associated with wildfires. However, interactions between peatland moisture, vegetation composition and flammability, and fire regime in forested peatland in Eurasia remain largely unexplored, despite their huge extent in boreal regions. To address this knowledge gap, we reconstructed the Holocene fire regime, vegetation composition and peatland hydrology at two sites in Western Siberia near Tomsk Oblast, Russia. The palaeoecological records originate from forested peatland areas in predominantly light taiga (*Pinus-Betula*) with increase in dark taiga communities (*Pinus sibirica*, *Picea obovata*, *Abies sibirica*) towards the east. We found that the past water level fluctuated between 8 and 30 cm below the peat surface. Wet peatland conditions promoted broadleaf trees (*Betula*), whereas dry peatland conditions favoured conifers and a greater forest density (dark-to-light-taiga ratio). The frequency and severity of fire increased with a declining water table that enhanced fuel dryness and flammability and at an intermediate forest density. We found that the probability of intensification in fire severity increased when the water level declined below 20 cm suggesting a tipping point in peatland hydrology at which wildfire regime intensifies. On a Holocene scale, we found two scenarios of moisture-vegetation-fire interactions. In the first, severe fires were recorded between 7.5 and 4.5 ka BP with lower water level and an increased proportion of dark taiga and fire avoiders (*Pinus sibirica* at Rybanya and *Abies sibirica* at Ulukh Chayakh) mixed into the dominantly light taiga and fire-resister community of *Pinus sylvestris*. The second occurred over the last 1.5 ka and was associated with fluctuating water tables, a declining abundance of fire avoiders, and an expansion of fire invaders (*Betula*). These findings suggest that frequent high-severity fires can lead to compositional and structural changes in forests when trees fail to reach reproductive maturity between fire events or where extensive forest gaps limit seed dispersal. This study also shows prolonged periods of synchronous fire activity across the sites, particularly during the early to mid-Holocene, suggesting a regional imprint of centennial to millennial-scale Holocene climate variability on wildfire activity. Increasing human presence in the region of the Ulukh-Chayakh Mire near Teguldet over the last four centuries drastically enhanced ignitions compared to natural background levels. Frequent warm and dry spells predicted for the future in Siberia by climate change scenarios will enhance peatland drying and may convey a competitive advantage to conifer taxa. However, dry conditions, particularly a water table decline below the threshold of 20 cm, will probably exacerbate the frequency and severity of wildfire, disrupt conifers' successional pathway and accelerate shifts towards more fire-adapted broadleaf tree cover. Furthermore, climate-disturbance-fire feedbacks will accelerate changes in the carbon balance of forested boreal peatlands and affect their overall future resilience to climate change.

## 1 Introduction

Wildfire is the most common type of disturbance in boreal forests. It can change forest composition and accelerate climate warming via carbon release into the atmosphere and alteration of the radiative balance due to changes in land surface albedo (Rogers et al., 2015; Kharuk et al., 2021). However, the impacts of wildfire on vegetation and climate strongly depend on the fire regime. High-intensity crown fires kill most trees and alter species composition for an extended period. In the short term,

65 such fires release black carbon aerosols (Rogers et al., 2015). When these aerosols persist in the atmosphere, it leads to a  
medium-term increase in albedo and ultimately to regional cooling. Contrastingly, surface fires typically do not kill mature  
trees or trigger stand-scale forest replacement and have little effect on albedo. Fire regimes in the Siberian boreal forests are  
often litter-fuelled surface fires that infrequently transition to the crown, depending on forest composition (Sannikov and  
Goldammer, 1996; Grooth et al., 2013; Kharuk et al., 2021). A high diversity of fire-related plant functional types (PFT),  
70 including resisters (*Pinus sylvestris*, *Larix sibirica*, *L. gmelinii*), avoiders (*Abies sibirica*, *Picea obovata*, *Pinus sibirica*),  
invaders (*Betula pubescens*, *B. pendula*) and endurers (*Populus tremula*, *B. pubescens*) dominate these forests (Rowe, 1983;  
Agee, 1998; Wirth, 2005). Fire resisters, invaders, and endurers are commonly associated with high-frequency but low-  
intensity surface fire regime, whereas avoiders are associated with low-frequency but high-intensity crown fire regimes  
(Goldammer and Furyaev, 1996; Wirth, 2005). As these two types of fire can have a different net effect on forest composition  
and climate, it is essential to understand the drivers behind each fire regime to improve the prediction of the impact of changes  
75 in the extent, frequency, and severity of fire in the future.

A wildfire regime emerges from the combination of ignition sources, climatic conditions, fuel properties and human activities.  
The interactions between these factors are spatiotemporally complex (Moritz et al., 2014). The spatial complexity of wildfire  
patterns is particularly accentuated in open and forested peatlands, where variability in local peat moisture content, vegetation  
composition and structure results in pronounced small-scale heterogeneity (Camill et al., 2009; Magnan et al., 2012;  
80 Kuosmanen et al., 2014; Remy et al., 2018; Barhoumi et al., 2019; Stivrins et al., 2019; Feurdean et al., 2020a). The water-  
logged conditions that prevail in peatlands can limit the burning depth of the fuel bed. However, this attenuation effect  
decreases with water table decline and increasing tree cover (Whitman et al., 2018). Unlike drained peatlands with shrub and  
tree-dominated communities, well-hydrated peatlands composed of a dense *Sphagnum* cover remain wet despite droughts and  
exhibit only slight to medium fire damage (Whitman et al., 2018; Gewin, 2020). This pattern in fire dynamics is particularly  
85 concerning because climate warming accelerates woody encroachment in peatlands and increases fuel availability for forest  
fires (Kharuk et al., 2021). Intensification of fire severity may also lead to a shift from conifer towards broadleaf tree dominance  
(Kelly et al., 2013; Mekonnen et al., 2019). Understanding how hydrological conditions in peatlands are influenced by climate  
change and how this may interact with forest peatland composition and fuel flammability is a key research priority that remains  
largely unexplored (Page et al., 2009; Walker et al., 2009; Kharuk et al., 2021).

90 Reducing uncertainty in predicting future trajectories of fire regimes and the impact of changing fire activity on the functioning  
of boreal ecosystems requires approaches with a broad spatial and temporal scope (Kasischke et al., 2010). Forest ecosystems  
have long successional cycles ranging between decades and centuries. Palaeoecological records capture long time scales and  
are, therefore, particularly suitable to track the fire dynamics of forest ecosystems (Whitlock et al., 2018). However, studies of  
past millennial-scale variability in fire regimes in Siberian boreal forests started to emerge only recently (Feurdean et al.,  
95 2020a; Rudaya et al., 2020; Glückner et al., 2021; Barhoumi et al., 2021). No studies have explicitly explored the interactions  
between peatland moisture, vegetation composition and fire regime in Siberia to this date.

In this study, we used a multi-proxy (pollen, macrocharcoal morphologies, testate amoeba) analysis on two new peat records from Tomsk Oblast to explore the patterns and drivers of the western Siberian fire regime throughout the Holocene. Specifically, we have determined how peatland moisture has interacted with community composition (with regard in plant functional types) and fuel flammability in driving the frequency and type of fires. Combining our new data with our two other published records from the region allowed a quantification of the degree of spatiotemporal synchronicity in fire activity.

## 2 Material and Methods

### 2.1 Geographical location and charcoal site selection

The study areas stretch along a west-east transect in a permafrost-free area in Tomsk Oblast, Siberia (Bleuten and Filippov, 2008; Kirpotin et al., 2021). The region has a continental climate with subarctic influences. The mean annual temperature is 0°C, the mean temperature of the coldest/warmest season is -17°C/17°C, and the mean annual precipitation is ~ 525 mm falling predominantly in the warm season (www.climexp.knmi.nl). Typical forests in this region are characterised as light taiga type composed of *Pinus sylvestris*, *Betula pubescens*, *B. pendula*, with a greater proportion of dark taiga, including *Pinus sibirica*, *Picea obovata*, and *Abies sibirica* towards the east (Berezin et al., 2014; Rybina et al., 2014). Fires, at present primarily ignited by humans (80%), occur predominantly between spring and early autumn, but summer and autumn fires are more frequently of greater severity (Kukavskaya et al., 2014, 2016; Kharuk et al., 2021).

We cored two sites, Rybnaya Mire (N57,27566800°, E84,48758900°) located on the river Rybnaya, a tributary of the Ob river, and Ulukh-Chayakh Mire (N57.34326197°, E88,32306189°) located on a terrace of the Chulym river, near the village of Teguldet at the border of the Krasnoyarsk Krai (Fig. 1). The local vegetation at both coring sites includes mesotrophic open sedge-*Sphagnum* communities with young birch trees at Rybnaya Mire and standing dead tree trunks at Ulukh-Chayakh Mire. The dead trees reflect a rise in water levels across the mire due to road construction in the 1960s. Peat cores (50 cm length, 5 cm diameter) totalling 400 cm at Rybnaya Mire and 348 cm at Ulukh-Chayakh Mire were extracted with a Russian-type corer in 2017 and 2019, respectively.

### 2.2 Chronology

We established the chronology of both cores based on AMS radiocarbon measurements performed at Isotoptech, Debrecen, Hungary (File S1). The <sup>14</sup>C AMS age estimates were converted to calendar years BP using the IntCal20 data set of Reimer et al. (2020) and we constructed the age-depth models using the smooth spline method implemented in the CLAM software (Blaauw, 2010). In the age-depth models, we assigned a surface age of -67 (coring year 2017 for Rybnaya) and -69 (coring year 2019 for Ulukh-Chayakh) to the surface samples of each sequence.

### 2.3 Fire history

#### 2.3.1 Charcoal-based reconstructions of fire history

We inferred changes in local-scale fire regime based on peat samples of 2 cm<sup>3</sup> extracted at 1 cm contiguous intervals (Whitlock  
130 and Larsen, 2001). Charcoal preparation, identification and the categorisation of charcoal morphotypes followed Feurdean et  
al. (2020a) and Feurdean (2021). To deduce the predominant fire type burnt, we pooled the charcoal morphologies into two  
categories: non-woody (graminoids, forbs) and woody types (deciduous leaves, wood, and resins) and calculated their ratio.  
These two categories represent the dominant fuel sources for surface and crown fires, respectively (Enache et al., 2006; Jensen  
et al., 2007; Courtney-Mustaphi and Pisaric, 2014; Feurdean et al., 2017; 2020a; Feurdean, 2021). At Ulukh-Chayakh, we  
135 additionally measured the aspect ratio (length:width) of charcoal particles in selected samples to discriminate between the  
relative dominance of graminoids versus leaves and wood morphologies (Feurdean, 2021; Vachula et al., 2021). We separated  
the charcoal fractions into two size classes (150-500 µm and >500 µm) to deduce the approximative location of fires, i.e., local  
versus on-site fire events. We calculated the influx of charcoal morphotypes and size classes (particles cm<sup>-2</sup> yr<sup>-1</sup>) by dividing  
their respective concentration (particles/cm<sup>3</sup>) by the sediment deposition rate determined from the age-depth models (yr/cm).  
140 We estimated the frequency and severity of fire episodes using charcoal peaks identified from macrocharcoal particles using  
the method of Higuera et al. (2009). This methodology involved interpolating CHAR values to constant time steps (30 yr),  
decomposing the record into a background and a peak component (local fire episodes) using a robust LOWESS smoother (900  
yr), and evaluating charcoal peaks using the 95th percentile of the modelled noise distribution. We used the signal-to-noise  
index (SNI) to assess the suitability of the record for peak detection (Kelly et al. 2011; File S2).  
145 To integrate fire history across the study area, we created composite records of CHAR and fire frequency (FF) by combining  
the two new records with our two published profiles from Plotnikovo Mire (Feurdean et al., 2019; 2020a; Fig. 1). Composite  
CHAR was created using the Power et al. (2008) protocol implemented in the R palaeofire package version 4.0 (Blarquez et  
al., 2014) with the following setup for Z score transformation: 8.5 ka to present as the base period, and LOWESS smoothing  
to a 25-yr mean. The composite FF was created by pooling the identified fire events from all four records and applying a 150-  
150 yr smoothing.

### 2.3.2 Fire type identification from satellite images and forest statistics

To evaluate the ability of charcoal records to capture the occurrence and severity of fires near the two sites, we used satellite  
imagery of vegetation cover from LANDSAT 4-5 TM, LANDSAT-7 ETM+, and LANDSAT 8 OLI/TIRS  
(<https://earthexplorer.usgs.gov/>). We also used observation-based fire data from the Forest Department of the Tomsk Region  
155 from 1950 to 2020 CE and data from MODIS sensors onboard the NASA Terra-1 and Aqua-1, which detect forest fires  
(<http://fires.ru/>). All maps and images were processed using ESRI ArcGIS version 10.8.

### 2.4 Pollen-based reconstruction of vegetation dynamics

To reconstruct past vegetation dynamics, we analysed pollen and spores mainly at 4 cm intervals in both profiles following  
the protocol of Willis and Bennett (2001). A pollen sum exceeding 500 terrestrial pollen grains, excluding Cyperaceae, was  
160 counted for most samples and converted into percentages based on the total terrestrial pollen sum. The percentages of

Cyperaceae, ferns and mosses were calculated relative to the terrestrial pollen sum and their respective individual sum. The bottom part of the Ulukh-Chayakh profile, i.e., from 300-340 cm (age >6500 cal yr BP), contained extremely poorly preserved pollen and was excluded from further analysis.

We assigned pollen-derived tree taxa to one of the fire-related functional PFT groups - resisters (*Pinus sylvestris*, *Larix* spp.),  
165 avoiders (*Picea obovata*, *Abies sibirica*, *Pinus sibirica*), or invaders (*Betula* spp.). The PFT-specific fire coping adaptations  
relate to a taxon's strategy to complete its life cycle in the context of a given fire regime (Gill, 1981; Wirth, 2005). We also  
separated the tree composition into taxa associated with dark taiga (*Pinus sibirica*, *Abies sibirica*, *Picea obovata*) and light  
taiga (*Pinus sylvestris*, *Betula* spp., *Larix* spp.) and creating an index for forest density by calculating the ratio between the  
relative abundance of dark taiga and light taiga tree taxa (Higuera et al., 2014). Additionally, we pooled the non-arboreal pollen  
170 types as shrubs, herbs, ferns and mosses. To determine the regional changes in forest composition, we created composite  
records of PFTs. This was done by averaging the Z-scores and smoothing them to 300 years using a locally weighted regression  
and a 95% confidence envelope on the same sites used for composite biomass burning reconstructions in the R palaeofire  
package.

## 175 2.5 Climate reconstruction based on testate amoebae and water table depth

To determine changes in peatland hydrology at each site, we used testate amoeba-based water table reconstructions. The testate  
amoebae preparation and identification were conducted at 4 cm intervals following the methods of Hendon and Charman  
(1997) and Charman et al. (2000). Based on the available literature (Grospietsch, 1958; Ogden and Hedley, 1980; Mazei and  
Tsyganov, 2006), we identified and counted a minimum of 150 testate amoebae per sample. No testate amoebae were present  
180 in core segments below 285 cm (age > 6000 ka BP) in the Ulukh-Chayakh sequence. We used the transfer function developed  
for the pan-European region (Amesbury et al., 2016) to derive the water depth. For the composite water table reconstruction,  
we used the same setting as for pollen.

## 2.6 Numerical methods

To quantify the relationship between peatland moisture conditions, biomass burning, forest density and the relative abundances  
of PFTs, we performed a correlation analysis. We used microcharcoal influx (CHAR particles >150 µm) as a determination of  
biomass burning, pollen percentages as a determination of the three PFTs (resisters, invaders, avoiders, and others) and testate  
amoebae-based water table depth as a determination of peatland moisture. The group "others" includes pollen and spores of  
shrubs, herbs, ferns and moss. Before the analysis, we interpolated all datasets fed into the model to a 100- year interval using  
190 linear interpolation. We also developed generalised linear models (GLMs) to explore the response of biomass burning (CHAR)  
to changes in peatland moisture conditions (DTW) and to test for the existence of thresholds in the water level at which biomass  
burning may increase.

## 3. Results

### 195 3.1 Chronology

The age-depth model of the Rybnaya sequence spanned ~ the last 8400 years and showed a mean peat accumulation rate of 25 yr/cm (ranging between 6-36 yr/cm). The Ulukh-Chayakh sequence may cover ~ the last 8500 years, but the chronology of the bottom part of this site (>6000 years) relied on linear extrapolation and it is therefore highly uncertain (File S1). The subsequence covering the last 6000 years had an average temporal resolution of 21 yr/cm (ranging between 3-37 yr/cm).

200

### 3.2 Site-specific and composite record of biomass burning and fire frequency

Both records displayed a high signal-to-noise index (File S2) with almost all peaks well above 3 (a mean of 4.98 at Rybnaya and 6.45 at Ulukh-Chayakh), the theoretical minimum value for justification of peak analysis (Kelly et al., 2011). At Rybnaya, CHAR was highest between 7.5 and 6 ka and around 4.5 ka, whereas the frequency of high-severity fires inferred from the charcoal peak magnitude and abundance of woody morphologies ranged between 1 and 2 fires/900 yr (Figs. 2a,b, 4; Files S2, S3). At Ulukh-Chayakh, CHAR was highest >6 and 3.5 ka, and the fire frequency varied between 2 and 5 fires/900 yr. Both profiles showed a decline towards a minimum in CHAR and frequency of severe fires i.e., low peak magnitude and reduced occurrence of woody charcoal morphologies, approximately between 4 and 1.5 ka (3-1.5 ka at Ulukh-Chayakh). The CHAR increased towards the present at both sites, but the charcoal peak amplitude was considerably higher at Ulukh-Chayakh.

205

210 The composite CHAR record showed augmented regional biomass burning between 7.5 and 4 ka (positive Z-scores) with peaks centred at 7.5 and 4.5 ka (Fig. 5). We found a pattern of CHAR decline towards a minimum in the composite profiles between 4 and 2 ka (negative Z-scores), followed by another increase between 2 ka BP to the present (positive Z-scores). The composite fire frequency showed an increase until ca. 5-4.5 ka and then again from 2 ka to the present.

### 215 3.3 Site-specific and composite record of vegetation composition and forest density

Early Holocene data is only available from the Rybnaya site (8.5 and 7.5 ka BP), indicating that light taiga and the fire-invader *Betula* were most abundant (up to 60%) during that period, whereas other light taiga fire-resisters (*Pinus sylvestris*) and dark taiga and fire avoiders (mainly *Picea obovata*), had an abundance of 10% and 5%, respectively (Fig. 3; File S4a). The high proportion of light taiga resulted in a low forest density (dark-to-light taiga ratio of 0.1). Denser forests, with an increased dark-to-light taiga ratio (> 0.2), were identified between 7.5 and 4 ka at Rybnaya and between 5 and 2.5 ka at Ulukh-Chayakh (Fig. 5; File S4a,b). The light taiga was composed of up to 70% fire-resisters (*Pinus sylvestris* and *Larix spp.*), while the dark taiga, with its fire avoiders (*Pinus sibirica*, *Picea obovata*, and *Abies sibirica*), made up to 25% of the forest. A decline in fire-resisters (down to 50%) and forest density and increasing invader abundance (up to 60%) occurred after 4.5 ka at Rybnaya and after 2.5 ka at Ulukh-Chayakh, indicating a change in forest composition. Between-site variability was highest within the avoider group. *Picea obovata* had higher values at Rybnaya (up to 10%) than at Ulukh-Chayakh (3%), whereas *Abies sibirica* was more abundant at Ulukh-Chayakh (15%) than at Rybnaya (7%; Fig. 4). The composite vegetation record showed a higher proportion of fire-resisters between 7.5 and 5 ka, fire avoiders between 7.5 and 3 ka, and fire invaders over the last 4.5 ka (Fig. 5).

220

225

Understory vegetation primarily reflects local peatland development. It was predominantly composed of herbs/sedges  
230 (Cyperaceae) and ferns (Polypodiaceae and *Equisetum*) at both sites, with more shrubs (Ericaceae) at Rybnaya and Ericaceae  
and moss (*Sphagnum*) at Ulukh-Chayakh over the last 4.5 ka (Fig. 3; File S4a,b). The sum and individual levels of herbaceous  
taxa, including those potentially related to human impact (*Artemisia*, Asteraceae, Chenopodiaceae, Urticaceae, Brassicaceae,  
*Plantago lanceolata*), were constant throughout the profiles. However, their abundance increased slightly over the last 1.5 ka  
(Fig. 3; File S4a,b).

235

### 3.4 Site-specific and composite records of peatland moisture conditions

At Rybnaya, the testate amoeba-based reconstruction of the water table indicated relatively high levels (around 15 cm below  
surface) between 8.5 and 7.5 ka, 4 and 2.5 ka, and over the last 1 ka (Fig. 4). We reconstructed low levels (20-30 cm below  
surface) for the time interval between 7.5 and 4.5 ka and 2.5 and 1 ka (Fig. 5). At Ulukh-Chayakh, the water table was high  
240 between 3.5 and 2.5 ka, 2 and 0.5 ka, and towards the present day. There, times of low water table occurred between 6 and 3.5  
ka, 2.5 and 2 ka, and around 0.5 ka. The composite record of the water table showed high levels approximately between 8.5 to  
7.5 ka, 3.5 and 3 ka and during the last 1.5 ka, and low levels between 7.5 and 4.5 ka, and around 2.5 ka (Fig. 5).

### 3.5 Numerical analysis

245 The correlation analysis at both sites showed that the decline in water table position (higher values representing drier  
conditions) was positively associated with the proportion of fire avoiders, resisters, and forest density, and negatively with  
invaders and others (Fig. 6a, b). Although the correlation coefficients were stronger for Rybnaya than Ulukh-Chayakh, none  
of these were statistically significant (Appendix A1). The generalised linear model showed no significant influence of water  
levels above 20 cm on the probability of fire occurrence and severity at both sites (Fig. 6c,d). However, a drop in water level  
250 below 20 cm contributed statistically significantly to the increase in fire occurrence and severity at Rybnaya but had no  
statistically significant influence at Ulukh-Chayakh.

## 4 Discussion

### 4.1 Changes in fuel, fire type and fire frequency over the Holocene

255 Stand-replacing fires combust substantial amounts of biomass because they burn entire trees. Such fires manifest themselves  
in a greater abundance of charcoal particles that exceed the quantities typically produced by surface fires. This feature allows  
a distinct separation of charcoal peaks from charcoal background levels, which yields a higher signal-to-noise index (Higuera  
et al., 2005; 2009; Courtney Mustaphi and Pisaric 2014). Indeed, the comparison of sedimentary charcoal from sub-recent  
samples with satellite imagery of the region (Plotnikovo Mire) has confirmed that the marked increase in charcoal particles  
260 towards the present day at this location, closely agrees with the occurrence of high-severity fires (Feurdean et al., 2020a).  
Satellite images and official forest statistics show no evidence of recent fires in the vicinity of the current study sites, except  
for a small fire documented in 1993 near the Ulukh-Chayakh site (Fig.1). This aligns with the scarcity of charcoal peaks (1-2

pieces) from sub-surface samples in both cores (Fig. 2). A high-severity fire event occurred in 2015 some ca. 30 km from Ulukh-Chayakh, which is not documented in our surface charcoal record and corroborates the localised origin of charcoal  
265 found in this sedimentary profile. Samples from the Ulukh-Chayakh site show a minor increase in charcoal (2-7 pieces) ca. fifty years ago, possibly related to a local fire event in 1993. The first clear charcoal peak at this site (250 pieces), with numerous wood fragments, was found ca. 200 years ago, whereas the preceding charcoal peak (400 pieces) was ca. 900 years ago (Fig. 2a,b; File S3). These two peaks therefore demonstrate the intermittent occurrence of infrequent, high-severity local  
270 fires that produce large quantities of charcoal, embedded in what is otherwise predominately a surface fire type regime generating low levels of charcoal. It also indicates that the charcoal peak extraction method applied here reliably reflects the occurrence of high-severity local fires.

We reason that the prevalence of a high charcoal influx with well-defined charcoal peaks and abundant woody morphotypes found between ca. 7.5 and 4 (3) ka at both sites, and over the past 1.5 ka at Ulukh-Chayakh, is indicative of the predominance of high-severity local fires (Fig. 2; File S3). Between 4 (3) and 1.5 ka, the observed low charcoal influx and peak magnitude  
275 were coupled with a lower abundance of woody morphologies at both sites, although the latter feature was more pronounced at Ulukh-Chayakh (Fig. 2; File S3). For this period, we inferred predominately low-temperature surface fires that mostly burned understory biomass. Experimental production of charcoal additionally provides evidence that graminoids and *Sphagnum* produce little charcoal during high-temperature fires (Hudspith et al., 2017; Feurdean, 2021). Measurements of aspect ratio and surface area on selected charcoal samples at Ulukh-Chayakh show that the aspect ratio only partially agrees  
280 with the predominant fuel type inferred from charcoal morphologies. A lower aspect ratio of charcoal particles, typical for wood and leaf morphotypes, was what we expected at times of increased woody morphologies, and an increased aspect ratio with a rise in the relative proportion of graminoids (Feurdean, 2021; Vachula et al., 2021). This is probably the results of a mixed morphology of charcoal types in the same sample (Fig. 2). The overlapping morphologies of leaves and wood from trees and shrubs in the same sample also make it hard to distinguish between the dominant fire type as high-severity surface  
285 fires can combust both living shrubs and dead wood and leaves. Our measurements of the surface area indicate high values at times of an increased abundance of leaves (Fig. 2; File S3) with a typically high surface area (Crawford and Belcher, 2014; Feurdean, 2021), but also with the presence of larger size particles, which complicates any interpretation of a link between charcoal surface area and the increased predominance of leaves.

Our reconstructed fire return interval is ~ 450 yr (2 fires/900 yr) throughout most of the Holocene (Fig. 4). However, fire  
290 frequency (at Rybnaya) and severity (at Ulukh-Chayakh) increased over the last 1.5-2 ka BP compared to the long-term averages of both records suggesting an intensification of fire activity during the most recent two millennia. The composite fire frequency derived from all four records also shows increasing biomass burning and fire frequency over the last 2-1.5 ka (Fig. 5). The reconstructed fire return interval (FRI) in the study area is in line with those from other sites located in forested peatlands (*Pinus-Betula* dominated, *Picea obovata*, *Abies sibirica*) in Russia, which report an FRI range between 100 and 600  
295 yr (Barhoumi et al., 2019, 2020). In contrast to these studies, we have not found a gradual increase in fire frequency from the early Holocene towards the present, but rather two distinct periods of enhanced activity, between 7.5 and 4 ka, and

approximately over the last 2 ka (Fig. 5). A similar increase in fire frequency during the last two millennia has also been recorded at other sites in southern Siberia, such as Lake Baikal (Bourhami et al., 2021) and in the Altai Mountains (Rudaya et al., 2020).

300

#### 4.2 Drivers of vegetation and fire regime change

Climate conditions influence peatland moisture, fuel dryness, flammability and the composition of moisture- and fire-related PFTs. The relative abundances of the fire-related PFTs, in turn, influences the prevalence of specific fire regime types, e.g., low-intensity vs. high-intensity. Below, we discuss how climate change affects hydrological conditions in peatlands. We also highlight how climate and hydrology interact with forest and peatland plant composition, and fuel flammability.

305

##### 4.2.1 The influence of climate on peatland moisture and fuel flammability

Waterlogging in peatlands can limit fire severity and the burning depth in the peat. Moreover, the waterlogged horizon provides a deeper substrate that can serve as a seedbed for post-fire regeneration (Whitman et al., 2018; Gewin 2020). However, increasingly dry peatland conditions and consequently of the tree cover can reduce the limiting effect of waterlogging on fire severity (Magnan et al., 2012; Kettridge et al., 2015; Whitman et al., 2018; 2019). Deep burns can even smoulder over winter and re-ignite the following spring (Scholten et al., 2021). Our water table reconstructions indicate that the water level fluctuated between 8 and 30 cm below the peat surface and was around 20 cm at both sites during large parts of the Holocene (Fig. 4). We found that the probability of occurrence and intensification of fire severity was greater at times when the water level dropped below 20 cm (drier conditions), and lower at water levels between 10 and 20 cm below the surface (wetter conditions), a pattern that is more evident at Rybnaya (Fig. 6 c,d). The stronger moisture-fire relationship at Rybnaya may be related to the higher amplitude of changes in local hydrological states and the overall drier conditions at this site (8-30 cm) compared to Ulukh-Chayakh (10-23 cm), which remained moister over the Holocene (Fig. 6). Water tables of mesotrophic mires are co-regulated by the difference between precipitation (P) and evapotranspiration ( $E_t$ ) and external water inflow. The detrital element Ti, a possible indicator of water influx, was high in the bottom profiles that were rich in minerogenic material. Ti increased between 4 and 3 ka and 1.5-0.1 ka at Ulukh-Chayakh and only slightly over the last 1 ka at Rybnaya (File S5). This evidence suggests that, except of these time intervals, the water table reconstructions primarily reflect the P- $E_t$  balance.

310

315

320

At a Holocene scale, the intensity of fires and/or fire size was greatest between 7.5 and 6.5 ka and 5 and 4 ka, but not fully synchronous between the sites (Figs. 4, 5). From 9 to 4.5 ka, annual temperatures in the Northern Hemisphere were up to 3.5°C warmer than at present (Fig. 5) and exhibited a more pronounced seasonality, i.e., higher summer and lower winter temperatures (Kauffman et al., 2020; Bova et al., 2021). Proxy records from Siberia attest to warmer and drier-than-present climate conditions between 9 to 6 ka and a temperature and moisture optimum between 6 and 4.5 ka BP (Groisman et al., 2012). Warm summer temperatures likely enhanced evapotranspiration and consequently lowered peatland water levels, leading to drier surface conditions (Fig. 5). These conditions, in turn, increased fuel flammability, allowed a denser tree cover to establish on the peatlands and fostered enhanced fire severity (see 4.3).

325

330

Contrastingly, the interval of lowest biomass burning and fire severity approximately between 4 (3) and 1.5 ka BP coincides with one of the periods of wettest peatland conditions during the Holocene (at Rybnaya) or a highly fluctuating water table (at Ulukh-Chayakh; Fig. 4) Annual and summer temperatures declined after 4.5 ka to values below the present day (Kauffman et al., 2020; Bova et al., 2021). Regionally, this cooling trend, which started at approx. 4.5 ka (Groisman et al., 2012) led to high  
335 fuel moisture and reduced fuel flammability. Although biomass burning and the frequency of severe fires show more centennial-scale variability over the past 1.5 ka, this only partially matches known climatic fluctuations, such as the Medieval Climate Anomaly (MCA1200-650 cal yr BP) and the Little Ice Age (LIA; 700-400 cal yr BP). Notably, an increased charcoal peak amplitude occurred during the second part of the LIA (400-200 cal yr BP), at times of extremely wet conditions (Fig.4). We hypothesise that the climatic linkage between the cool and wet conditions that imply high fuel moisture conditions and  
340 typically low fire activity was likely disrupted by anthropogenic activity (Fig 3; File S4a, b). Historical records indicate the widespread colonisation of the region by the Russians at this time that was associated with the conversion of forest to arable land and pastures, and likely increased anthropogenic ignitions (Naumov, 2006). Most recently, local fire suppression near the village of Teguldet may have hampered contemporary fire spread on the mire leading to the recent pattern of low fire activity.

#### 345 **4.3 Feedbacks between peatland moisture, community PFT composition and fire regime**

Peatland moisture conditions affect the relative abundances of PFTs. Fire-related PFTs, in turn, create positive or negative feedbacks for fire regimes via specific fire-related traits (Feurdean et al., 2020a; Kharuk et al., 2021). We found a dominance of open light taiga species and fire invaders (*Betula* spp) at times of higher water table (wet conditions) between 8.5 and 7.5 ka and after 4.5 and 3.5 ka (Figs. 2, 4). However, *Betula* spp. also remained dominant during the periods of water table decline  
350 recorded between 2.5 and 1.5 ka. *B. pubescens* grows on wet peatlands, whereas *B. pendula* grows more frequently on drier soils and peatlands with higher fire incidence (Wirth, 2005; Groisman et al., 2012). Unfortunately, pollen analysis cannot differentiate the prevalence of birch species with contrasting hydrological and fire tolerances because their pollen is too similar. Denser forests of light taiga and fire-resisters (*Pinus sylvestris*) prevailed between 7.5 and 4.5 ka. Dark taiga taxa and fire avoiders, primarily *Pinus sibirica* at Rybnaya and *Abies sibirica* at Ulukh Chayakh (only from 5.5 ka), intersperse these forests  
355 (Fig.3; File S4a,b). This forest composition coincides with drier peatland conditions and an increased severity in fires. Although not statistically significant, our correlations suggest a positive association between a high-water level and *Betula*, and low water level conditions with all conifer types (Fig. 6 a,b). We deduce from this a greater tolerance of broadleaf trees to wetter conditions compared to conifers. Visual trends and correlation reveal that the biomass burning increase with forest density was probably connected to dry peat conditions (Figs. 4, 6). The greatest biomass burning was found for intermediate  
360 forest density indices from 0.15 to 0.3 (max. 0.6; Fig. 4). This finding is consistent with emerging evidence on fire-fuel relationships in boreal forests, which points to a higher fire hazard in less dense than denser forests, which allow fuel to dry (Scheffer et al., 2012; Feurdean et al., 2020b).

The presence of the fire-resister, such as *Pinus sylvestris*, in Siberia is associated with a light surface fire regime (mean FRI of 28 years) that alternates with longer-term (mean FRI of 200 yr) stand-replacing crown fires (Ivanova, 2005; Kukavskaya et

365 al., 2016). Fire avoiders typically experience severe stand-replacing crown fires at relatively long return intervals (mean FRI  
150 years; range 99 and 300 years; Goldammer and Furyaev, 1996; Schulze et al., 2005; Wirth, 2005; Kharuk et al., 2021).  
The post-fire regeneration pathway of conifer species involves recruitment directly after burning (*P. sylvestris*) or after an  
early successional phase initiated by *Betula* (*Pinus sibirica*, *Picea obovata*, and *Abies sibirica*). A mixed taiga forest with  
broadleaf trees and dark taiga conifer taxa typically develops between 60-120 years after a fire, followed by the dominance of  
370 conifers as a late-successional stage (Tautenhahn et al., 2016; Coop et al., 2020; Kharuk et al., 2021). We reason that the  
prevailing periodicity of severe fires (every 180 to 450 years) between 7.5 and 4.5 ka provided a fire-free period that was long  
enough for the fire avoiders *Pinus sibirica*, *Picea obovata*, and *Abies sibirica* to reach reproductive age. Alternatively, burning  
may have been too patchy to create sufficiently large forest gaps to limit seed dispersal and inhibit post fire recovery. *Pinus*  
*sibirica* is typically classified as a fire avoider but behaves like a fire resister when reaching old age, which could also explain  
375 its increased presence at times of high fire activity. Fire also allows dark taiga species to compete with *P. sylvestris* and become  
established beyond poor soils and boggy areas (Kharuk et al., 2021).

A different fire regime and altered vegetation feedbacks emerged over the last two millennia at Ulukh-Chayakh, the site that  
experienced more severe fire episodes. It should be acknowledged that each identified fire peak could have come a few  
consecutive fire events that we were not able separate using the charcoal records. The intensification of local fire severity at  
380 Ulukh-Chayakh paralleled a decline in the proportion of fire avoiders (mostly *Abies sibirica* and *Picea obovata*), an increase  
in fire invaders (*Betula*) and the abundant occurrence of heathland shrubs (Figs. 3. 4). Shrubs burn hotter than other surface  
fuel types and reach temperatures that kill most conifer seedlings (Tautenhahn et al., 2016). High severity burned areas have  
also been found to be more prone to repeated burning and have a more negative impact on conifers (Kukavskaya et al., 2016;  
Whitmann et al., 2019; Coop et al., 2020). We propose that the intensification in fire severity at Ulukh-Chayakh may have  
385 eliminated mature *Abies sibirica* and *Picea obovata*, limited their seed dispersal and disrupted their successional pathways.  
These dynamics further resulted in a shift in forest composition towards more post-fire-adapted invader communities with  
better dispersal capabilities, recruitment strategies for burned areas, and rapidly maturing taxa. Our results support emerging  
findings of increases in broadleaf trees (*Betula* or *Populus*) at the expense of evergreen conifers that are associated with  
contemporary warming and increasing fire severity in forests in Siberia and North America (Kelly et al., 2013; Tautenhahn et  
390 al., 2016; Mekkonen et al., 2019; Whitman et al., 2019; Kharuk et al., 2021). At Rybnaya, the modest increase in biomass  
burning over the past two millennia coincided with wet conditions and a forest composition remaining dominated by *Betula*,  
indicating that fire has played a more limited role in forest dynamics at this site.

## Conclusion

395 This study provides novel insights into past fire regime based on Holocene records from forested peatlands in western Siberia.  
It demonstrates that peatland hydrology is a critical determinant of fuel dryness, plant community composition (in terms of  
fire-related plant functional types) and fire regime. Wet peatland conditions promoted open forests with broadleaf trees  
typically classified as light-taiga taxa and fire invaders (*Betula*), whereas dry peatland conditions facilitated conifers and

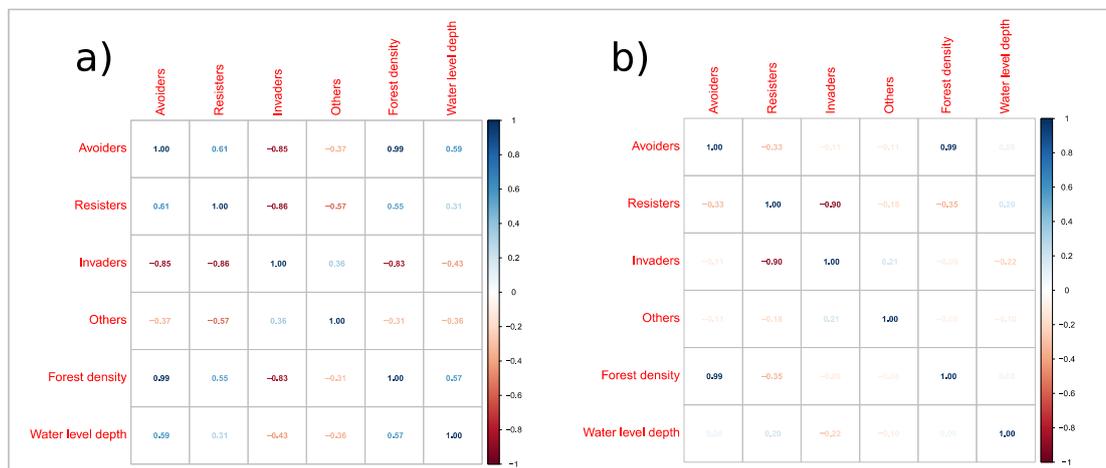

400 greater forest density. Although the probability of fire occurrence on these peatlands increased with drier conditions and forest  
density, the greatest fire incidence occurred when the water level declined below 20 cm and at an intermediate forest density.  
At a Holocene timescale, we found two scenarios of moisture-vegetation-fire interactions. In the first, an enhanced fire severity  
episode occurred between 7.5 and 4.5 ka and was associated with a low water level and a higher proportion of dark taiga/fire  
avoider taxa (mainly *Pinus sibirica* at Rybnaya and *Abies sibirica* at Ulukh Chayakh) in a light taiga and fire resister (*Pinus*  
405 *sylvestris*) dominant community. However, the second period of increased fire severity (i.e., ca. last 1.5 ka) coincided with a  
reduced abundance of fire avoiders (mostly *Abies sibirica* and *Picea obovata*) and an expansion of fire invaders (*Betula*).  
These community changes demonstrate that frequent fires of higher severity can lead to compositional changes in forests,  
either because the trees could not reach their reproductive age between burning events or the fires created substantial forest  
gaps that hindered seed dispersal. This study also shows certain prolonged periods of synchronous fire activity across sites,  
410 suggesting that the magnitude of centennial to millennial-scale climate variability over the Holocene was marked enough to  
drive fire regimes on a regional scale.

Based on our findings from fossil records, the frequent warm and dry spells predicted in Siberia for the future by climate  
change scenarios will likely enhance peatland drying and may convey a competitive advantage to some conifers, especially  
*Pinus sylvestris*. But dry peatland conditions, particularly water levels below 20 cm, will also exacerbate the likelihood of fire  
frequency, increase their severity, and likely disrupt the successional pathway of other typical taiga conifers, notably that of  
415 fire avoiders. Such a fire regime change may accelerate a shift towards broadleaf fire invader-type trees. Future climate-  
disturbance-fire feedbacks will not only accelerate changes in boreal forest structure and composition, but also impact the  
carbon balance of the forested peatlands and ultimately lead to albedo-mediated feedbacks on the regional climate system.

## Figures

645

**Figure 1.** Location of the study area in Eurasia, Russia and the Tomsk region (A). Satellite based images showing the location and spatial extent of vegetation types and the fire event at the previously published sites (B; Feurdean et al., 2020a) and the new study sites: Rybnaya (C) and Ulukh-Chayakh (D).

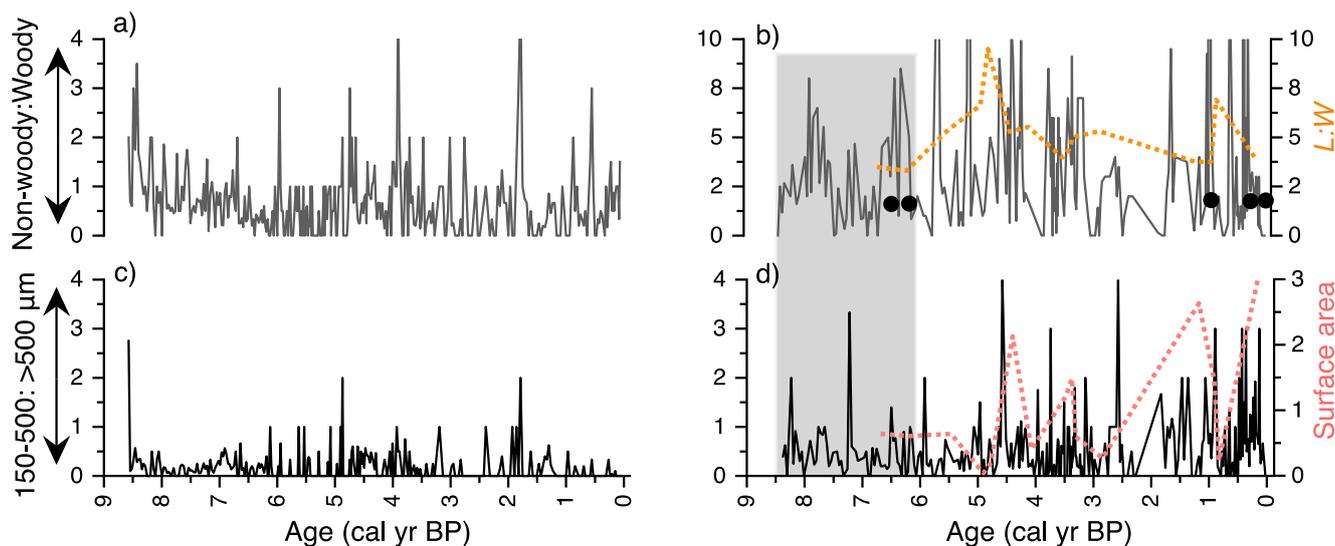

650

**Figure 2.** The ratio of charcoal morphotype influx ( $\#/\text{cm}^{-2}\text{yr}^{-1}$ ) of the two main categories: woody (wood, deciduous leaves, resins) and non-woody type (forbs, grass) in the Rybnaya (a) and Ulukh-Chayakh (b) sequences. The aspect ratio ( $L:W$ ) at Ulukh-Chayakh (b) used for fuel type identification. A high  $L:W$  ratio is typical for a higher abundance of the graminoids charcoal type, whereas a lower  $L:W$  ratio is typical for charcoal from wood and leaves. The ratio of charcoal influx ( $\#/\text{cm}^{-2}\text{yr}^{-1}$ ) of the two main two size classes: small  $150\text{--}500\ \mu\text{m}$  and large  $> 500\ \mu\text{m}$  in the Rybnaya (c) and Ulukh-Chayakh (d) sequences and the charcoal surface area ( $\mu\text{m}^2$ ) at Ulukh-Chayakh (d) (see File S3 for a full range of size classes). Bullets (b) represent the extra-large charcoal fraction ( $>1000\ \mu\text{m}$ ) identified during routine plant macrofossils analysis of sediment volumes of ca.  $20\ \text{cm}^3$ . The grey rectangle highlights the period with uncertain chronology.

660

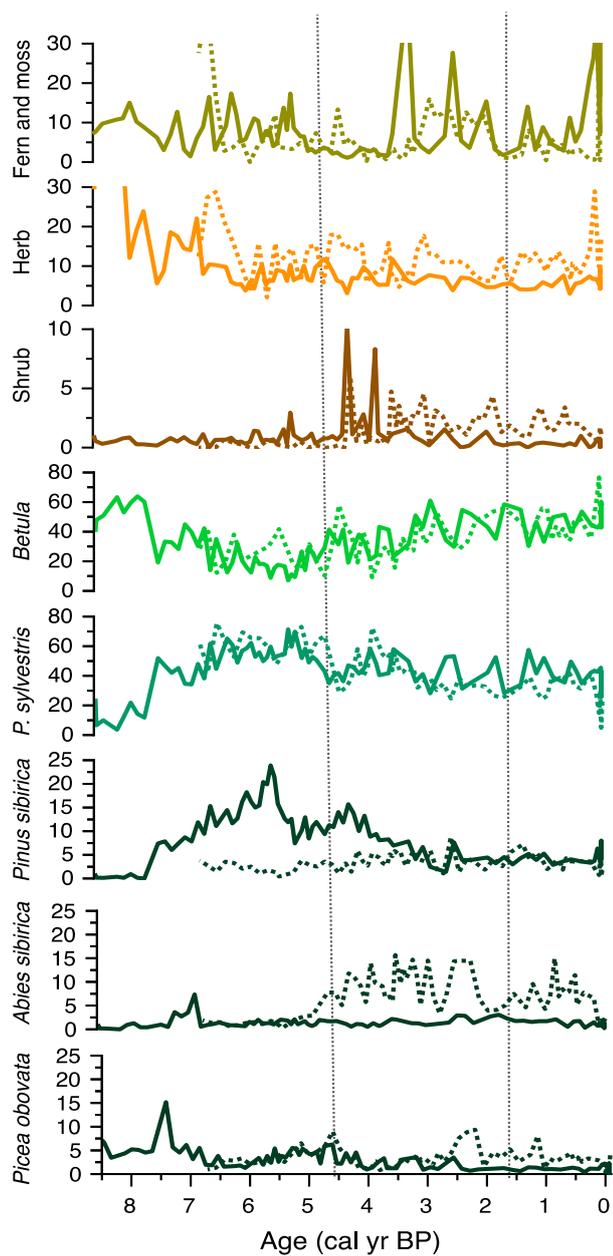

665

670

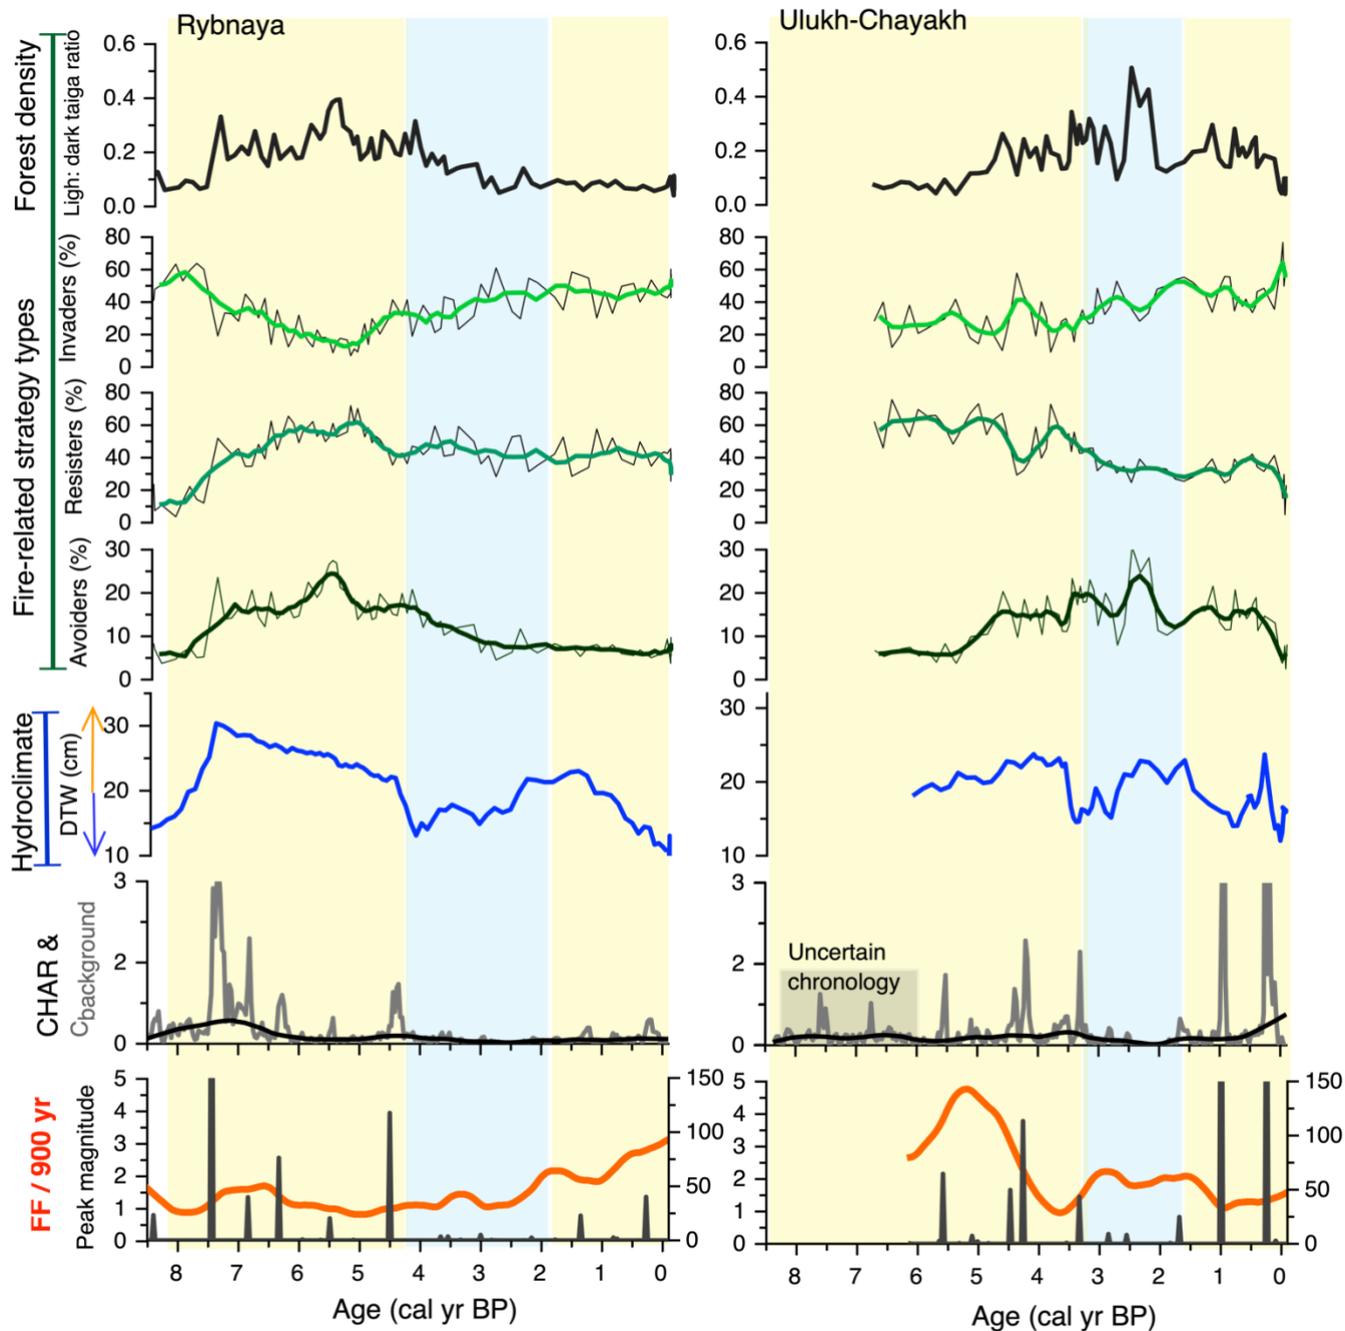

675 **Figure 3.** Temporal trends in the pollen and spore percentages of individual tree taxa and lumped group-wise for shrub, herb, fern and moss at Rybnaya (continuous line) and Ulukh-Chayakh (dashed line). Periods with substantial changes in fire regime are indicated by dotted vertical lines.

**Figure 4.** Temporal trends in the pollen percentages of the fire-related plant functional groups (invaders, resisters and avoiders) and the forest density index determined from the ratio between pollen percentages of dark taiga/ and light taiga tree taxa in the Rybnaya and Ulukh-Chayakh sequences. Hydrological conditions on the peatlands were derived from testate amoeba-based estimates of the water table location (DTW) where values range from 8 cm (high water level) to 30 cm (low water level). The fire metrics include burned biomass (CHAR), fire frequency (number of fires /900 years), and charcoal peak magnitude (the higher the values, the greater the fire severity) derived from macro-charcoal particles >150 µm. Colours in the background denote periods with marked changes in fire regime and vegetation composition, where a change from blue hues to orange hues indicates an intensification of the fire episodes.

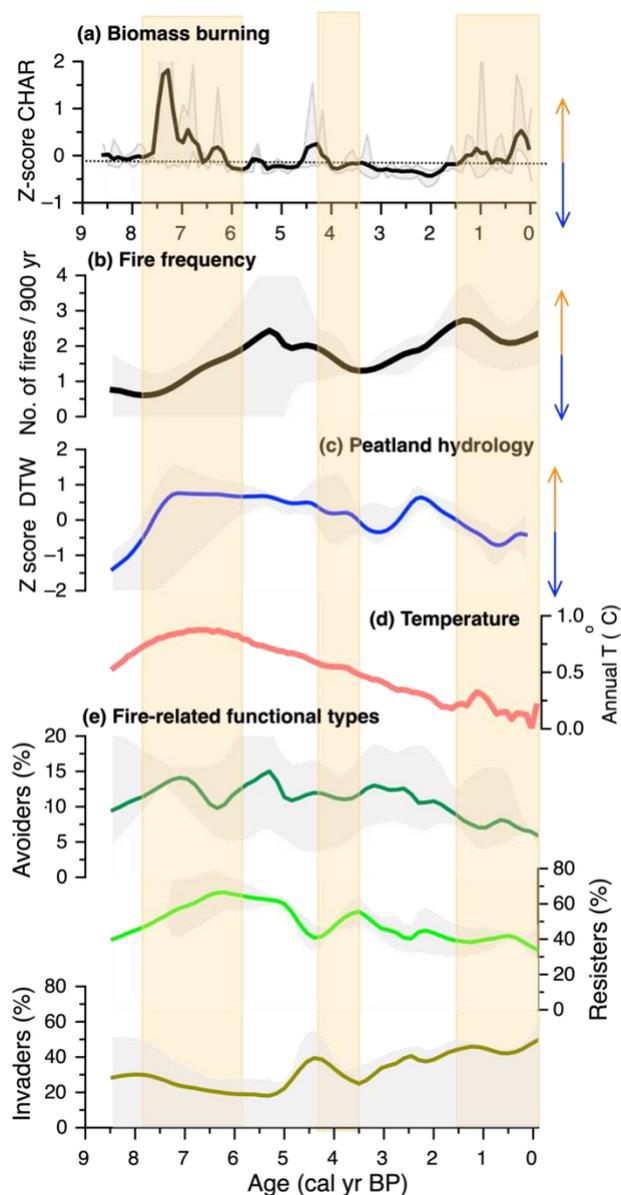

690

695

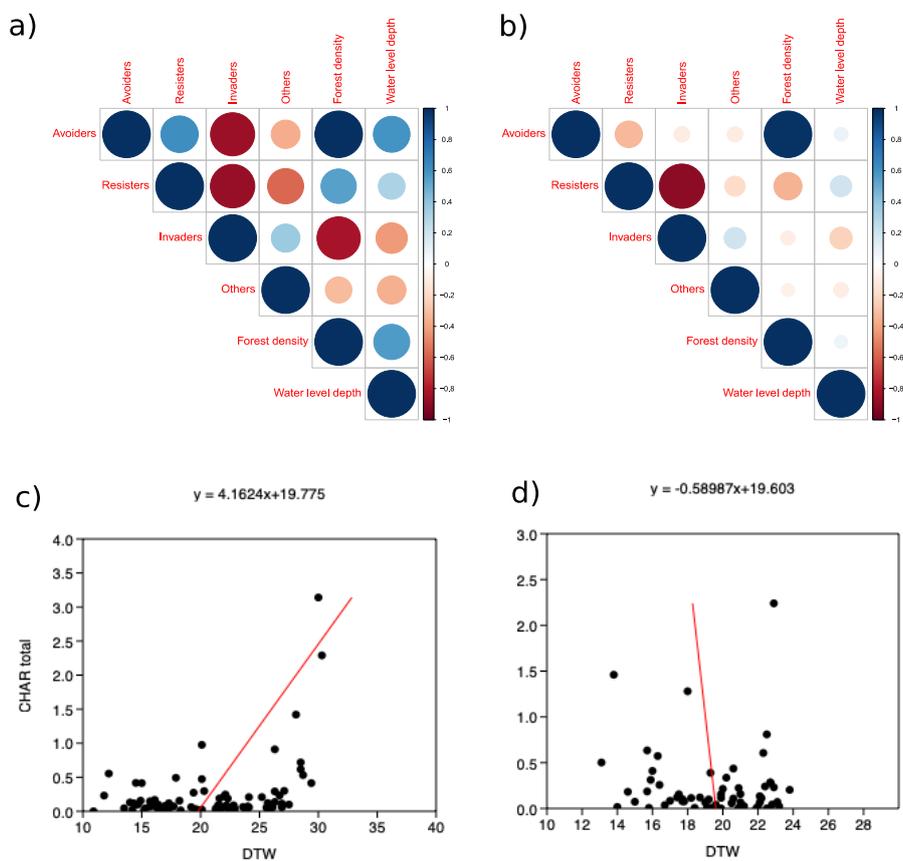

700 **Figures 5.** Composite record of biomass burning (n=4) based on Z-score charcoal influx where positive/negative Z-score  
values represent greater-than-mean/lower-than-mean charcoal influx over the base period (a). Composite record of fire  
frequency (n=4) (b). Composite record of peatland hydrology (n=4) from testate amoeba where positive/negative Z-score  
values represent lower/higher-than mean water level (c). Annual temperature (anomalies) for 30-60 °N (Kaufman et al., 2020)  
(d). Composite record (n=4) of the relative abundance of avoiders, resisters, and invaders determined from pollen percentages  
705 (e). Grey curves represent confidence intervals. Colours highlight the periods with higher biomass burning in the composite  
record.

710 **Figure 6.** Correlation analysis between water table position and the main plant functional types and forest density for Rybnaya (a) and Ulukh-Chayakh (b). Generalised linear models (GLMs) showing the response of biomass burning (CHAR) to changes in peatland moisture conditions (higher values in depth to water table=DTW representing drier conditions) for Rybnaya (c) and Ulukh-Chayakh (d).
