Abstract.

Enhanced summer insolation over North Africa induced a monsoon precipitation increase during the mid-Holocene, about 6000 years ago, and led to a widespread expansion of lakes and wetlands in the present-day Sahara. This expansion of lakes and wetlands is documented in paleoenvironmental sediment records, but the spatially sparse and often discontinuous sediment records provide only a fragmentary picture. Former simulation studies prescribed either a small lake and wetland extent from reconstructions or focused on documented mega-lakes only to investigate their effect on the mid-Holocene climate. In contrast to these studies, we investigate the possible range of mid-Holocene precipitation changes in response to a small lake extent and a potential maximum lake and wetland extent.

~~Results show that the maximum lake and wetland extent shift the North~~ Our study shows that during the summer monsoon season, the isohyets of the African rain belt ~~about 3~~ are shifted about 2 ° to 7 ° farther northward than the north in simulations with a maximum lake or wetland extent than in simulations with a small lake extent. ~~Vegetated wetlands cause a larger precipitation increase than the equally large lakes due to their~~ This northward extent is caused by a stronger and prolonged monsoon rainfall season over the North Africa which is associated with an increased monsoon precipitation over the southern Sahara and an increased precipitation from tropical plumes over the northwestern Sahara. Replacing lakes with vegetated wetlands causes an enhanced precipitation increase which is likely due to the high surface roughness of the wetlands. A moisture budget analysis reveals that both, lakes and wetlands, ~~cause an enhanced~~ not only cause a local precipitation increase by enhanced evaporation, but also by a stronger inland moisture transport and local moisture recycling to ~~their southern side. In contrast, increased moisture advection by the Harmattan winds causes a drying response to the north~~ the south of Lake Chad and the West Saharan lakes. Analysis of the dynamic response show that lakes and wetlands cause a circulation response inverted to the one associated with the Saharan heat low. Depending on the latitudinal position of the lakes and wetlands, they predominantly cause a northward shift or a decay of the African Easterly Jet. These results indicate that the latitudinal position of the lakes and wetlands ~~influences the northward extensions~~ strongly affects the northward extension of the African summer monsoon. ~~In the sensitivity experiments, the northern position of West Saharan lakes and wetlands substantially contributes to the strong monsoon northward shift seen in the maximum lake and wetland simulations.~~

1 Introduction

Paleoenvironmental sediment records reveal that North African lakes and wetlands spatially expanded during the mid-Holocene, as a result of increased summer monsoon precipitation (Holmes and Hoelzmann, 2017; Lézine et al., 2011). This precipitation increase was initiated by changes in the orbital forcing Kutzbach (1981), but reinforced by surface changes such as the expansion of vegetation (Kutzbach et al., 1996; Claussen and Gayler, 1997), the formation of soil (Levis et al., 2004; Vamborg et al., 2011) and the extent of lakes and wetlands (Coe and Bonan, 1997; Broström et al., 1998; Carrington et al., 2001; Krinner et al., 2012; Chandan and Peltier, 2020). Even though the extent of lakes and wetlands during the mid-Holocene is visible in sediment records, these records are spatially sparse and most of them are temporally discontinuous (Holmes and Hoelzmann, 2017; Lézine et al., 2011). Additionally, reconstructions widely differ regarding the existence of mega-lakes (Quade et al., 2018). Given this spatially and temporally limited information from reconstructions, investigating the effect of lakes and wetlands on the mid-Holocene climate becomes a scientific challenge.

~~Former-Previous~~ simulation studies used different approaches to prescribe mid-Holocene lakes and wetlands to investigate their effect on the North African climate. The majority of these studies prescribed a small lake and wetland extent ~~by Hoelzmann et al. (1998) that only considers mega-lake Chad using the reconstruction map by Hoelzmann et al. (1998)~~ (Broström et al., 1998; Carrington et al., 2001; Krinner et al., 2012). Results from these investigations show that a small lake and wetland extent only causes a marginal northward shift of the North African rain belt (Coe and Bonan, 1997; Broström et al., 1998; Carrington et al., 2001). A larger shift is caused, though, when this initial precipitation response is reinforced by vegetation feedback (Krinner et al., 2012). A more recent simulation study by Chandan and Peltier (2020) that considers several documented mega-lakes (e.g. Lake Ahnet, Chotts, Fezzan, Dafur and Chad) indicates that these large lakes only have a little impact on the northward penetration of the North African rain belt, but induce a precipitation increase over the Sahel region. These prior simulation studies all follow the approach of prescribing lakes and wetlands that are documented by reconstructions.

Comparison between dust emission simulations and marine sediment cores indicate that mid-Holocene lakes and wetlands might have expanded much stronger over the Western Sahara (Tegen et al., 2002; Egerer et al., 2018) than prescribed in any mid-Holocene simulations (Hoelzmann et al., 1998; Chandan and Peltier, 2020). Moreover, little research has been done regarding the role of vegetated wetlands during the mid-Holocene ~~(Carrington et al., 2001). Present investigations on the effect of vegetated wetlands prescribed a small extent in the western Sahara and~~ Vegetated wetlands have been prescribed in the vicinity of mega-lake Chad ~~(Carrington et al., 2001; Hoelzmann et al., 1998). Apart from mega-lake Chad, (Carrington et al., 2001; Hoelzmann et al., 1998), yet~~ the existence of vegetated wetlands in the vicinity of other documented mega-lakes is also conceivable. In addition, vegetated wetlands may have formed as a result of seasonal flooding, as seen in the Okavango Delta in South Africa.

Thus, the limited availability ~~in of~~ mid-Holocene sediment records entail interpretative uncertainties in the effect of lakes and wetlands on the mid-Holocene climate. Therefore, we investigate the possible range of mid-Holocene precipitation changes by

exploring the effect of a small (Hoelzmann et al., 1998) and a potential maximum lake and wetland extent (Tegen et al., 2002), rather than following the approach of prescribing lakes and wetlands documented in reconstructions. This includes larger lakes and wetlands over the western Sahara, which might strongly affect the Saharan heat low and, thus, the West African monsoon precipitation itself.

2 Methods

In order to investigate the potential range of mid-Holocene precipitation changes induced by extended lakes and wetlands, we conduct four mid-Holocene sensitivity experiments. The sensitivity experiments are performed using the atmosphere model ICON-A (Giorgetta et al., 2018) and the land model JSBACH4 (Schneck et al., 2021; Reick et al., 2021) at ~160 km horizontal resolution and 47 vertical hybrid sigma level. This coupled atmosphere-land model is forced with climatological 6 kyr BP orbital parameters (Berger, 1978) and greenhouse gas concentrations (Brovkin et al., 2019). The 6 kyr BP climatological vegetation distribution is prescribed based on a 6-kyr-BP-transient mid-Holocene MPI-ESM PMIP4-CMIP6 simulation (Brierley et al., 2020; Brown et al., 2020) simulation (Dallmeyer et al., 2021).

The ICON-ESM simulates regional sea-surface temperatures (SST) biases of up to 5 K (Jungclaus et al., 2021), which causes a latitudinal displacement of the North African summer monsoon (Zhao et al., 2007). In order to simulate the latitudinal position of the North African summer monsoon in better agreement with proxy data, we use observation-based AMIP2 data to prescribe the SST and sea-ice concentration (SIC) (Taylor et al., 2000; Kanamitsu et al., 2002). The SST and SIC boundary conditions are derived as the following: monthly climatological differences between a 6 kyr BP (Jungclaus et al., 2019; Brierley et al., 2020) historical (1980-2014) (Wieners et al., 2019) MPI-ESM PMIP4-CMIP6 simulation are superimposed onto a AMIP2 climatology (1980-2014). To take into account the seasonal SST and SIC variability, transient monthly SST and SIC anomalies from the 6 kyr BP simulation are added to the AMIP2-like mid-Holocene climatology. Since Sahel rainfall responds non-linearly to SST changes (Neupane and Cook, 2013), particularly over the tropical Atlantic (e.g. Rodríguez-Fonseca et al. (2015)), adding transient monthly anomalies to the climatological monthly mean SST, affects the overall mean state of the North African monsoon system.

Using this setup, the individual sensitivity experiments are run for 35 years, in which only the last 30 years are used as evaluation period. The individual sensitivity experiments differ only in their lake and wetland extent over North Africa: (1) present lakes, (2) small lake extent, (3) maximum lake extent, (4) maximum wetland extent. In the control simulation, the present lake map for standard ICON AMIP2 simulations is used (Fig. 1a). The small lake extent is given by the reconstruction map from Hoelzmann et al. (1998) that is based on paleo-environmental records (Fig. 1ab). The maximum lake extent is represented by the potential maximum lake extent simulated by Tegen et al. (2002) using the hydrological model HYDRA (Fig. 1bc). The same potential maximum extent map is also used to prescribe the maximum extent of wetlands (Fig. 1bc).

The lakes and wetlands are treated as fractional grid cell types in the land model JSBACH4. The lakes are represented by a simple constant-depth mixed-layer (10 m) approach (Roeckner et al., 2003). The surface temperature of the lakes is uniquely dependent on the net surface heat flux, and the lake albedo is set to a constant value of 0.07 (Roeckner et al., 2003). The wetland

Figure 1. (a) standard AMIP2 present-day lake fraction from the JSBACH4-ICON model, (b) mid-Holocene small lake fraction derived from paleoenvironmental paleoecological reconstructions (Hoelzmann et al., 1998), and (c) mid-Holocene maximum lake fraction derived using the hydrological routing algorithm (HYDRA) (Tegen et al., 2002). The present-day lake fraction of Lake Chad is less than 10% per grid box, which falls into the lowest subsection of the plotting scale. The labels in the lower left corner of the plots indicate the lake fraction averaged over the North African region (5 °N (black line)–38°N and 20 °W–50 °W).

surface cover type was implemented into JSBACH4 for the purpose of this study and is defined as moisture saturated soil with an equal ratio of C3 and C4 grasses growing on it. This representation of wetlands is similar to the one used by Carrington et al. (2001). In contrast to lakes, wetlands have a higher surface roughness and a dynamic background albedo that depends on the vegetation’s net primary productivity.

95 As indicated in the former section, the changes of the Saharan desert ground due to litter production from the vegetation is taken into account. Previous simulation studies showed that these changes in the background albedo (surface albedo without vegetation) substantially influence the mid-Holocene precipitation over the Sahel/Sahara region (Vamborg et al., 2011). To prescribe these background albedo changes, we use a parameterization-parameterization scheme that is based on the concept by Egerer et al. (2018):

$$100 \quad \alpha_{background} = \alpha_{mineral} - (\alpha_{mineral} - \alpha_{soil}) \times MIN \left(\sum_{PFT}^{i=1} f_i \frac{\overline{NPP}_i}{NPP_{soil,i}}, 1.0 \right) \quad (1)$$

The scheme by Egerer et al. (2018) prescribes the albedo changes of a mineral desert ground ($\alpha_{mineral}$) towards a organic soil ground α_{soil} due to the dead biomass production-production of dead biomass from the vegetation growing on the desert groundand, thus, the formation of organic soil in the mineral ground. The background albedo changes depend linearly on the 5-year mean net primary productivity (NPP) \overline{NPP} of the vegetation -The relative to the fixed annual NPP needed to completely cover the ground with one layer of dead organic material NPP_{soil} . By considering this linear relation Eq. (1), the scheme by Egerer et al. (2018) neglects non-linear processes such as the overlapping of dead leaves and litter with increasing coverage of

the ground with organic material. Therefore, we here use the following ~~inverse~~ exponential function to describe the background albedo changes during the mid-Holocene:

$$110 \quad \alpha_{background} = \alpha_{mineral} - (\alpha_{mineral} - \alpha_{soil}) \times e^{-\sum_{i=1}^{NPP} f_i \frac{\overline{NPP}_i}{NPP_{soil,i}}} \quad (2)$$

~~$\alpha_{background}$ denotes the background albedo that depends on changes in the 5-year mean annual NPP \overline{NPP} . NPP_{soil} represents the annual NPP needed to completely cover the ground with one layer of dead organic material (Egerer et al., 2018). $\alpha_{mineral}$ represents the mineral ground albedo and The soil albedo α_{soil} is the organic soil albedo reached, when the whole~~
 115 ~~ground is covered with dead biomass (Egerer et al., 2018).~~ α_{soil} is set to a mean value of 0.13 for the visible range and a mean value of 0.22 for the near-infrared range (Egerer et al., 2018) as suggested by Egerer et al. (2018). $\alpha_{mineral}$ is derived by inverting Eq. (???) and then calculating $\alpha_{mineral}$ for each grid cell using \overline{NPP} from a standard AMIP ICON simulation and $\alpha_{background}$ obtained from MODIS observation data (Otto et al., 2011). Since the background albedo scheme prescribed the transition from a mineral desert ground to a savanna landscape, this scheme is applied only in the North African Sahel-Sahara
 120 region (10 °N-35 °N; 20 °W-35 °W). Results reveal that the ~~parametrization~~ exponential parameterization scheme is able to capture the relation between background albedo and NPP (not shown).

In ~~order to investigate the precipitation~~ this study, the mid-Holocene climate response to the prescribed extended lakes and wetlands is calculated by the 30-year mean difference between the control simulation (present-day lakes) and the sensitivity simulations (extended lakes and wetlands):

$$125 \quad \delta(\cdot) = (\cdot)_{sensitivity} - (\cdot)_{control} \quad (3)$$

Under this stationary state, the moisture budget response of the individual sensitivity experiments is analyzed. As proposed by changes can be divided into:

$$\delta P = \delta E + \delta(P - E) \quad (4)$$

130 where δP is the precipitation response, which consists of a local evaporation response δE and a moisture convergence response $\delta(P - E)$ that indicates local drying or wetting. Following Seager et al. (2010), the moisture budget response is convergence response can be separated into a dynamic δDY , a thermodynamic δTH , a transient eddy δTE , a non-linear δNL and a surface term δS . The results reveal which processes — beside the direct evaporation effect — mainly contribute to the precipitation δS . In this study, the δS is relatively small, so that the moisture convergence response can be expressed as:

$$\delta(P - E) \approx \delta DY + \delta TH + \delta TE + \delta NL \quad (5)$$

$$\delta DY = -\frac{1}{g\rho_w} \int_0^{p_s} \nabla \cdot ([\delta\bar{u}]\bar{q}_{control}) dp \quad (6)$$

$$\delta TH = -\frac{1}{g\rho_w} \int_0^{p_s} \nabla \cdot (\bar{u}_{control}[\delta\bar{q}]) dp \quad (7)$$

140

$$\delta TE = -\frac{1}{g\rho_w} \int_0^{p_s} \nabla \cdot \delta(\overline{u'q'}) dp \quad (8)$$

$$\delta NL = -\frac{1}{g\rho_w} \int_0^{p_s} \nabla \cdot (\delta\bar{u}\delta\bar{q}) dp \quad (9)$$

145 where an overbar indicates a monthly mean and, a primed variable, deviation from the monthly mean. δDY (Eq. 6) represent changes in the moisture convergence due to changes in the mean circulation $\delta\bar{u}$ and δTH (Eq. 7) indicates changes in the individual sensitivity experiments moisture convergence due to changes in the mean specific humidity $\delta\bar{q}$. The δTE (Eq. 8) and δNL (Eq. 9) account for moisture convergence changes caused by coherent changes in the wind and specific humidity. The terms of the moisture budget equation provide information about the mechanisms that affect the simulated precipitation response induced by the prescribed extended lakes and wetlands.

150 3 Results Spatial and temporal precipitation response

The maximum lake extent shifts the mid-Holocene North African rain belt about 2° to 3° farther northward north into the Sahel region (11°N to 17°N) than the small lake extent (Fig. ??). This precipitation difference is primarily caused by the increased evaporation over the western Sahara in the maximum lake experiment. The West Saharan lakes in the maximum lake experiment are located relatively far northward compared to the lakes in the small lake experiment (Fig. 1). These results indicate that 2). The line between savanna and desert landscape, marked by the Sahel rainfall threshold (200 mm/year), is shifted about 7° farther north in the simulation with the maximum lake extent than in the simulation with the small lake extent (Fig. 2). Comparison of the maximum lake and wetland experiments shows that replacing lakes with vegetated wetlands leads to an overall increase of precipitation over North Africa (Fig. 2). The relative precipitation difference is particularly strong over the northern Sahara (22°N - 30°N).

160 The annual course of the zonally averaged daily precipitation shows that the expansion of lakes and wetlands prolongs the rainfall season over North Africa (Fig. 3 a-d). Hagos and Cook (2007) define the onset and offset of the rain season over North

Figure 2. Mid-Holocene 30-year mean annual precipitation zonally averaged over Africa (10 °E – 30 °W).

Africa as a jump of the precipitation maximum from 5 °N (near the Gulf of Guinea) to 10 °N. Accordingly, the duration of the North African rainfall season is marked by the period in which the core of maximum rainfall lies above 10 °N (black solid line in Fig. 3 a-d). Results show that, by this definition, the rainfall season is almost twice as long in the maximum lake and wetland simulations than in the control simulation. Prescribing a small lake extent in the latitudinal position of the Saharan lakes likely plays a key role in shifting the simulated rain belt northward, particularly over the western Sahara where mid-Holocene simulation, however, only causes marginally longer duration of the North African rainfall season.

In all sensitivity experiments, the earlier onset and later offset of the monsoon season is associated with an enhanced monsoon precipitation over the rain belt region between the Tropical Easterly Jet (TEJ) and the African Easterly Jet is strongest and where the Saharan heat low is located (AEJ) (Fig. 3). In the maximum lake and wetland experiments, the prolonged rainfall season is also associated with an increased rainfall over the northwestern Sahara (20 °N-35°N) during September (Fig. 3 c-d and g-h). In the maximum wetland experiment, this enhanced rainfall over the northwestern Sahara also occurs at the rain season onset in June (Fig. 3 h).

Comparison between the Beside seasonal changes, we also analyze the spatial precipitation response to the prescribed extended lakes and wetlands for the summer months (JJAS). Results show that the small and the maximum lake extent, both, cause a local prescription increase over the southern Saharan (Fig. 3 f-g). The maximum lake extent, additionally, causes an enhanced monsoon precipitation increase over the rain belt region (between the AEJ and TEJ), as well as increased precipitation over the center of tropical-extratropical interaction in the northwestern Sahara (Fig. 3 e and g). Comparison of the maximum lake and wetlands experiment maximum wetland experiments shows that replacing the lakes with vegetated wetland leads to an overall increase of the summer monsoon precipitation over North Africa (Fig. ??). This positive precipitation response to vegetated wetlands is associated with the high surface roughness. According to these results, regions where mega-lake were absent during the mid-Holocene, a seasonal flooding and formation of wetlands still might have strongly influenced the North African precipitation. The vegetated wetlands cause a spatially broader precipitation increase, compared to the local precipitation peak induced by the lakes (Fig. 3 g-f).

4 Moisture convergence response

In order to better understand the influences of the lakes and wetlands on the mid-Holocene precipitation, changes in the moisture budget ~~and changes in the atmospheric circulation terms~~ are analyzed.

4.1 **Moisture budget response**

190 ~~The moisture budget response $\delta(P-E)$ describes changes in the hydrological cycle that are caused by mechanisms other than the direct evaporation response induced by the~~ Changes in evaporation and moisture convergence, both, substantially contribute to the summer precipitation increase over North Africa (Fig. 4). A local evaporation increase over the prescribed lakes and wetlands (Seager et al., 2010). These hydrological changes can be separated into a dynamic response δDY induced by changes in the atmospheric circulation, a thermodynamic response δTH induced by changes in specific humidity, and a
195 mean δNL and transient δTE eddy response describing simultaneous changes in specific humidity and atmospheric circulation (Seager et al., 2010).

~~Schematic of African summer monsoon features for present conditions (1979-2020): the near-surface wind (monsoon south westerlies and Harmattan northeasterlies), the position of the Sahara heat low (L), the mid-troposphere African Easterly Jet (AEJ), the Tropical Easterly Jet (TEJ) and the rain belt region between both jets. The near-surface wind is given by the~~
200 ~~NCEP-DOE reanalysis 2 (Kanamitsu et al., 2002) and the precipitation is given by GPCP observations (Adler et al., 2003).~~

~~Results reveal that the prescribed lakes and wetlands cause a dipole-like moisture budget response $\delta(P-E)$ over North Africa, with a wetting response corresponds to an enhanced precipitation over the northern Sahara and Lake Chad (Fig. 4 a-c). The moisture convergence response shows a dipole pattern with a drying response over the northern Sahara and north of Lake Chad and a wetting response over the southern Sahara, the Sahel region and south of Lake Chad (Fig. 4 d-f). Results show that~~
205 ~~evaporation changes are the major cause for the precipitation increase over the northern Sahara and over Lake Chad, whereas enhanced moisture convergence primarily contributes to the rainfall increase over the southern Sahara and a Sahel region.~~

~~The moisture divergence and, thus, drying response over the northern Sahara and north of Lake Chad counteract the effect of increased evaporation in this region (Fig. 4a-e). The~~. In the maximum lake and wetland experiments, the drying response over the northeastern Sahara completely compensates the local effect of increased evaporation (Fig. 4 b-c and e-f). Accordingly,
210 ~~the summer precipitation is unchanged over the northeast Saharan lakes and wetlands in the maximum lake and wetland experiments (Fig. 3 g-h).~~

~~Results also show that the latitudinal position of the dipole-like response relates wet-south-dry-north dipole pattern differs between the small lake extent and the maximum lake and wetland extent experiments. The boundaries between wetting and drying response is related to the latitudinal position of the prescribed lakes~~. ~~The~~ ~~and wetlands over the western Sahara and the~~
215 ~~Chad region. In the maximum lake and wetland experiments, the~~ line between wet and dry response reaches up to 20 °N over the western Sahara ~~in the maximum lake experiment and up~~, whereas this line is restricted to 15 °N by lake Chad in the small lake experiment ~~(Fig. 4 a-b). This north-south~~.

Figure 4. Mid-Holocene 30-year mean summer (JJAS) (a-c) evaporation and (d-f) moisture convergence response to a (left) small lake extent, (middle) maximum lake extent and (right) maximum wetland extent. The sum of the evaporation and moisture convergence response is equal to the precipitation response shown in Fig.3 f-h.

In order to investigate the causes for this dipole-like moisture convergence response $\delta(P - E)$ over North Africa, $\delta(P - E)$ is split into a dynamic δDY , thermodynamic δTH , transient eddy δTE and non-linear term δNL following Seager et al. (2010). Results indicate that the dipole-like response is primarily caused by dynamic and thermodynamic changes of the moisture budget that affect the moisture convergence (Fig. 4 d-i). Therefore, we only analyze the dynamic and thermodynamic response δDY and δTH in detail.

The dynamic response δDY indicates that enhanced monsoon westerlies induce an increased inland moisture transport to the south of the thermodynamic response δTH reflects the near-surface convergence-divergence pattern associated with the mean summer monsoon circulation (Fig. 5 a-c). This response is associated with a general increase in the near-surface mean specific humidity caused by the prescribed lakes and wetlands. Increased moisture convergence occurs to the south and north of the AEJ, particularly near the African West coast (Fig. 4 d-f). Over the Western Sahara, the maximum lakes induce an inland moisture transport that is much stronger and extends farther north than the inland moisture transport caused by the small lake extent 5 a-c). This region is associated with the southern and northern track of the African Easterly Waves (e.g Nicholson (2009)). Increased moisture convergence also occurs near the northwest Saharan coast (Fig. 4 d-e). The maximum lake and wetland extent, in contrast, cause a similar response pattern, but the wetlands induce a stronger response amplitude 5 b-c), where the cyclonic flow from the Saharan heat low and the anticyclonic flow from the extra-tropical Azores high converge (e.g Nicholson (2009)). Moisture divergence and, thus, a drying response is visible over the northeastern Sahara (Fig. 5 a-c), where hot and dry northeasterlies, known as Harmattan winds, likely transport moisture away from the lakes and wetlands

235 (Fig. 4 e-f). These result suggest that the position of West Saharan lakes and wetlands substantially influence the northward
 extent of the West African summer monsoon (Fig. 3 e). Comparison of the individual sensitivity experiments shows that δTH is
 relatively weak in the small lake extent experiment compared to the maximum lake extent experiment. The maximum wetland
 extent causes generally larger changes of δTH than the maximum lake extent. The changes in δTH relate to the strength of
 the evaporation increase and, thus, the increase in the specific humidity caused by the prescribed lake and wetlands extent in
 240 the individual sensitivity experiments.

The thermodynamic response δTH shows that moisture is locally recycled over the south-western Sahara, whereas moisture
 is advected away from the

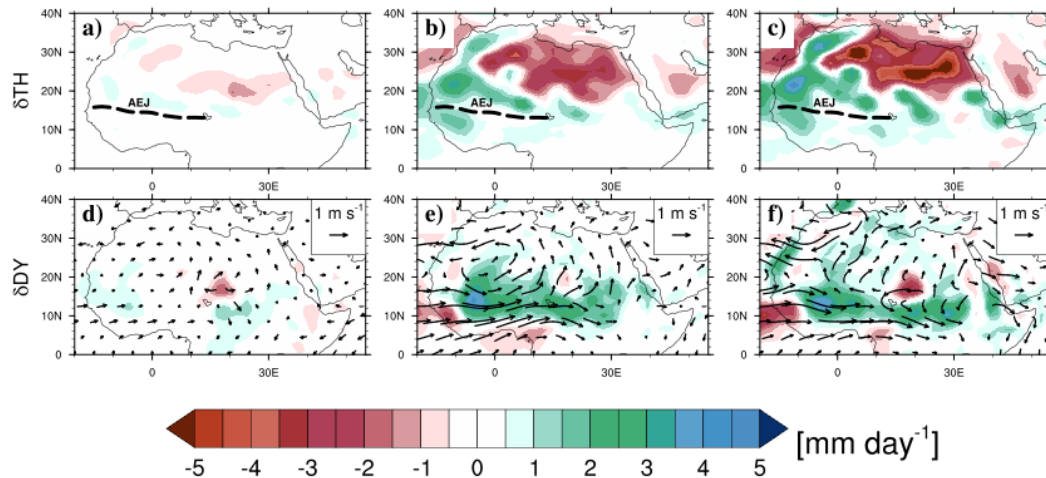

Figure 5. Mid-Holocene 30-year mean summer (JJAS) (a-c) thermodynamic δTH and (d-f) dynamic moisture convergence response δDY to a (left) small lake extent, (middle) maximum lake extent and (right) maximum wetland extent. Changes in the moisture convergence (precipitation response minus evaporation response) are primarily caused by changes in the dynamic component δDY and thermodynamic component δTH .

The dynamic response δDY reveals that the prescribed lakes and wetlands by the Harmattan winds over the north-eastern
 Sahara enhance the moisture convergence in the southern West Saharan and the southern Chad region (Fig. 4 g-i; ??). Increased
 245 moisture recycling occurs in the uplift region of the North African rain belt (Fig. 5 a-c). This increased moisture convergence
 is associated with the southern track of the African Easterly Waves stronger near-surface monsoon westerlies that enhance the
 inland moisture transport from the Atlantic ocean to the North African continent (Fig. 4 g-i; Fig. ??). Additionally, the West
 Saharan lakes and wetlands cause an even stronger moisture recycling at the northern track of the African Easterly Waves
 near the African West coast (22°N) (Fig. 5 a-c). A weakening of the AEJ (Fig. 6 b-c) additionally contributes to this moisture
 250 convergence increase by decreasing the moisture export from the North African continent to the Atlantic ocean. A comparison

between the small and large lake experiments shows that the maximum extent of the lake induces a stronger monsoon westerly wind acceleration that reaches farther to the north (Fig. 5 a-b). Accordingly, the moisture convergence increases stronger and reaches higher up north in the maximum lake experiment (Fig. 4 h-i). Over the southern Sahara, a warm and dry northeasterly Harmattan surface wind (Fig. 5 a-b). Since these differences are particularly strong over the western Sahara, the west Saharan lakes are likely the primary cause for the stronger inland moisture transport seen in the maximum lake extent experiment. Besides, the size of Lake Chad is nearly similar in the small and maximum lake extent experiments (Fig. ??) transports the moist air away from the lakes and wetlands during the summer season, which leads to a drying response over the northeast Sahara (Fig. 4 b-c). The dynamic response to the maximum lake and wetland extent shows similar changes in the mean monsoon circulation over the southern Sahara, which results in a similar δDY pattern (Fig. 4 g-i-e-f).

The mean non-linear response δNL and transient eddy response δTE , causes a reversed and less pronounced dipole, but less pronounced response pattern compared to the dynamic and thermodynamic response (not shown). This dry-south wet-north dipole pattern is primarily associated with the northward shift of the ITCZ. This near surface convergence shift – in combination with the evaporation increase over North Africa – leads to the wet response over to the north and dry response to the south of the ITCZ simulated in the control simulation.

The similar pattern (Fig. A1 a-c) and is, therefore, overcompensated. The transient eddy response δTE causes a moisture convergence decrease over the West Saharan lakes (around 25°N) in the maximum lake and wetland extent experiments (Fig. A1 e-f), but shows only marginal changes in other regions (Fig. A1 d-f). Thus, the total moisture convergence changes primarily emerge from the dynamic and thermodynamic term of the moisture budget response caused in the individual sensitivity experiment indicates that lakes and wetlands affect the summer monsoon circulation and precipitation in a similar way. To understand the mechanism that lead to the circulation changes indicated by the dynamic moisture budget response, the dynamic changes in the sensitivity experiments are analyzed equation.

5 Atmospheric circulation response

In the sensitivity experiments, the largest precipitation increase occurs in the Chad region and western Sahara. Therefore, we analyze the circulation response to Lake Chad in the small extent experiment and the circulation response to the West Saharan lakes and wetlands in the maximum extent experiments.

5.1 Dynamic Response

The zonal wind response shows that the Lake Chad and the West Saharan lakes and wetlands cause a northward generally cause a northwards shift of the North African summer monsoon in all sensitivity experiment (Fig. ??). This northward extended monsoon which is associated with a stronger Tropical Easterly Jet, a northward shift of the African Easterly Jet and stronger monsoon westerlies. These monsoon circulation changes are induced by the increased latent and decreased sensible heat flux over the lakes and wetlands enhanced monsoon westerlies and a northward shifted and weakened AEJ (Fig. 6). These local

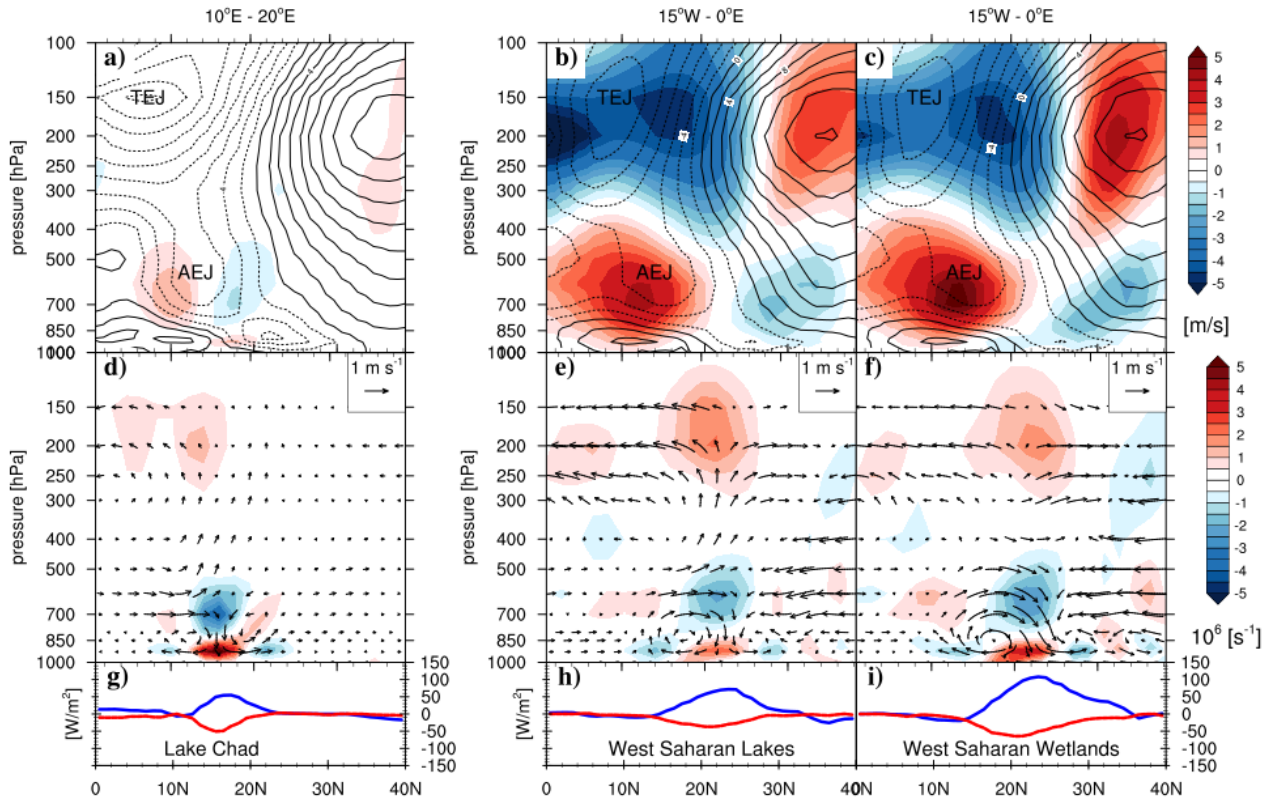

Figure 6. Mid-Holocene 30-year mean summer (JJAS) moisture budget-circulation response: (a-c) zonal wind response (colored shading), (d-f) divergence response (colored shading) and vertical wind response (black arrows) and (g-i) latent (blue) and sensible (red) heat flux response to a-the (left) small lake extent (zonally averaged over the Chad region: $10^{\circ}\text{E} - 20^{\circ}\text{E}$), (middle) the maximum lake extent and (right) the maximum wetland extent. Changes in (zonally averaged over the moisture budget Western Sahara: $15^{\circ}\text{W} - 0^{\circ}\text{E}$); (a-c: precipitation minus evaporation) are primarily caused by changes in black contours show the mid-Holocene 30-year mean summer (d-f) JJAS dynamic component zonal wind climatology zonally averaged over the Chad and thermodynamic component (g-f) West Saharan region.

turbulent heat flux changes induce a-c. Evaporative cooling above the lakes and wetlands induces a circulation response which is inverse-inverted to the one associated with the Saharan heat low -

285 Mid-Holocene 30-year mean summer (JJAS) zonal wind response (colored shadings) to (a) the small lake extent, (b) the maximum lake extent and (c) the maximum wetland extent zonally averaged over North Africa ($10^{\circ}\text{E} - 30^{\circ}\text{W}$). Black contours show the mid-Holocene 30-year mean summer (JJAS) zonal wind climatology zonally averaged over North Africa ($10^{\circ}\text{E} - 30^{\circ}\text{W}$).

290 The strong evaporative cooling effect of the lakes and wetlands leads to (Fig. 6 d-f). A decreased sensible heat flux and increased latent heat flux from the surface to the atmosphere causes descending motions over the cold the lakes and wetlands - which causes a high pressure response at the surface and a low pressure and ascending motions in their warmer vicinity. The

resulting overturning circulation response is associated with a near surface divergence response and a convergence response aloft, at the mid-troposphere (Fig. 6). In the warmer vicinity of the lakes and wetlands, the moist air rises and converges again into the mid-troposphere low located above the lakes and wetlands. The resulting lower-level meridional overturning circulation causes. The convergence increase and, thus, low pressure response at the mid-troposphere induces, by Coriolis force, a westerly wind response to the south and an easterly wind response to the north of the mid-troposphere low lakes and wetlands at about 700 hPa (Fig. ??). This leads to the 6 a-c).

The location of this dipole-like zonal wind response depends on the latitudinal position of the lakes and wetlands (Fig. 6 a-c). The existence of Lake Chad leads to a dipole-like zonal wind response around 14 °N, which corresponds to a northward shift of the AEJ. The West Saharan lakes and wetlands induce a dipole-like zonal wind response at around 23 °N, which corresponds primarily to a strong weakening of the AEJ over the western Sahara. Accordingly, lakes located near the AEJ induce a northward shift of the African Easterly Jet and strengthening of the monsoon westerlies shown in the zonal wind response (Fig. ??) AEJ, while lakes and wetlands located north of the AEJ primarily weaken the AEJ.

Additionally, the overturning circulation Beside lower level circulation changes, lakes and wetlands enhance the convergence of moist air causes an increased moisture availability at the mid-troposphere low. This moisture convergence induces an increased which favors moist convection in the mid- and to upper troposphere above the lakes and wetlands (Fig. 6 d-f). The associated ascending motions and upper level divergence and, thus, high pressure response lead to a strengthening of the Tropical Easterly Jet easterly wind acceleration to the south and westerly wind acceleration to the north of the West Saharan lakes and wetlands (Fig. ??). This stronger Tropical Easterly Jet contributes to the northward shift of the North African monsoon system 6 b-c). Accordingly, the TEJ is strengthened in the maximum lakes and wetlands experiments. Lake Chad, in contrast, only causes marginal changes in the upper level mean zonal wind.

Beside these general circulation changes, the response amplitude and northward shift of the monsoon system substantially differs between the individual sensitivity experiments. Results show again that the stronger evaporation in the maximum wetland experiment compared to the maximum lake experiment causes a more pronounced monsoon circulation response Wetlands cause an overturning circulation response that extends higher into the troposphere than the overturning circulation response induced by lakes (Fig. ??). Comparison between the small and maximum lake extent reveals that the West Saharan lakes induce a further northward shift of the monsoon system than Lake Chad 6 e-f). Accordingly, wetlands cause a higher convection increase than lakes in their vicinity. In contrast, lakes induce a stronger convection increase than wetlands above their water surface in the mid- to upper troposphere. The strong convection increase above the lakes and the strong convection increase in the vicinity of the wetlands likely causes the prescription peak over the prescribed lakes and a rather broad rainfall increase over and around the wetlands (Fig. 6 a-b). These results are in accordance with the changes seen in the moisture budget. 3 g).

Mid-Holocene 30-year mean summer (JJAS) divergence response (colored shadings) to (a) the small lake extent (zonally averaged over the Chad region: 10 °E – 20 °E), (b) the maximum lake extent and (c) the maximum wetland extent (zonally averaged over the Western Sahara: 10 °W – 0 °E). Black arrows show the mid-Holocene 30-year mean summer (JJAS) circulation response to (a) the small lake extent (zonally averaged over the Chad region: 10 °E – 20 °E), (b) the maximum lake

extent and (c) the maximum wetland extent (zonally averaged over the Western Sahara: $10^{\circ}\text{W} - 0^{\circ}\text{E}$). The bottom plots show the mid-Holocene 30-year mean summer (JJAS) (blue) latent and (red) sensible heat flux response to (a) the small lake extent (zonally averaged over the Chad region: $10^{\circ}\text{E} - 20^{\circ}\text{E}$), (b) the maximum lake extent and (c) the maximum wetland extent (zonally averaged over the Western Sahara: $10^{\circ}\text{W} - 0^{\circ}\text{E}$)

330 6 Discussion and Conclusions

~~The precipitation response to the extended lakes and wetlands is probably reinforced by background albedo and evaporation feedback. Our study corroborates the results of previous studies, which show that lakes in the Sahara likely enhanced the West African summer monsoon during the mid-Holocene (Krinner et al., 2012). The simulated rain belt northward shift of about $1.5 \pm 1^{\circ}$ in the small lake experiments extent experiment is relatively large compared to the northward shift simulated by former most studies that prescribe the same a similar small lake extent (Broström et al., 1998; Carrington et al., 2001) (Coe and Bonan, 1997; Broström et al., 2001) an even larger lake extent (Chandan and Peltier, 2020). Only the study by Krinner et al. (2012) shows an equally large northward shift northward shift of 1.5° in response to this small lake extent. In contrast to other studies, Krinner et al. (2012) use a dynamic vegetation that presumably reinforces the precipitation response to the prescribed lakes. Since the vegetation distribution is prescribed in our sensitivity experiments, this enhanced precipitation response likely results from changes in the background albedo due to the increased NPP from the vegetation. These albedo changes involve a positive evaporation feedback (Rachmayani et al., 2015).~~

~~In contrast to Chandan and Peltier (2020), our results indicate that the location of the lakes and wetlands influences experiments, the precipitation response of the North African summer monsoon substantially. This is particularly the case over the Western Sahara, where the African Easterly Jet is strongest and where Saharan heat low is located. In the study by Chandan and Peltier (2020) large lakes or wetlands are absent in the western Sahara. Instead lakes were distributed homogeneously over North Africa to investigate the potential effect of the lake position. Considering that lakes induce a strong moisture response to the northern and southern edge of the lakes, a broad homogeneous band of lakes over the Sahara would result in a positive precipitation response over the Sahel region.~~

~~Mid-Holocene reconstructions (Lézine et al., 2011) and transient mid-Holocene simulations (Dallmeyer et al., 2020) reveal that the African Humid Period ended earlier in the East Sahara than in the West Sahara. Reconstructions indicate that the maximum extent of mid-Holocene lakes lagged the peak of maximum summer insolation during the mid-Holocene (Lézine et al., 2011). According to our results, a widespread expansion of such persistent lakes over the western Sahara would have increased the West Saharan precipitation and, therefore, delayed the end of the African Humid Period in this region. to the extended lakes and wetlands in our study can likely be attributed to background and evaporation feedback.~~

~~We also speculate that west Saharan lakes and wetlands might have increased the autumn precipitation and, therefore, prolonged the rainfall season. A simulation study by Skinner and Poulsen (2016) shows that increased moisture availability throughout northern Africa during the mid-Holocene enhanced the formation of rainfall-producing tropical plumes over the western Sahara. Tropical plumes are elongated cloud bands that occur during the fall season as a result of extratropical-tropical~~

interaction between an extratropical Atlantic trough and the Saharan heat low. Results by Dallmeyer et al. (2020) reveal that these rain-bringing systems prolonged the mid-Holocene rainfall season and delayed the end of the African Humid Period over the western Sahara. Our results show that west-Saharan lakes and wetlands push the North African rain belt northward, which would provide moisture for the formation of tropical plumes over the western Sahara. In our study we only focus on the monsoon summer season, but it is conceivable that West Saharan lakes and wetlands contributed to the formation of tropical plumes and, thus, prolonged mid-Holocene rainfall season and delayed end of the African Humid Period.

The prescribed lakes and wetlands all induce a northward shift of the North African rain belt. The the maximum lake extent shifts the isohyets of the mid-Holocene rain belt about $3-2^{\circ}$ to 7° farther northward-north than the small lake extent (Fig.??). This difference in the northward shift is mainly caused by the additional lakes over the western Sahara. The western Sahara represent, while the prescribed Lake Chad is nearly of similar size in both experiments. The West Saharan lakes strongly affect the monsoon circulation because they lie in a region where the African Easterly Jet-AEJ is strongest and where the Saharan heat low is located (Fig. ??). The prescribed west-Saharan lakes weaken the Saharan heat low and shift the monsoon system, including the African Easterly Jet, northward (Fig.??). This northward displacement of the monsoon relates to latitudinal position of the prescribed lakes. Based on our results, we conclude that the influence of the mid-Holocene. Thus, the location of the prescribed lakes on the summer monsoon circulation is particularly strong over the western Sahara and that the latitudinal position of west-Saharan lakes strongly influences the northward shift of the monsoon rain belt. Further on, results reveal and

wetlands likely plays a major role for the northward extent of the African summer monsoon. These findings disagree with the results of Chandan and Peltier (2020) who conducted two mid-Holocene simulation: one with reconstructed lakes and one with a homogeneous lake extent over North African (plus Lake Chad). We suppose that the difference between our simulations results can be attributed to the fact that in their simulation, large lakes over the Western Sahara are missing.

Our study also shows that that vegetated wetlands cause a stronger precipitation increase than equally-large lakes (Fig. ??) lakes of the same size. This strong precipitation response to vegetated wetlands is likely caused by a higher-surface roughness. high surface roughness which is associated with an enhanced evaporation and surface cooling over the wetlands. Due to this strong surface cooling and, thus, local subsidence, wetlands cause a high precipitation increase in their vicinity. In contrast, lakes show a local precipitation peak above their water surface.

Beside these differences, lakes and wetlands both affect the summer monsoon circulation and precipitation in a similar way. Lakes and wetlands induce a decrease in lower-level dry convection and increase in upper-level moist convection. The resulting descending motion in the lower troposphere and ascending motion in the upper troposphere causes a circulation response which is inverse to the one. Analysis of the annual course of precipitation shows that the maximum lake and wetland extent over North Africa causes a prolonged rainfall season. This prolonged rainfall season is associated with an earlier onset and later offset of the monsoon season over North Africa. While an enhanced summer monsoon precipitation in the rain belt region occurs in all sensitivity experiments, the maximum lake and wetland extent additionally causes an increased precipitation over the northwestern Sahara during spring and autumn. Precipitation in the northwestern Sahara during fall is presumably associated with the occurrence of rain-bringing tropical plumes. These elongated cloud bands result from extratropical-tropical interaction between an extra-tropical Atlantic trough and the Saharan heat low (Fig. 6). The resulting

395 ~~mid-troposphere westerly wind response to the south and easterly wind response to the north of the~~. A model study by Skinner and Poulsen (2016) showed that increased moisture availability throughout North Africa during the mid-Holocene enhanced the formation of rainfall-producing tropical plumes over the northwestern Sahara which prolongs the rainfall season. Our results indicate that the west Saharan lakes and wetlands ~~pushes the African Easterly Jet northward and strengthens the near-surface monsoon westerlies (Fig. ??)~~. This northward extension of the monsoon system affects the local moisture budget (~~precipitation minus evaporation~~) over the Sahara provide moisture for the formation of tropical plumes by increasing the local evaporation and by shifting the North African rain belt northward, which likely prolongs rainfall season.

400 Analysis of the moisture budget ~~show~~ shows that the simulated precipitation increase in the sensitivity experiments is primarily caused by ~~the evaporation from a local evaporation increase of~~ the lakes and wetlands ~~But over the northwestern Sahara and by a enhanced moisture convergence over the southern Sahara and Sahel region. The increased precipitation over the southern Sahara is caused by~~ enhanced inland moisture transports and a local moisture recycling to the south of the west Saharan lakes and lake Chad ~~contribute to the simulated precipitation increase. This causes a wetting response over the southern Sahara (Fig. 4). Moisture~~. In contrast, moisture advection by the Harmattan wind transport moisture away from the lakes and wetlands ~~and causes a over the northeastern Sahara. This local drying response over the northern Sahara (Fig. 4). This northeastern Sahara indicates why lakes and wetlands do not enhance the local precipitation in this region. The~~ wet-south dry-north moisture budget convergence response indicate that lakes and wetlands received ~~access excess~~ water primarily from the southern part of their catchment during the summer months. A simulation study by Skinner and Poulsen (2016) and Dallmeyer et al. (2020) showed that the enhanced occurrence of rain-bringing tropical plumes during the mid-Holocene fall season substantially increased the annual precipitation over the western Sahara. ~~This indicates that Thus,~~ West Saharan lakes and wetlands also ~~received access might have received excess~~ water during the fall season.

415 The dynamic response in sensitivity experiments shows that lakes and wetlands cause a circulation response inverse to the one associate with the Saharan heat low. Evaporative cooling causes descending motions above the lakes and wetlands, whereas ascending motions occur in their warmer vicinity. This overturning circulation response causes a convergence increase in the a mid-troposphere and, by Coriolis force, an westerly wind response to the south and an easterly wind response to the north of the lakes and wetlands. This dipole-like zonal wind response induces either a northward shift of the AEJ or a weakening of the AEJ depending on the latitudinal position of the lakes and wetlands. E.g. Lake Chad causes a northward shift of the AEJ, whereas the higher up north located West Saharan lakes nearly cause a strong decay of the AEJ. Along with this shift or weakening of the AEJ the near-surface monsoon westerlies extent farther to the north. These circulation responses indicate that at the latitudinal position of the lakes and wetlands strongly affects the monsoon circulation.

425 Finally, our study shows that the border between savanna and Sahara, the 200 mm/year isohyet, is shifted by about 7 ° farther north in the maximum extent experiment than in the small extent experiment. This implies that lakes might had a substantial influence on the vegetation expansion during the mid-Holocene. In this study, we ~~prescribe~~ prescribed the vegetation, lakes and wetlands and ~~, therefore, neglect their dynamic interaction. Investigating the dynamic interaction between the atmosphere, vegetation, wetlands and lakes would provide information about mid-Holocene climate changes and gives insights into the dynamic extent of lakes and wetlands during the~~ thus, neglect any dynamic feedback. Yet, this dynamic

430 interaction might play a key role in understanding the termination of the African Humid Period. Mid-Holocene reconstructions
(Shanahan et al., 2015; Lézine et al., 2011) and transient mid-Holocene ~~that are not provided by sediment records.~~ simulations
(Dallmeyer et al., 2020) reveal that the African Humid Period ended earlier in the East Sahara than in the West Sahara.
This immediately raises questions about the different time-scales of vegetation dynamics and lake dynamics and how they
interactively affect the termination of the African Humid Period. Hence in a follow-up study we will explore the effect of
dynamic lakes on the African Humid Period and how dynamic lakes and a dynamic vegetation interact with each other in this
435 context.

Code availability. TEXT

Data availability. The paleo-environmental lake reconstruction map by Hoelzmann et al. (1998) - used to prescribe a small lake extent - is accessible at the National Center for Environmental Information of the National Oceanic and Atmospheric Administration (<https://www1.ncdc.noaa.gov/pub/data/paleo/pollen/africa6k>). The potential maximum lake area - used to prescribe a maximum lake and wetland extent -
440 originates from the simulation study by Tegen et al. (2002). The potential maximum lake area data are accessible at T63 resolution at the German Climate Computing Center (https://cera-www.dkrz.de/WDCC/ui/cersearch/entry?acronym=DKRZ_LTA_060_ds00002) and were provided by Egerer et al. (2018). For the purpose of this study the T63 reference data were interpolated to a R2B4 ICON grid.
