27 Abstract

The Valley of Lakes basin (Mongolia) contains a unique continental sedimentary archive, 28 29 suitable for constraining the influence of tectonics and climate change on the aridification of 30 Central Asia in the Cenozoic. We identify the sedimentary provenance, the (post)depositional environment and the palaeo-climate based on sedimentological, petrographical, mineralogical 31 32 and (isotope) geochemical signatures recorded in authigenic and detrital silicates as well as soil 33 carbonates in a sedimentary succession spanning ~34 to 21 Ma. The depositional setting was characterized by an ephemeral braided river system draining prograding alluvial fans, with 34 35 episodes of lake, playa or open steppe sedimentation. Metamorphics from the northern adjacent 36 Neoarchean to late Proterozoic hinterlands provided a continuous influx of silicate detritus to 37 the basin, as indicated by K-Ar ages of detrital muscovite (~798-728 Ma) and discrimination 38 function analysis. The authigenic clay fraction is dominated by illite-smectite and "hairy" illite 39 (K-Ar ages: ~34-25 Ma), which formed during coupled petrogenesis and precipitation from 40 hydrothermal fluids originating from major basalt flow events (~32-29 Ma and ~29-25 Ma). Changes in hydroclimate are recorded in δ^{18} O and δ^{13} C profiles of soil carbonates and in silicate 41 mineral weathering patterns, indicating comparatively humid to semi-arid conditions prevailed 42 in the late(st) Eocene, changing into arid conditions in the Oligocene and back to humid to 43 semi-arid conditions in the early Miocene. Aridification steps are indicated at ~34-33 Ma, ~31 44 Ma, ~28 Ma and ~23 Ma and coincide with some episodes of high-latitude ice sheet expansion 45 inferred from marine deep-sea sedimentary records. This suggests long-term variations of the 46 ocean/atmosphere circulation patterns due to pCO_2 fall, re-configurations of ocean gateways 47 and ice-sheet expansion in Antarctica could have impacted the hydroclimate and weathering 48 regime in the basin. We conclude that the aridification in Central Asia was triggered by reduced 49 moisture influx by westerly winds driven by Cenozoic climate forcing and the exhumation of 50 51 the Tian Shan and Altai mountains and modulate by global climate events.

52 1. Introduction

The Cenozoic Era (66 Ma to the present day) saw several dramatic changes of the marine and 53 54 continental ecosystems (e.g., evolution of large plankton feeders such as baleen whales, shift 55 towards cold-water, high nutrient plankton assemblages at high latitude, expansion of terrestrial mammals) major tectonic events (e.g., opening of Southern Hemisphere Oceanic gateways, 56 57 shift to the 4-layer structure of the modern ocean, collision of the African-Arabian-Eurasian 58 plates, uplift of the Alpine and Himalayan mountain belt) and global climate forcing (e.g., change from greenhouse to icehouse conditions) (Cerling, 1997; Houben et al., 2013; Norris et 59 60 al., 2013; Cermeño et al., 2015; Mutz et al., 2018; Komar and Zeebe, 2021). The acceleration 61 of Cenozoic climate cooling started after the Early Eocene Climatic Optimum (EECO; ~52-50 Ma), with temperatures $\sim 10-12$ °C warmer than the modern deep ocean, followed by the 62 63 appearance and expansion of the Antarctic ice-sheets after the Eocene-Oligocene Transition 64 (EOT; ~34 Ma) and ultimately culminating in the extensive Northern Hemisphere glaciation of the Pleistocene (~2.6-0.01 Ma; Zachos et al., 2001; Lear et al., 2008; Mudelsee et al., 2014; 65 66 Abdullayev et al., 2021). This long-term transition in Earth's climate is well documented in marine sedimentary archives, but its impact on the evolution of continental ecosystems remains 67 poorly constrained, mainly because continuous, well preserved terrestrial records are scarce 68 69 and the responses to climate change in these settings are highly complex, depending on latitude, 70 proximity to coast and mountain ranges, position relative to climatic winds, vegetation etc. (e.g., Caves Rugenstein and Chamberlain, 2018; Baldermann et al., 2020). An exception is the 71 sedimentary archive of the Valley of Lakes (Mongolia), which hosts a ~34-21 Ma record of 72 73 continental sedimentation in Central Asia. The biostratigraphy and the correlation between different outcrops in this basin are well established based on mammalian communities and 74 75 gastropod records (Harzhauser et al., 2017), magnetostratigraphy (Sun and Windley, 2015) and 76 radiometric age dating of different basalt horizons (Daxner-Höck et al., 2017), rendering this

locality suitable for constraining the links between tectonism and climate change in Central 77 Asia during the Cenozoic. The Eocene to Miocene of Central Asia was characterized by 78 accelerated aridification (Dupont-Nivet et al., 2007; Xiao et al., 2010; Bosboom et al., 2014; 79 80 Li et al., 2016), expressed as a substantially expanded Gobi Desert relative to today (Guo et al., 2008; Lu et al., 2019) and a sudden turnover in the mammal record (Harzhauser et al., 2016; 81 82 Barbolini et al., 2020). Several, partially opposing hypotheses have been proposed to explain 83 the aridification of Central Asia, including a combination of orbitally-driven climate forcing, 84 the stepwise retreat of the proto-Paratethys Sea and uplift of the Tibetan Plateau (Pälike et al., 85 2006; Zhongshi et al., 2007; Li et al., 2020) or a continuous decrease of moisture transport by the westerlies due to exhumation of the Tian Shan and Altai mountains (Caves et al., 2014; 86 Caves et al., 2015; Caves Rugenstein and Chamberlain, 2018). However, the evolution of 87 88 Central Asia's hydroclimate in the Cenozoic was not a period of continuous aridification; 89 indeed, the climatic conditions in particular in the Oligocene were highly complex and characterized by numerous glacial-interglacial cycles (Xiao et al., 2012). Recently, Richoz et 90 91 al. (2017) have identified two aridification pulses in Central Asia, in the early and late Oligocene, which they assigned to global climatic events. To date, a correlation of the global 92 marine record with the terrestrial record of Mongolia is barely developed (Harzhauser et al., 93 94 2016; Harzhauser et al., 2017; Richoz et al., 2017), which limits our understanding of the 95 relative influences of climate change and regional tectonics on the evolution of hydroclimate and weathering conditions in Central Asia in the Cenozoic. 96

In this contribution, we greatly extend the existing mineralogical and (isotope) geochemical
dataset previously reported in Richoz et al. (2017) for the Eocene-Miocene sediments from the
Valley of Lakes (Mongolia): K-Ar ages and polytype analysis of detrital and authigenic illitic
phases coupled with discrimination function analysis and sedimentological-petrographicalgeochemical inspection are used to constrain provenance, palaeo-environmental conditions and

- 102 post-depositional alteration history of this sedimentary succession. Systematic, coherent 103 changes in the weathering patterns of silicate detritus and pristine δ^{18} O and δ^{13} C signatures 104 recorded in paleosols carbonates allow us to revise and refine the evolution of hydroclimate 105 and weathering conditions in Central Asia in the Cenozoic.
- 106

107 2. Geological framework

108 The Valley of Lakes is an ESE-WNW striking sedimentary basin with ~500 km extension in largest dimension. It is located in Central Mongolia and bordered by the Khangai mountains in 109 110 the north and the Gobi Altai mountains in the south (Fig. 1a). The geological super-units in the 111 north of Mongolia contain Neoarchean, Proterozoic and Palaeozoic rocks of the Caledonian orogen as well as late Neoproterozoic to Ordovician (Tuva-Mongol) magmatic arc and related 112 113 back- and fore-arc intrusions, accretionary wedge sequences and ophiolites (Porter, 2016). The 114 geological super-units in the south are characterized mainly by a Palaeozoic orogen, especially 115 the Kazakh-Mongol magmatic arc, which forms the border between Mongolia and China. 116 These units include mainly Devonian to Carboniferous island arc volcanic rocks, Ordovician to Silurian volcanics, Ordovician to Carboniferous metamorphosed sedimentary sequences and 117 Permo-Carboniferous granitoids (Porter, 2016). 118

119 Regarding the regional lithostratigraphic context, the northern structural units of the Valley of Lakes basin in the Taastsiin Gol area comprise dominantly fault- and thrust-bounded crystalline 120 basement of Neoarchean to Palaeozoic age (Fig. 1b). These include the Baidrag (high-grade 121 gneisses, charnockites and amphibolites, up to 2.65 Ga old) and the Burdgol zone (metapelites, 122 metapsammites and metacherts, 699 ± 35 Ma) in its southernmost end (Teraoka et al., 1996). 123 Further structural units towards the north are the Bayan Khongor (metamorphosed basic rocks, 124 125 ophiolites and pelitic schists, 450 Ma), the Dzag (metapelites and metapsammites, 440 ± 22 126 Ma and 395 ± 20 Ma) and the Khangai zone (unmetamorphosed, but tectonically deformed

127 sandstones, mudstones and intercalated olistolith sequences of unspecified Devonian to 128 Carboniferous age) (Teraoka et al., 1996; Höck et al., 1999). All of these zones are intruded by 129 numerous granitoids of variable age (Proterozoic to Cretaceous) and composition (Höck et al., 130 1999). The major zones located in the south of the Valley of Lakes basin comprise the Baga 131 Bogd, the Ikh Bogd and the Bogd som, which are petrographically indistinguishable from the 132 time-equivalent metasediments and metavolcanics of the Bayan Khongor zone and of the 133 Permian quartzitic conglomerates from the adjacent Mount Ushgoeg (Höck et al., 1999).

134 In the focus of this study are the fossiliferous siliciclastic sediments of the Taatsiin Gol Basin, 135 which record important information about changes in sediment provenance, weathering paths and conditions and palaeo-climate in Central Asia during the Eocene to Miocene. The herein 136 investigated sedimentary sections span the Tsagaan Ovoo Formation (upper Eocene), the 137 138 Hsanda Gol Formation (Oligocene) and the Loh Formation (lower Miocene). Five sections, 139 namely Taatsiin Gol right (TGR-AB), Taatsiin Gol south (TGR-C), Hsanda Gol (SHG-D), Tatal Gol (TAT-E) and Hotuliin Teeg (HTE), were chosen for this study, because of the well-140 141 constrained biostratigraphy at these localities. These sections form an integrated sedimentary succession with a thickness of ~115 m (Richoz et al., 2017). Two prominent stratigraphic 142 marker beds, the basalt I group (32.4-29.1 Ma) and the basalt II group (28.7-24.9 Ma) crop out 143 at ~40-41 m and at ~94-100 m in the sedimentary profile (Daxner-Höck et al., 2017). A younger 144 basalt III group (13.2–12.2 Ma) dates back to the middle Miocene, but is not part of the 145 sedimentary succession investigated here. Further details about the local nomenclature, the 146 investigated profiles, profile correlation and lithostratigraphic relationships are provided in 147 Harzhauser et al. (2017), Daxner-Höck et al. (2017) and Richoz et al. (2017). Due to the 148 complex architecture of the Valley of Lakes basin and adjacent areas, a mixed provenance has 149 been proposed for the basin fill, however, detailed knowledge about the palaeo-depositional 150 151 environment and source area relationships remain poorly constrained (Höck et al., 1999).

152 3. Materials and Methods

153 3.1 Materials

154 Representative bulk sediment samples (140 in total) were taken from different outcrops, which 155 cover the entire sedimentary succession of the Valley of Lakes from the upper Eocene to the lower Miocene. The layers sampled vary in color, composition, texture, fossil and carbonate 156 157 content, etc., however, they do not show optical signs of alteration, such as recent surface 158 weathering. Samples for geochemical, isotopic and mineralogical analysis were crushed in a ball mill for 10 min and micronized using a McCrone mill for 8 min, with ethanol addition. 159 160 Samples with a high clay mineral content based on an initial mineralogical inspection were 161 selected further for an identification of the clay mineral suite, which is defined here as $< 2 \,\mu m$ size fraction (Rafiei et al., 2020). As for the clay mineral separation, 5 g of the bulk material 162 163 was reacted with 5 % HCl for 10 min to remove the carbonates, followed by standard Atterberg 164 sedimentation and subsequent collection and drying of the $< 2 \,\mu m$ size fraction at 40 °C. Fast acid digestion was used to reduce leaching or dissolution of the clay minerals under acidic 165 166 conditions (Baldermann et al., 2012). Four samples from the Hsanda Gol Formation with a high amount of illitic phases were used for an illite polytype and K-Ar analysis. To this end, 167 three sub-fractions ($< 1 \,\mu m$, 1-2 μm and 2-10 μm) were separated by Atterberg sedimentation, 168 169 which all represent mixtures of authigenic illitic phases and detrital illite/muscovite.

170

171 3.2 Analytical methods

The major, minor and trace element composition of a sub-set of samples (91 in total) was
analyzed via a Philips PW2404 wavelength dispersive X-ray fluorescence (XRF) spectrometer.
Fine powdered samples (0.8 g) were heated to 1050 °C to remove the volatile components
(CO₂, H₂O, etc.), following determination of the loss on ignition (LOI) by gravimetric analysis.
The residuals were fused at 1200 °C using LiBO₂ (4 g) as the fluent agent. The standard glass

- tablets were analyzed together with a set of USGS standards (analytical error: ± 0.5 wt% for
- the major elements; Richoz et al., 2017).
- 179 Sediment origin and variations in the detrital influx among the different provenance areas were
- 180 depicted using discrimination plots calculated on the basis of major oxide compositions (Roser
- 181 and Korsch, 1988). The weathering paths and intensities in the source rock areas were assessed
- 182 through changes in the weathering indices, such as the chemical index of alteration (CIA), the
- 183 chemical index of weathering (CIW) and the plagioclase index of alteration (PIA), which were
- 184 calculated based on the major oxide compositions using the following equations (Nesbitt and
- 185 Young, 1982; Abdullayev et al., 2021):
- 186 $CIA = (Al_2O_3 / (Al_2O_3 + CaO^* + Na_2O + K_2O)) \times 100$
- 187 $CIW = (Al_2O_3 / (Al_2O_3 + CaO^* + Na_2O) \times 100)$
- 188 $PIA = (Al_2O_3 K_2O) / (Al_2O_3 + CaO^* + Na_2O K_2O) \times 100,$

where CaO* denotes the fraction of CaO present in the silicate fraction. CaO* was calculated by subtraction of the total CaO content of the bulk sediments (determined by XRF analyses) from the CaO content associated with carbonate minerals (determined by XRD analyses, see below). The weathering conditions of the source areas were identified further using $Al_2O_3 -$ CaO* + Na₂O - K₂O (A-CN-K) ternary diagrams (Nesbitt and Young, 1984).

The mineralogical composition of all bulk samples was determined by Rietveld-based analysis 194 195 of X-ray diffraction (XRD) patterns recorded on a PANalytical X'Pert PRO diffractometer 196 (Co-K α ; 40 kV and 40 mA) equipped with a high-speed Scientific X'Celerator detector. The top loading technique was used for the preparation of randomly oriented samples, which were 197 examined in the range from 4-85 2 θ with 0.008°2 θ /s step size and 40 s count time. The 198 199 PANanalytical X'Pert Highscore Plus software and a pdf-4 database were used for mineral quantification (analytical error: < 3 wt%; Baldermann et al., 2021). The separated grain size 200 sub-fractions were X-rayed under identical operational conditions. The amounts of authigenic 201

- 202 (1M and $1M_d$ polytype) and detrital (2M₁ polytype) illitic phases were calculated using the
- 203 following equations (Grathoff and Moore, 1996):
- 204 $\% 2M_1 = 2.05 + 360 \times A_{(114)}/A_{(2.6 \text{ Å band})}$
- $205 \qquad \% \, 1M = 4.98 + 136 \times A_{(\text{-}112)} / A_{(2.6 \ \text{\AA band})}$
- 206 %1 $M_d = 100 \%1M$ or $100 \%2M_1$
- where A is the area (in $cps \cdot 2\theta$) of the polytype-specific hkl-reflections of illite and of the 2.6
- 208 Å band, respectively (analytical error: $\sim \pm 5$ %; Baldermann et al., 2017).

Oriented clay films were prepared for the further characterization of the clay mineral fraction 209 210 $(\leq 2 \mu m)$ using a Phillips PW 1830 diffractometer (Cu-K α ; 40 kV and 30 mA) outfitted with a graphite monochromator and a scintillation counter. The clay films were prepared by mixing 211 50 mg of clay fraction with 5 mL of deionized water, following ultrasonic treatment in a water 212 213 bath for 10 min to produce a clay-in-suspension, which was subsequently sucked through a 214 porous ceramic tile of ~4 cm² size (Baldermann et al., 2014). The clay films were examined in the range from $3-30^{\circ} 2\theta$ with $0.02^{\circ} 2\theta$ step size and 2 s/step count time, each at air-dry states, 215 216 after solvation with ethylene glycol (EG) and after heat treatment at 550 °C for 1 h. The proportion of illite layers (%Ilt) in mixed-layered illite-smectite (Ilt-Smc) was calculated based 217 on the position of the 002-reflections obtained from XRD patterns of EG-solvated clay films 218 219 $(d_{EG-002} \text{ in Å})$ following the equation (analytical precision: ± 5 %; Baldermann et al., 2017):

220 % IIt = $60.8 \times d_{EG-002} - 504.5$.

Illite crystallization ages were calculated through coupled illite polytype and K-Ar analysis carried out on the separated grain size sub-fractions. The K₂O content of these samples was determined in digested aliquots (1M HF and HNO₃ mixture) in duplicate via a BWB-XP flame photometerTM using 1 % CsCl as the ionization buffer and 5 % LiCl as the internal standard. The Ar isotopic composition was analyzed in a stainless steel extraction and purification line connected to a Thermo Scientific ARGUS VITM noble gas mass spectrometer operated in static

mode at the University of Göttingen (Germany). The radiogenic ⁴⁰Ar content was measured using the standard isotope dilution method applying a highly enriched ³⁸Ar spike calibrated against the biotite standard HD-B1. K-Ar age calculations were made based on the constants recommended by the IUGS (for details see Wemmer et al., 2011). The grain size sub-fractions are free of K-containing mineral phases other than mica/illite group minerals, which would disturb the radiogenic K-Ar ages.

A scanning electron microscopy (SEM) study was carried out to characterize the mineralogy,
chemical composition, microfabrics and alteration patterns of the authigenic and detrital (clay)
minerals present in the sediments. Therefore, specimens were prepared on standard SEM stubs,
coated with carbon and analyzed using a GEMINI® Zeiss Ultra 55 microscope operated at 515 kV of accelerating voltage and equipped with a high efficiency in-lens secondary electron
(SE) detector and an EDAX Si(Li)-detector for high-resolution imaging and energy-dispersive
X-ray spectrometry (EDX) analysis.

The δ^{13} C and δ^{18} O isotopic composition of the carbonate fraction was analyzed to constrain the 240 241 palaeo-climatic trends recorded in the paleosols. In a previous study (Richoz et al., 2017) it was shown that the soil carbonates (calcrete nodules, lenses and crusts) mostly record pristine 242 δ^{13} C and δ^{18} O isotopic compositions reflective of conditions during their formation and are not 243 244 influenced by detrital or secondary carbonates, such as calcite spar or dolomite. The samples 245 (139 in total) were reacted with 102 % phosphoric acid at 70 °C in a Kiel II automated reaction system and the liberated CO₂ gas analyzed with a ThermoFinnigan mass spectrometer MAT 246 247 Delta. The measured δ^{13} C and δ^{18} O values were corrected against the NBS19 standard and are 248 reported in per mill (‰) relative to the Vienna-PeeDee Belemnite (V-PDB) standard (analytical precision: < 0.05 ‰ for δ^{13} C and < 0.1 ‰ for δ^{18} O; Richoz et al., 2017). 249

250 **4. Results**

251 4.1 Sediment petrography

An integrated lithostratigraphic profile of the investigated sedimentary succession (upperEocene to lower Miocene) from the Taatsiin Gol region, which is a part of the Valley of Lakes,

including the biozonation and some field impressions, is presented in Figure 2.

The sediments from the Tsagaan Ovoo Formation (upper Eocene) are dominantly coarse clastic sand and gravel deposits of white-greyish color with embedded clay and silt layers of greyishyellow-green to reddish-brown color, depending on the Fe content (Richoz et al., 2017). The coarser beds show cross-bedding and are frequently poorly sorted, while the finer layers show trough and planar cross-bedding, lamination, inverse to normal grading, rarely ripples and channel fills, and are better sorted. Roots and plant debris and bioturbation features, such as burrows, indicate local paleosol formation (Richoz et al., 2017).

262 The overlying Hsanda Gol Formation (Oligocene) has a higher fossil content (mainly remains of small mammals) and appears as horizontally bedded and poorly sorted clay to silt layers of 263 264 brick-red to reddish-brown color with intercalated cross-bedded sandstone beds and minor sand and granule lenses of greyish color (Fig. 2c). Paleosol formation is documented by abundant 265 crypto- to microcrystalline calcite nodules and calcite crusts of centimeter to decimeter size 266 267 encapsulating soil and plant materials (Fig. 2b; Richoz et al., 2017). These calcrete layers of 268 greyish-white color are partially intergrown with Fe- and Mn-(oxy)hydroxides of orangegreyish-black color. The basalt I and basalt II horizons are exposed at ~40-41 m and at ~94-269

270 100 m and interfinger with the sediments from the Hsanda Gol Formation (Fig. 2b,d).

The Loh Formation (lower Miocene) comprises generally poorly sorted and structure-less siltyclayey horizons with embedded pebbles and lenses of greyish-white to reddish-brown color as well as trough to planar cross-bedded sand and gravel beds of greenish-yellow-red color, which are deposited in alternate mode. Sedimentary structures seen in the coarser beds include inverse

- to normal grading, ripple marks, channel and scour fills and overbank fines (Richoz et al.,
 2017). Most horizons are highly fossiliferous (remains of small mammals and gastropods) and
 show signs of paleosol formation, such as calcite nodules and crusts incorporating plant debris,
 and burrow structures (Harzhauser et al., 2017).
- 279

280 4.2 Bulk and clay mineralogy

281 The mineralogical composition of the Valley of Lakes samples is dominated by quartz (10-55 wt%), illite/muscovite (10-50 wt%), calcite (0-70 wt%), feldspar (5-15 wt%; mainly albite and 282 283 plagioclase and minor orthoclase) and hematite (0-10 wt%) (Table S1). XRD analysis identifies the illite/muscovite as an almost pure illitic phase composed of > 95 % Ilt layers and < 5 % 284 Smc layers (Fig. S1) with the $1M_d$ polytype structure dominating (~90-95 % of the total illite 285 286 fraction; Fig. S2). The proportions of the 1M and $2M_1$ polytype structures of illite do not exceed 287 ~5-10 % of the total illite fraction. Kaolinite, chlorite (Mg-rich), mixed-layered Ilt-Smc comprised of ~30-10 % Ilt layers and ~70-90 % Smc layers (Fig. S1) as well as Ti-oxides (rutile 288 289 and anatase) represent minor constituents (Fig. S2), accounting altogether for less than ~5 wt% of the sediments. Trace amounts of zeolite and amphibole (< 5 wt%) are documented between 290 291 ~35 and 45 m and between ~90 and 110 m in the sedimentary succession, i.e., adjacent to the 292 basalt I and II groups. Vermiculite, dolomite, ankerite, anhydrite, halite and pyrite were not 293 identified in the samples, which contrasts observations made by Höck et al. (1999).

The sediments from the Tsagaan Ovoo Formation have the highest proportions of quartz, illite, feldspar and hematite and the lowest content of calcite compared to the other two formations, consistent with less abundant calcrete horizons developed in the upper Eocene sediments (Fig. 3a). The sediments from the Oligocene Hsanda Gol and lower Miocene Loh formations have highly variable, but on average higher calcite contents than the Tsagaan Ovoo Formation due to abundant paleosol formation and related lower contents of silicate minerals and hematite

- (Fig. 3b,c). The depletion of hematite in these samples argues for a detrital origin and for the
 precipitation of this mineral phase on silicate detritus during sediment transportation under oxic
 conditions. No systematic trends in the abundance of the mineral phases was observed across
 the investigated profile (cf. Table S1).
- 304

305 4.3 Microfabrics and illite crystallization ages

306 A microstructural study of weakly consolidated samples taken from the Hsanda Gol Formation 307 reveals (sub)angular to rounded detrital quartz grains (Fig. S3a), which are partly overgrown 308 by diagenetic quartz cement (Fig. S3b), as well as partially dissolved feldspar grains (Fig. S3c). 309 Calichized areas are cemented by calcite spar, which appears as crypto- to microcrystalline 310 material with aggregate particle sizes in the micrometer to millimeter range (Fig. S3d). All 311 these components are covered or intergrown by fine hematite particles (Fig. S3e), although silt-312 size hematite grains are also observable. Coarse chlorite flakes as well as tiny, rounded to 313 vermiform kaolinite particles are barely seen (Fig. S3f). Indeed, the clay mineral suite is 314 dominated by two types of illite and one type of Ilt-Smc. SEM-EDX analysis suggests the illites have higher contents of Al₂O₃ and K₂O, but lower contents of SiO₂ and Na₂O than the Ilt-Smc. 315 The illites occur either as micrometer-sized particles with platy or pseudohexagonal forms 316 317 being evenly dispersed throughout the matrix (type 1: Fig. 4a,c,e,g) or as long (micrometer-318 scale), but thin laths and fibers, which grow into the open pore space (type 2: Fig. 4b,d,f,g,h). The latter type of illite is often referred to as "hairy illite" (Güven et al., 1980; Rafiei et al., 319 2020). The Ilt-Smc is a nanometer-sized material with flaky to irregular particle forms, which 320 321 covers detrital grains or grows into the open pore space (type 3: Fig. 4b,d,h).

When viewed together with the results of the illite polytype analysis and measured K-Ar ages (Table 1), all sub-samples represent physical mixtures of detrital $2M_1$ illite/muscovite (type 1), authigenic $1M_d/1M$ illite (type 2) and authigenic $1M_d$ Ilt-Smc (type 3). Accordingly, the plot

- of the proportion of $2M_1$ illite/muscovite against the K-Ar age of a given sub-sample (Fig. 5) provides individual crystallization ages for the detrital and authigenic illitic phases (Grathoff and Moore, 1996): The upper intercept of the best-fitting line at 100 % of $2M_1$ reveals the crystallization age of detrital illite/muscovite, which is 727.6 to 797.9 Ma. The lower intercept of the best-fitting lines at 100 % of $1M_d + 1M$ gives crystallization ages for the authigenic clay minerals, which vary between 25.2 and 34.2 Ma.
- 331

332 4.4 Geochemistry and weathering indices

333 Variations in the major element composition of the samples (Table S2) follow changes in the 334 abundance of silicate minerals (e.g., quartz, feldspar and clay minerals) relative to calcite and 335 hematite across the sedimentary succession. No distinct trends among the different formations 336 are seen, except for a lower CaO content and higher contents of SiO₂, Al₂O₃, K₂O, Na₂O, MgO 337 and Fe₂O₃, on average, in the Tsagaan Ovoo Formation, compared to the Hsanda Gol and Loh formations, corroborating the mineralogical and petrographic results (cf. Table S1 and Fig. 3). 338 339 Minor amounts of TiO₂ belong to rutile and anatase and traces of MnO and P₂O₅ correspond to Mn-oxides and apatite. The positive correlations of Cu, Ga, Rb and Zn with Al₂O₃ as well 340 341 as Ce, La, Y and Zr with TiO_2 and Sr with CaO point to their association with clay minerals 342 (i.e., structural incorporation or sorption onto the clay mineral surface), heavy minerals and 343 carbonate minerals, respectively (Abdullayev et al., 2021). Ba, Co, Cr, Hf, Nb, Ni, Pb, Sc, Th, V and U are inconspicuous due to lack of correlation with Al₂O₃ and TiO₂ or low concentration 344 in the samples. 345

The plot of the chemical data in the A-CN-K ternary diagram (Fig. 6) shows the samples fall within or plot slightly above the compositional range of Post-Archean Australian Shale (PAAS) and Average Proterozoic Shale (APS) and thus follow the predicted weathering trend for basalt protoliths and Upper Continental Crust (UCC) rocks (Nesbitt and Young, 1984; Bahlburg and

350	Dobrzinski, 2011). The shift of most of the data toward the K pole of the diagrams indicates
351	K-metasomatism has affected the chemical composition of the sediments through the growth
352	of authigenic illite and Ilt-Smc (Fedo et al., 1995), consistent with petrographic observations
353	and clay polytype analyses. The CIA, CIW and PIA values vary from 70-83, 83-97 and 79-96
354	across the different formations, which averages of 79, 94 and 92 for the Loh Formation and 76,
355	90 and 88 for both the Hsanda Gol and Tsagaan Ovoo formations, respectively (Table S3).
356	

357 4.5 Soil carbonate δ^{18} O and δ^{13} C isotopic composition

The δ^{18} O and δ^{13} C values of the soil carbonates vary in the range from -11.7 to -0.2 ‰ and -358 8.1 to -3.8 ‰ across the sedimentary succession of the Valley of Lakes (Table S4). Six samples 359 taken close to the basalt I and II groups show comparatively lighter isotope values, -12.9 to -360 8.6 % of δ^{18} O and -9.4 to -8.3 % of δ^{13} C, which indicates post-depositional overprinting. 361 Therefore, these samples are not considered further. A high scatter in δ^{18} O values (-9.3 to -0.2 362 ‰) and relatively light δ^{13} C values (-7.5 to -6.4 ‰) are seen in the lower part of the Hsanda 363 Gol Formation, changing into less fluctuating δ^{18} O values (-10.3 to -7.0 ‰) and systematically 364 heavier δ^{13} C values (-7.6 to -3.8 ‰) in the middle and upper part of the Hsanda Gol Formation 365 until the lower Miocene. Around the series/stage boundary, a gradual shift towards lighter δ^{18} O 366 values (-11.7 to -8.6 ‰) and fluctuating, but lighter δ^{13} C values (-8.1 to -4.4 ‰) are evident. 367

368

369 5. Discussion

370 5.1 Sediment provenance

The time interval from the Neoarchean to the late Permian saw the development of large parts of the fault- and thrust-bounded crystalline basement of Mongolia. The main lithological units forming this basement include Neoarchean metamorphic rocks and Palaeozoic metasediments and magmatic rocks, which are all intruded by volcanic and magmatic rocks of various age,

composition and provenance (Zorin et al., 1993). This complex architecture and the denudation 375 376 processes in the Mesozoic, which formed the Valley of Lakes basin and created the presentday regional landscape and relief, are documented in the heavy mineral spectra of the Cenozoic 377 378 basin fill (Höck et al., 1999): the presence of epidote, amphibole, garnet, rutile, pyroxene, sphene, zircon and tourmaline suggest that a mountainous region in the area of the present-day 379 380 Khangai mountains were the potential source areas (McLennan et al., 1993). Quartz, pegmatite, 381 granite, siltstone, basalt and carbonate clasts found in the gravel fraction (Höck et al., 1999) are also indicative of a heterogeneous provenance for the Valley of Lakes sediments. 382

383 The major oxide compositions of the sediments from the Valley of Lakes mainly plot in the "P4-quartzose sedimentary provenance" field and only a few samples plot into the "P1-mafic 384 igneous provenance" field in the Roser and Korsch (1988) discrimination diagram (Fig. 7). 385 386 This indicates metamorphosed sediments rich in quartz and poor in feldspar and subordinate 387 mafic to intermediate igneous and metamorphic rocks are the source rocks for the Valley of Lakes sediments. These rock types are common to all lithological units exposed in the adjacent 388 389 lands of the Valley of Lakes (Höck et al., 1999). However, if considering the crystallization ages of the 2M1 detrital illite/muscovite (727.6 to 797.9 Ma, cf. Fig. 5), a robust assignment to 390 provenance areas in the adjacent northern Burdgol zone and Baidrag zone is possible. The 391 392 Burdgol zone hosts dominantly metapelites, metapsammites and metacherts, which have an 393 age of 699 ± 35 Ma, as inferred from K-Ar dating of muscovite (Teraoka et al., 1996), which closely matches the detrital illite/muscovite ages measured in the sediments from the Valley of 394 Lakes. The shift towards older ages can be explained by a minor contribution of Neoarchean 395 rocks from the nearby Baidrag zone (~ 2.65 Ga old), which are comprised of high-grade 396 gneisses, charnockites and amphibolites. Both source areas coincide with the heavy mineral 397 398 spectra and gravel lithologies of the Valley of Lakes sediments (Höck et al., 1999).

399	Assuming the detrital illite/muscovite in the Valley of Lakes sediments is a mixture of eroded,
400	metamorphosed and/or intruded material from both source regions, a relative contribution of
401	\sim 95 % from the Burdgol zone and \sim 5 % from the Baidrag zone to the total detrital mica
402	fraction can be calculated. Detrital silicate influx from the northernmost Bayan Khongor zone,
403	Dzag zone and Khangai zone is considered to be unlikely, as these source areas are geologically
404	younger (Ordovician to Cretaceous) (Teraoka et al., 1996). Mixtures of different proportions
405	of detritus from the Burdgol zone and some younger and older material are unlikely as well, as
406	constant source proportions over time would be required to explain the same ages for the four
407	investigated samples. Therefore, the source area relationships of the sediments from the Valley
408	of Lakes are less complex than previously thought with most detritus delivered from the
409	regionally adjacent northern areas located within a 100 km range.

410

411 5.2 Depositional environment

The poorly sorted, massive to partly cross-bedded sand and gravel beds of the Tsagaan Ovoo 412 Formation are interpreted as debris flow deposits in alluvial fans, according to the classification 413 of Miall (1996) for fluvial sediments. These were generated during or soon after heavy rainfall 414 415 events, which caused the water-saturated regolith to move down slope (Hubert and Filipov, 416 1989). The finer, laminated layers with ripple marks, inverse to normal grading and channel 417 fills deposited in-between the coarser clastic beds represent the background sedimentation in the upper Eocene, i.e., braided river deposits developed in close vicinity to propagating alluvial 418 419 fans (Miall, 1996). Imbrications of pebbles, cobbles and clasts within these beds suggest a 420 palaeo-current direction from north to south (Höck et al. 1999), which is consistent with major sediment source areas in the northern Burdgol Zone. Although we found no petrographic-421 422 sedimentological evidence for sediment deposition in a lake or playa environment in the upper 423 Eocene, as previously proposed by Badamgarav (1993) and Daxner-Höck et al. (2017), the

scatter in the δ^{18} O isotopic composition of the soil carbonates, which has been attributed to

varying amounts of evaporation (Richoz et al., 2017), may support this assertion.

The poorly sorted, often horizontally bedded and fossiliferous clay-silt-sand(stone) beds of the 426 427 Hsanda Gol Formation were deposited in a complex environment: the finer beds have likely been developed in ephemeral lakes or braided rivers systems draining proximal alluvial fans, 428 429 as indicated by the presence of channel sand bodies with basal channel scour lags and cross-430 bedded sand fill. The sandier beds are interpreted as open steppe deposits, which have been temporarily affected by ephemeral river and playa lake sedimentation (Miall, 1996), as it can 431 432 be inferred from occasional mud cracks and salt crusts (halite; Höck et al., 1999). On the 433 contrary, Sun and Windley (2015) have proposed an eolian origin for the Oligocene sediments and interpreted them as loess deposits, which were transported by westerly winds, based on 434 435 REE patterns and comparison with grain size distributions obtained from recent Loess deposits 436 from Kansas (USA) and the Chinese Loess Plateau. Although we cannot exclude long-distance transport and subsequent deposition of dust has contributed to at least a minor proportion to 437 438 the total basin fill of the Valley of Lakes, we found no petrographic evidence for any aeolian influences, such as ripples, coarsening up laminae or climbing translatent strata, ventifacts, 439 440 mud curls or even quartz grains with crescentic percussion marks (Kenig, 2006; Li et al., 2020). The lithological variability of the Loh Formation (i.e., poorly sorted and highly fossiliferous 441 442 clay-silt-sand-gravel beds deposited in alternate mode) can be best explained by a combination of debris flow deposits in alluvial fans (coarse clastic material) and abandoned channel deposits 443 and waning flood sedimentation (fine clastic material) of a shallow, perennial flowing braided 444 river system Miall (1996). Imbrication of gravels and flow structures in the basalt III group still 445 indicate a palaeo-current direction from north to south (Höck et al., 1999), which suggests the 446 447 Burdgol Zone is the main source area at least up to the upper lower Miocene.

448 5.3 Origin of hairy illite and Ilt-Smc

449	Höck et al. (1999) and Sun and Windley (2015) have proposed an aeolian origin or a coupled
450	aeolian-fluviatile origin for the finest fraction of the Valley of Lakes sediments, while Richoz
451	et al. (2017) concluded the finest fraction is authigenic and has been formed during or shortly
452	after the flows of the different basalt groups. However, in none of the above studies radiometric
453	ages of the clay fraction have been presented to confirm their assertions. Our XRD and SEM
454	study shows the clay mineral fraction of the Oligocene Hsanda Gol Formation is dominated by
455	hairy illite and subordinate flake-shaped Ilt-Smc, which cover detrital grains or grow into the
456	pore space (Fig. 4). All these features that are typical for authigenic illitic phases (Güven et al.,
457	1980; Rafiei et al., 2020). The polytype analysis and K-Ar age dating reveal these illitic phases
458	have been precipitated between 34.2 and 25.2 Ma (Fig. 5), which (within uncertainty) is well
459	within the documented intrusion ages of the basalt I group (32.4-29.1 Ma) and basalt II group
460	(28.7-24.9 Ma) (Daxner-Höck et al., 2017) and closely matches the biozonation reported in
461	Harzhauser et al. (2017).

462 The origin of Ilt-Smc in the Valley of Lakes sediments is difficult to constrain: it could have been formed during low temperature pedogenesis from smectite or kaolinite precursors of 463 'zero' age (Huggett et al., 2016), which were deposited due to wind (allochthonous clay source) 464 or soil water (autochthonous source) action, through a dissolution-(re)precipitation mechanism. 465 466 Pedogenic degradation of detrital illitic minerals to produce Ilt-Smc under acidic conditions at low temperature has also been observed (Meenakshi et al., 2020). Contrary, several published 467 468 studies question a low temperature origin of Ilt-Smc in sedimentary successions: Ilt-Smc found in paleosols from the Illinois Basin was shown to be the alteration product of siliceous parental 469 470 phases, which interacted with hydrothermal brines generated during burial diagenesis rather 471 than of ancient soil formation processes (McIntosh et al., 2020). Środoń (1984) concluded that 472 smectite and Ilt-Smc phases are relatively stable in surface-near surroundings until the elevated

temperatures of deep diagenesis are reached, which is consistent with slow kinetics of smectite
illitization calculated for shallow buried sediments and/or low temperature settings (Cuadros,
2006). In the case of the Valley of Lakes sediments, the relatively low Ilt content in Ilt-Smc
(~10-30 % Ilt layers) and the stratigraphic age-progression of the authigenic illitic phases upsection in the sedimentary succession may indicate a pedogenic origin of the Ilt-Smc.
Contrary to the Ilt-Smc, a pedogenic origin of the hairy illite is unlikely, because the formation

479 of this mineral phase requires temperatures well around 100 °C (Güven et al., 1980; Nadeau et al. 1985; Baldermann et al., 2017), which is unrealistic high to occur in a developing soil profile 480 481 that has experienced a maximum burial depth of only a few hundred meters (Richoz et al., 2017). The high Ilt content (> 95 % Ilt layers) and the hairy appearance of the illite argue for a 482 formation at elevated temperatures, which likely developed simultaneously or shortly after the 483 484 prominent and recurrent basalt flows, consistent with a basalt-mediated diagenesis. Under such conditions, pore fluids rich in K⁺, Al³⁺ and silicic acid are generated through the dissolution of 485 unstable components, such as feldspar, which subsequently infiltrated the poorly consolidated 486 487 (porous) Valley of Lakes sediments, thereby promoting the direct precipitation and growth of hairy illite in open pores (Fig. 4) and/or the hydrothermal alteration of pre-existing pedogenic 488 Ilt-Scm to hairy illite (Baldermann et al., 2017). This mechanism is applicable to explain the 489 490 shift of the chemical data towards the K pole in the A-CN-K ternary diagram (Fig. 6).

491

492 5.5. Palaeo-climate and weathering conditions

Climatic conditions are a primary control of the intensity and type of terrestrial weathering processes, where humid periods favor chemical weathering and arid periods favor physical weathering (Chamley, 1989). Analogously, hydroclimatic conditions take a key control on the intensity of pedogenic processes, which can be recorded in the δ^{13} C and δ^{18} O isotopic signature of authigenic carbonates (i.e., calcrete in paleosols), where wetter conditions favor an excursion

498	towards lighter $\delta^{13}C$ and $\delta^{18}O$ values and drier conditions favor an excursion towards heavier
499	δ^{13} C and δ^{18} O values (Richoz et al., 2017). Hence, variations in chemical weathering indicators
500	(CIA, PIA and CIW) and in the $\delta^{13}C$ and $\delta^{18}O$ profiles of soil carbonates across a sedimentary
501	succession can be used to trace and assess fluctuations in the climatic conditions that prevailed
502	in the source areas and in the sedimentary basin at the time of sediment deposition, and during
503	pedogenesis (Nesbitt and Young, 1982; Bahlburg and Dobrzinski, 2011; Fischer-Femal and
504	Bowen, 2020; Kelson et al., 2020; Zamanian et al., 2021). The formation of soil carbonates is
505	a highly complex process that can complicate the interpretation of their $\delta^{13}C$ and $\delta^{18}O$ isotopic
506	values (Richoz et al., 2017), as global climatic trends may be overprinted by regional factors,
507	such as contamination with detrital carbonates, dolomitization, meteoric diagenesis, maturation
508	or oxidation of organic matter, dis-equilibrium conditions between atmospheric (or biogenic)
509	CO2 and soil solution, evaporation, basalt hydrothermalism, etc. (Kaufman and Knoll, 1995;
510	Kent-Corson et al., 2009; Caves et al., 2014; Li et al., 2016; Baldermann et al., 2020; Li et al.,
511	2020). However, if considering that the pristine soil carbonate $\delta^{13}C$ and $\delta^{18}O$ isotopic signature
512	is almost well preserved in the Valley of Lakes sediments, their use for palaeo-environmental
513	reconstructions is possible.

The analysis of the δ^{13} C and δ^{18} O isotopic profiles recorded in the soil carbonates from the 514 Valley of Lakes (~34-21 Ma) yielded the following palaeo-climatic trends, which are consistent 515 with inverse shifts seen in the chemical weathering indices (dashed orange lines in Fig. 8), i.e., 516 periods with increased precipitation coincide with higher chemical weathering indices and vice 517 518 versa. This inverse relation is a robust recorder of changing humid/arid climatic conditions in 519 an overall arid climate through the Cenozoic in Central Asia, if considering that the source 520 areas providing the silicate detritus have not changed over time in the investigated sedimentary 521 succession. Accordingly, during the late Eocene to the earliest Oligocene comparatively humid 522 to semi-arid climatic conditions prevailed in Central Asia (phase i); biozone A to bottom part

523	of biozone B; ~34-31 Ma), which is followed by an early Oligocene aridification (phase ii);
524	bottom part of biozone B; ~31 Ma) and the establishment of more arid climatic conditions
525	afterwards until the terminal Oligocene (phase iii); upper part of biozone B to biozone C1-D;
526	~31-23.5 Ma). A shift back towards comparatively humid to semi-arid climatic conditions is
527	evident in the late Oligocene to earliest Miocene (phase iv); transition between biozones C1-D
528	and D; ~23.5-23 Ma), which is followed by the establishment of these conditions in the early
529	Miocene (phase v); biozone D; ~23-21 Ma).

Global cooling events established from δ^{13} C and δ^{18} O isotope records of marine deep-sea 530 531 sediments (Zachos et al., 2001; Gallagher et al., 2020), such as the Oi-1a/b Glaciation (~34-33 Ma) or the Oligocene Glacial Maximum (~28 Ma) are barely recorded in the soil carbonate 532 δ^{13} C and δ^{18} O isotope profiles. However, they are visible by increases in chemical weathering 533 indices at exactly these time intervals (blue bars and arrows in Fig. 8) and correspond to 534 535 important faunal turnovers (Harzhauser et al., 2016). The early Oligocene aridification (~31 536 Ma) is seen by an excursion towards heavier isotopic values between ~55 and 60 m in the rock 537 record, but do not correspond to an important faunal turnover (Harzhauser et al., 2016). On the contrary, the Oligocene warming event (~25 Ma), marked by an important extinction of the 538 mammal community, is not seen in the δ^{13} C and δ^{18} O isotopic profiles. However, in the interval 539 540 from ~87 to 92 m (upper part of biozone C1) an increase of all chemical weathering indices is 541 evident, which we attribute to strong illitization and local overprinting of the pristine chemical 542 signature of these sediments. The following Mi-1 Glaciation (~23 Ma) records high chemical 543 weathering patterns, but shows the expected excursion towards lighter δ^{13} C and δ^{18} O isotopic values. 544

The reasons for the Cenozoic climate change are hotly debated in the literature, but a strong decrease in atmospheric pCO₂ (Pagani et al., 2011; Anagnostou et al., 2016), major tectonic events, such as the collision of India with Asia and progressing exhumation of the Himalaya,

- as well as re-adjustments in oceanic gateway configurations are widely considered to have
 altered the global ocean/atmosphere circulation patterns (Caves Rugenstein and Chamberlain,
 2018). This resulted in large-scale shifts in Earth's climate at this time, which expressed, for
 example, in the formation and expansion of the Antarctica ice-sheets and periods of intensified
 chemical weathering on land (Zachos et al., 2001, and references therein).
- 553

554 5.6 Hydroclimate and tectonics evolution in Central Asia

The links between the regional tectonic evolution and climate change in Central Asia have been 555 556 extensively studied over the past decades. Recently, Caves Rugenstein and Chamberlain (2018) 557 have concluded Central Asia has received moisture through the mid-latitude westerlies, maintaining stable semi-arid to arid climatic conditions ever since the early Eocene, based on 558 the analysis of δ^{18} O and δ^{13} C isotope systematics of more than 7700 terrestrial authigenic 559 carbonate samples from across Asia. On the contrary, southern Tibet, the central Tibetan 560 Plateau, China and India dominantly received southerly monsoonal moisture, favoring more 561 562 humid climatic conditions in these regions compared to Central Asia (Ingalls et al., 2018; Sandeep et al., 2018). Our data support this viewpoint: consistently higher δ^{18} O and δ^{13} C values 563 measured for the soil carbonates from the Valley of Lakes (Fig. 8), compared to the surrounding 564 565 regions, indicate less precipitation and long-term, sustained arid climatic conditions prevailed 566 in the late Eocene until the early Miocene (Cerling and Quade, 1993; Kent-Corson et al., 2009; Takeuchi et al., 2010; Caves et al., 2015; Li et al., 2016; Caves Rugenstein and Chamberlain, 567 2018). An influence of the height and extension of the Tibetan Plateau or the retreat of the 568 Paratethys on the hydroclimate in Central Asia at this time (An et al., 2001; Zhang et al., 2007) 569 is barely documented in the sedimentary record of the Valley of Lakes, but cannot be excluded, 570 571 which would express in monsoon-dominant environmental pattern and varying amounts of 572 precipitation (Zhongshi et al., 2007).

The increase in the δ^{13} C values of the soil carbonates in the Oligocene and the decrease in the 573 574 δ^{18} O values in the terminal Oligocene are ultimately linked to coupled effects arising from the Cenozoic global cooling and the uplift of the Tian Shan and Altai from the early Neogene 575 576 onward, which caused changes in the seasonality and quantity of precipitation (Hendrix et al., 1994; Macaulay et al., 2016; Hellwig et al., 2017; Wang et al., 2020). The resultant effects on 577 the fractionation of δ^{18} O and δ^{13} C isotopes in soil carbonates are detailed in Caves Rugenstein 578 579 and Chamberlain (2018), but are directly related to the development and the establishment of the Altai rain shadow front. As a consequence, on the leeward side of the Altai, sustained, long-580 581 term drying occurred, which is expressed by systematic changes seen in the isotope profiles and chemical weathering indices (Fig. 8). This aridification led to a concurrent extension of the 582 Gobi Desert, causing shifts and turnovers in mammalian and gastropod assemblages observed 583 584 in soils of western Mongolia and in the adjacent eastern Valley of Lakes basin at this time 585 (Neubauer et al., 2013; Harzhauser et al., 2017; Barbolini et al., 2020). We conclude the climatic and environmental evolution of Central Asia in the Cenozoic was closely coupled to 586 587 global climate change, regional tectonic events and adaptions of the circulation pattern of the westerly winds, transporting less moisture to continental Mongolia, which favored 588 aridification. 589

Figure 1: (a) Location of the study site in the Taatsiin Gol region, a part of the Valley of Lakes,
in Mongolia (Central Asia). Altitude in meters is indicated on the right. (b) Geological map of
the Taatsiin Gol area within the Valley of Lakes with the sampling sites marked in alphabetical
order (modified after Daxner-Höck et al., 2017).

Figure 2: (a) Integrated lithostratigraphic profile of the investigated sedimentary succession
from the Taatsiin Gol region, Valley of Lakes (modified after Richoz et al., 2017), with
biozonation (modified after Harzhauser et al., 2017). (b-d) Field impressions of the sections
Hotuliin Teeg (HTE) with calichized basalt II group, Tatal Gol (TAT-E) sediments and Taatsiin
Gol right (TGR-B) section with basalt I group (modified after Daxner-Höck et al., 2017).

913 Figure 3: Averaged mineralogical composition (in wt%) of the sediments from the (a) upper

914 Eocene Tsagaan Ovoo Formation, (b) Oligocene Hsanda Gol Formation and (c) lower Miocene

915 Loh Formation from the Valley of Lakes, determined by XRD analysis.

916

Figure 4: Secondary electron images of partly calichized and illitized silty to sandy deposits
from the of the Oligocene Hsanda Gol Formation, Valley of Lakes, collected from (a-b) TAT
section (~90.5 m), (c-d) TGR-C section (~78.0 m), (e-f) SHG-D section (~55.5 m) and (g-h)
TGR-AB section (~35.0 m). The detrital illite/muscovite (left panel) occurs as coarse, rounded
or pseudohexagonal platelets, whereas authigenic illite-smectite (Ilt-Smc) and hairy illite (right
panel) appear either as fine, flaky to irregular particles or as long, but thin laths and fibers, both
covering detrital grains or growing into the open pores.

Figure 5: Crystallization ages of detrital $2M_1$ illite/muscovite and of authigenic $1M_d/1M$ illite and illite-smectite (Ilt-Smc) from the Valley of Lakes, calculated for sediments collected from (a) TAT section (~90.5 m), (b) TGR-C section (~78.0 m), (c) SHG-D section (~55.5 m) and (d) TGR-AB section (~35.0 m) using illite polytype quantification and K-Ar age systematics of different grain size sub-fractions (from left to right: < 1 μ m, 1-2 μ m and 2-10 μ m).

930

Figure 6: Al₂O₃-(CaO*+Na₂O)-K₂O (A-CN-K) ternary diagram of Nesbitt and Young (1984) showing the compositional ranges of sediments from the Valley of Lakes from (a) upper Eocene Tsagaan Ovoo Formation, (b) Oligocene Hsanda Gol Formation and (c) lower Miocene Loh Formation. Note that most samples are shifted to the K pole of the diagram, which indicates a post-depositional enrichment of K₂O due to illitization. The composition of Upper Continental Crust (UCC), Average Proterozoic Shale (APS) and Post-Archean Australian Shale (PAAS) are included for comparison.

938

Figure 7: Discrimination plot of discriminant function 1 and 2 indicating a narrow provenance

940 range (mainly type P4-quartzose) for the sediments from the Valley of Lakes, Mongolia.

941

942 Figure 8: Lithostratigraphic framework of the sediments from the Valley of Lakes (Mongolia, 943 Central Asia) showing the biozonation (modified after Harzhauser et al., 2017) and formation ages of authigenic illitic (Ilt) phases obtained in this study (red asterisks), as well as soil 944 carbonate δ^{18} O and δ^{13} C isotope profiles and shifts in the silicate mineral-derived chemical 945 946 weathering indicators. Note that these hydroclimate proxies are inversely correlated and follow long-term trends (indicated by orange dashed lines) in aridification or gain of humidity in this 947 region (indicated by black arrows). Increased chemical weathering degrees (highlighted with 948 949 blue bars and blue arrows) coincide with glaciation events documented in time-equivalent marine deep-sea deposits (Zachos et al., 2001; Gallagher et al., 2020). Samples and intervals 950 outlined with grey circles are most likely modified due to the flows of the basalt I and II groups 951 952 or local strong illitization, and are therefore excluded from the palaeo-climatic interpretation.
