**Abstract.** While several processes have been identified to explain the decrease in atmospheric CO<sub>2</sub> during glaciations, a better quantification of the contribution of each of these processes is needed. For example, enhanced aeolian iron input into the ocean during glacial times has been suggested to drive a 5 to 28 ppm atmospheric CO<sub>2</sub> decrease. Here, we constrain this contribution by performing a set of sensitivity experiments with different aeolian iron input patterns and iron solubility factors under boundary conditions corresponding to 70 thousand years before present (70 ka BP), a time period characterised by the first observed peak in glacial dust flux. We show that the decrease in CO<sub>2</sub> as a function of the Southern Ocean iron input follows an exponential decay relationship. This exponential decay response arises due to the saturation of the biological pump efficiency and levels out at ~21 ppm in our simulations. Using a best estimate of surface water iron solubility between 3 and 5%, a ~9 to 11 ppm CO<sub>2</sub> decrease is simulated at 70 ka BP, while a plausible range of CO<sub>2</sub> draw-down between 4 to 16 ppm is obtained using the wider but possible range of 1 to 10%. This would account for ~12-50% of the reconstructed decrease in atmospheric CO<sub>2</sub> (~32 ppm) between 71 and 64 ka BP. We further find that in our simulations the decrease in atmospheric CO<sub>2</sub> concentrations is solely driven by iron fluxes south of the Antarctic polar front, while iron fertilization elsewhere plays a negligible role.

## 1 Introduction

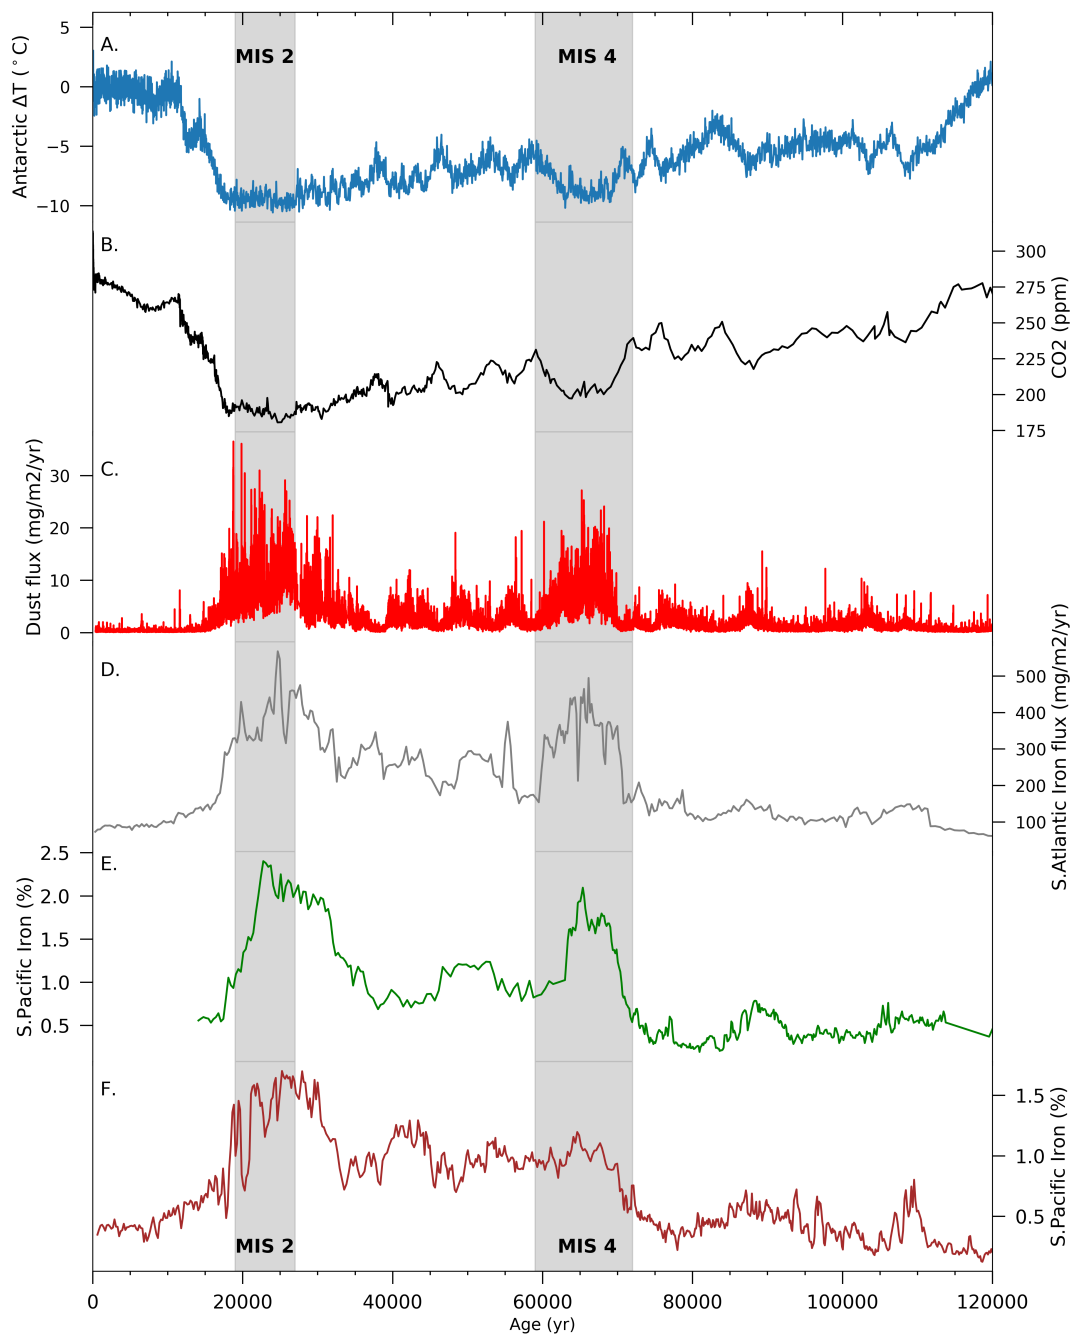

CO<sub>2</sub> draw-down during the last glacial period occurred in multiple steps before reaching a minimum level of ~190 ppm at the Last Glacial Maximum (LGM, 21,000 years ago) (EPICA Community Members et al., 2004; Ahn and Brook, 2008; Lüthi et al., 2008; Bereiter et al., 2012, 2015). One of the last major drops in atmospheric CO<sub>2</sub> concentration occurred at the beginning of Marine Isotope Stage (MIS) 4 (71-59 thousand years ago, ka BP hereafter) when CO<sub>2</sub> decreased from ~233±8 ppm to ~201±4 between 71 ka and 64 ka (Figure 1b). This period also coincided with the minimum summer insolation at high northern latitudes (~70 ka BP, Berger (1978)), which led to the most pronounced episode of ice sheet growth in the Northern Hemisphere (NH) over the glaciation (Bassinot et al., 1994; Petit et al., 1999; Grant et al., 2012). Even though NH ice sheet extent and volume during MIS4 and MIS3 are not well constrained, numerical modelling experiments and observational records have shown that the extent of the Cordilleran and Scandinavian ice sheets was larger during MIS4 than during the LGM,

whereas the Laurentide and Greenland ice sheets were smaller (Lambeck et al., 2010; Kleman et al., 2013; Batchelor et al.,  
25 2019). As a result of the glaciation occurring during the early part of MIS4, it is suggested that the global sea level dropped to  
about 80m below present day sea level (Waelbroeck et al., 2002; Grant et al., 2012; Batchelor et al., 2019; De Deckker et al.,  
2019). Global sea surface temperatures (SSTs) also show a rapid decline by  $\sim 1^\circ\text{C}$  in the early MIS4 transition and an overall  
 $\sim 1.5^\circ$  drop across MIS4, before rising again to pre-MIS4 levels around 59 ka BP (Kohfeld and Chase, 2017).

30 Several mechanisms have been put forward to explain the draw-down of atmospheric  $\text{CO}_2$  during glaciations, including the  
 $\sim 32$  ppm drop in  $\text{CO}_2$  during the MIS4 transition. These mechanisms include higher solubility of  $\text{CO}_2$  in colder ocean waters  
(Heinze et al., 1991; Kucera et al., 2005; Williams and Follows, 2011; Khatiwala et al., 2019); higher carbon sequestration  
associated with a weaker Atlantic Meridional Overturning Circulation (AMOC) and thus lower ventilation rates during glacial  
periods (Sigman and Boyle, 2000; Toggweiler, 2008; Sigman et al., 2010; Watson et al., 2015; Jaccard et al., 2016; Yu et al.,  
35 2016; Menviel et al., 2017; Kohfeld and Chase, 2017); and the expansion of sea ice cover leading to more stratified Southern  
Ocean (SO) waters and smaller air-sea gas exchange (Francois et al., 1998; Stephens and Keeling, 2000; Ferrari et al., 2014).  
However, it has been argued that sea ice expansion does not correlate well with the timing of  $\text{CO}_2$  draw-down at 70 ka (Kohfeld  
and Chase, 2017), and that the major drivers during this transition might in fact be due to a shallower AMOC (Piotrowski et al.,  
2005; Thornalley et al., 2013; Yu et al., 2016), or a more efficient biological pump due to enhanced iron input to the ocean  
40 (Brovkin et al., 2012; Menviel et al., 2012; Anderson et al., 2014; Lamy et al., 2014; Martínez-García et al., 2014).

The efficiency of the biological pump is partly dependent on the relative abundance of different marine phytoplankton  
communities, which further depends on the availability of both macro and micro nutrients (Kvale et al., 2015a; Saini et al.,  
2021). Martin (1990) suggested that the micro nutrient iron plays a crucial role as a limiting nutrient in phytoplankton growth,  
45 and thus put forward the hypothesis that iron fertilisation, through an increase in dustiness, might have increased marine net  
primary production (NPP) in the Southern Ocean during glaciations, leading to a decrease in atmospheric  $\text{CO}_2$  concentrations.  
Antarctic ice core records indeed show peaks in dust fluxes that coincide with lower Antarctic temperatures and lower  $\text{CO}_2$   
levels (Figure 1) during MIS4 and MIS2 (27-19 ka) (Wolff et al., 2006, 2010; Lambert et al., 2008, 2012; Martínez-García  
et al., 2011, 2014; Lamy et al., 2014). However, even though some marine proxy records point to increased export production  
50 (EP) in the Southern Ocean during the LGM (Kohfeld et al., 2005, 2013; Martínez-García et al., 2014), there is little evidence  
of increased Southern Ocean export production at 70 ka BP (Lamy et al., 2014; Martínez-García et al., 2014). Numerous  
modelling studies have explored the changes in Southern Ocean biogeochemistry due to enhanced aeolian iron input either  
under pre-industrial (PI) (Aumont and Bopp, 2006; Tagliabue et al., 2009a, 2014) or LGM conditions (Aumont et al., 2003;  
Bopp et al., 2003; Oka et al., 2011; Lambert et al., 2015; Muglia et al., 2017; Khatiwala et al., 2019; Yamamoto et al., 2019;  
55 Lambert et al., 2021; Saini et al., 2021), but not under MIS4 conditions. An exception is Menviel et al. (2012) who simulated  
a  $\sim 12$  ppm  $\text{CO}_2$  drop as a result of enhanced aeolian iron fluxes into the Southern Ocean at 70 ka in a transient simulation of  
the last glacial cycle.

**Figure 1.** Time series of (a) Antarctic temperature anomalies from present day ( $^{\circ}\text{C}$ ) (Jouzel et al., 2007), (b) atmospheric  $\text{CO}_2$  concentration (ppm) (Bereiter et al., 2015), and (c) dust flux ( $\text{mg}/\text{m}^2/\text{yr}$ ) (Lambert et al., 2012) as recorded in EPICA DOME C ice core; (d) iron dust accumulation rates ( $\text{mg}/\text{m}^2/\text{yr}$ ) from ODP Site 177-1090 (Atlantic) (Martínez-García et al., 2011), iron (%) records in the South Pacific from Lamy et al. (2014) at sites (e) PS75-076 and (f) PS75-059. Shaded areas represent the two glacial stages, MIS2 (27-19 ka BP) and MIS4 (71-59 ka BP).

In this study, we constrain the impact of enhanced aeolian iron input on atmospheric CO<sub>2</sub> concentration during the MIS4 transition. We perform a set of sensitivity experiments with different aeolian iron flux masks and different iron solubilities under 70 ka boundary conditions, using a model of intermediate complexity, which includes an ocean general circulation model (OGCM) coupled to a recently developed complex ecosystem model (Kvale et al., 2021; Saini et al., 2021). The ecosystem model used here includes calcifying and silicifying plankton and an iron cycle, which makes it well-suited for studying CO<sub>2</sub> uptake in the Southern Ocean.

## 2 Methods

### 2.1 Model description

This study uses the 2.9 version of the University of Victoria Earth System Climate Model (UVic ESCM), which consists of a sea ice model (Semtner Jr, 1976; Hibler, 1979; Hunke and Dukowicz, 1997) coupled to the ocean general circulation model MOM2 (Pacanowski, 1995), with 19 ocean depth layers and a spatial resolution of 3.6° by 1.8°. It also includes a dynamic vegetation model (Meissner et al., 2003), a land surface scheme (Meissner et al., 2003), a 2-D atmospheric energy moisture balance model integrated vertically (Fanning and Weaver, 1996) and a sediment model (Archer and Maier-Reimer, 1994; Meissner et al., 2012). The model is forced with seasonally varying wind stress and wind fields (Kalnay et al., 1996) and seasonal variations in solar insolation at the top of the atmosphere. Full physical and structural descriptions of the model can be found in Weaver et al. (2001), Meissner et al. (2003), Eby et al. (2009), and Mengis et al. (2020).

The marine carbon cycle is represented by the newly developed Kiel Marine Biogeochemistry Model, version 3 (KMBM3) (Kvale et al., 2021) which is based on the Nutrient Phytoplankton Detritus Zooplankton model of Schmittner et al. (2005) and Keller et al. (2012), and additionally includes calcifying (coccolithophores) and silicifying (diatoms) plankton, along with prognostic CaCO<sub>3</sub> and silica tracers (Kvale et al., 2015b, a, 2021), dissolved nitrate, phosphate, iron, and silica as nutrients. The model also incorporates an iron cycle (Nickelsen et al., 2015), including hydrothermal sources. The ecosystem model is described in detail in Kvale et al. (2021).

### 2.2 Experimental design

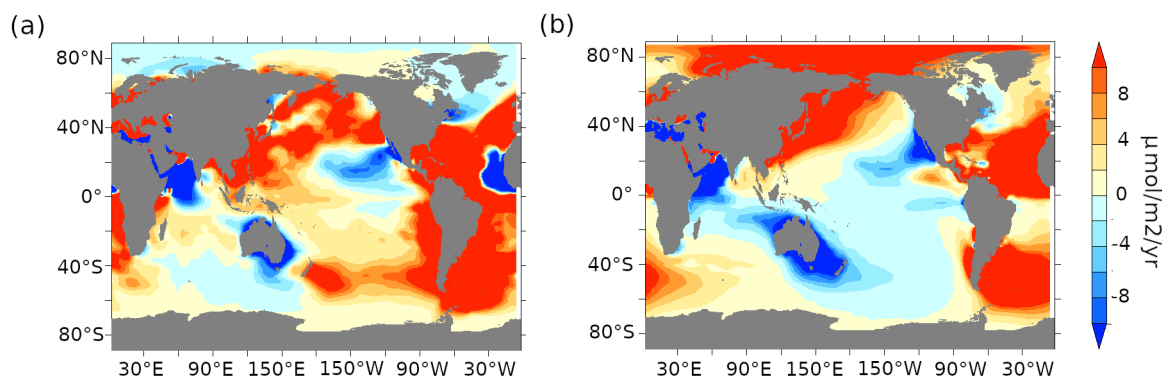

A pre-industrial control simulation (PI-control) is integrated under PI boundary conditions, including an atmospheric CO<sub>2</sub> concentration of 283.86 ppm, and PI iron (pife) and silica (pisi) fluxes. The PI aeolian dust fluxes are based on the PI-BASE dust flux simulation of Mahowald et al. (2006). To obtain iron and silica fluxes, we multiply the dust flux with the percentage distribution of iron and silica in dust (Zhang et al., 2015), respectively. The solubility factor for iron in the control simulation is set to 1%.

All the other experiments are run under 70 ka boundary conditions, including orbital parameters corresponding to the year 70 ka BP according to Berger (1978), and a continental ice sheet topography generated by an offline ice-sheet simulation performed with IcIES (Ice sheet model for Integrated Earth system Studies, Abe-Ouchi et al. (2013)). The global mean ocean

**Table 1.** Aeolian iron fluxes for each experiment.

Experiment	Total iron flux into the ocean (Gmolyr <sup>-1</sup> )	Iron flux into the Southern Ocean south of 47°S (Gmolyr <sup>-1</sup> )
PI-control	3.47	0.0092
70ka-control	3.47	0.0092
lambfe1%	9.072	0.461
lambfe3%	27.44	1.383
lambfe5%	45.73	2.305
lambfe7%	64.02	3.227
lambfe10%	91.46	4.610
lambfe20%	182.9	9.221
glacfe1%	6.532	0.4425
glacfe3%	19.6	1.328
glacfe10%	65.32	4.425
glacfe20%	139.1	8.850

lambfe10%-40S	13.94	4.610
lambfe10%-50S	6.05	2.66
lambfe10%-60S	3.9	0.5
lambfe50%-47S	27.09	23.05

**Figure 2.** Iron dust flux ( $\mu\text{mol m}^{-2} \text{yr}^{-1}$ ) anomalies for (a) lambfe1% minus pife and (b) glacfe1% minus pife.

alkalinity was adjusted on the basis of sea level differences. For the control simulation (70ka-control), the model is run into equilibrium with an atmospheric CO<sub>2</sub> concentration of 222.5 ppm (Bereiter et al., 2015), after which the simulation is integrated for an additional 200 years with prognostic atmospheric CO<sub>2</sub>. 70ka-control is forced with pife and pisi fluxes.

From this control simulation, we branch off a suite of sensitivity experiments with prognostic atmospheric CO<sub>2</sub>, using two different glacial dust flux estimates. The first dust flux, *lambfe*, is obtained from the LGM simulation of Lambert et al. (2015). The second, *glacfe*, is derived from the *LGMglac.a* simulation of Ohgaito et al. (2018) and includes glaciogenic dust sources  
95 in addition to the usual desert dust sources.

The iron delivered to the ocean surface via aeolian dust deposition needs to be dissolved before it can become available to phytoplankton. The solubility factor of iron is therefore an important parameter that defines the magnitude of iron fertilization. Iron solubility varies depending on both provenance and speciation. For example, Baker et al. (2006) find that solubilities in samples of Saharan dust (median of 1.7%) are significantly lower than solubilities in aerosols from other source regions  
100 feeding into the Atlantic ocean (median of 5.2%). Schroth et al. (2009) find a significant difference in iron solubility between arid soils (1%), glacial flour (2-3%) and, of lesser importance to our study, oil combustion products (77-81%). In the present day Southern Ocean, observations of iron solubilities vary between 0.2 and 48% (Ito et al., 2019), with the higher values being hypothesized to be caused by pyrogenic iron. The majority of the observational data in the present day Southern Ocean lies between 1 and 12% (Ito et al., 2019). Quantifying iron solubilities during past climates is even more challenging. Conway et al.  
105 (2015) estimate iron solubility at the Last Glacial Maximum (LGM) based on dust particles in the EPICA Dome C and Berkner Island ice cores. They find that iron solubility was very variable during the LGM interval at Dome C (1-42%), with a mean of 10% and a median of 6%. On the other hand, iron solubility at Berkner Island was 1-5% at the LGM, and in average ~3% between 23 and 50 ka. The lower iron solubility at Berkner Island is thought to be due to the aerosol composition. Due to its proximity to South America, the solubility found at Berkner island might better represent large-scale aeolian dust deposited in  
110 the Southern Ocean. In this study, we test a global mean solubility range between 1% and 20% (Table 1). Based on the studies mentioned above, we define the most likely range for an average iron solubility at 70 ka BP to be between 1 and 10%, with an increased likelihood at 3-5%.

The aeolian iron fluxes based on *glacfe* and *lambfe* dust patterns compared to the PI iron flux (*pipe*), and assuming a 1% solubility, are shown in Figure 2, while the full dust deposition maps for PI and the two LGM reconstructions are available in  
115 the supplementary material of Saini et al. (2021). The integrated aeolian iron input for all experiments is listed in Table 1.

We perform five additional sensitivity experiments (Figure A1) to better quantify the contribution of the Southern Ocean to the total CO<sub>2</sub> draw-down. In these experiments, the aeolian iron flux in the Southern Ocean follows the *lambfe* mask while the PI aeolian iron fluxes are applied outside of the Southern Ocean. In four of these experiments (*lambfe*10%-30S, *lambfe*10%-40S, *lambfe*10%-50S, *lambfe*10%-60S), the *lambfe* mask with 10% solubility is applied south of 30°S, 40°S, 50°S and 60°S,  
120 respectively. In the fifth sensitivity experiment (*lambfe*50%-47S), the aeolian iron input south of 47°S follows the *lambfe* mask with a solubility factor of 50% (Figure A1f). This leads to 23.05 Gmol yr<sup>-1</sup> iron input in the Southern Ocean south of 47°S and provides an upper limit on the potential CO<sub>2</sub> draw-down.

## 2.3 Carbon decomposition

To better understand the changes in ocean carbon, we decompose the simulated dissolved inorganic carbon (DIC) into its three major components: respired organic carbon ( $C_{reg}$ ), DIC generated by dissolution of calcium carbonate ( $C_{CaCO_3}$ ) and preformed carbon ( $C_{pref}$ ) as described below.

$C_{reg}$  is calculated based on the remineralized phosphate in the ocean ( $P_{reg}$ ) and the carbon to phosphate stoichiometric ratio ( $R_{C/P}=106$ ):

$$\Delta C_{reg} = \Delta P_{reg} \times R_{C/P} \quad (1)$$

$P_{reg}$  is approximated based on Apparent Oxygen Utilisation (AOU) and the phosphate to oxygen stoichiometric ratio ( $R_{P/O_2}=1/160$ ),  $\Delta P_{reg} = \Delta AOU \times R_{P/O_2}$ , where AOU is estimated as the difference between the saturated oxygen concentration ( $O_{2sat}$ ) and the dissolved oxygen concentration in the ocean ( $O_2$ );  $AOU = O_{2sat} - O_2$ .

$C_{CaCO_3}$  is calculated as:

$$\Delta C_{CaCO_3} = 0.5(\Delta ALK + R_{N/P} \times \Delta P_{tot}) \quad (2)$$

where  $R_{N/P}=16$ . And finally,  $C_{pref}$  is calculated as the remainder:

$$\Delta C_{pref} = \Delta DIC - \Delta C_{reg} - \Delta C_{CaCO_3} \quad (3)$$

To further assess the efficiency of the biological pump, we calculate global  $P^*$  (Ito and Follows, 2005), defined as:

$$P^* = P_{reg}/P_{total} \quad (4)$$

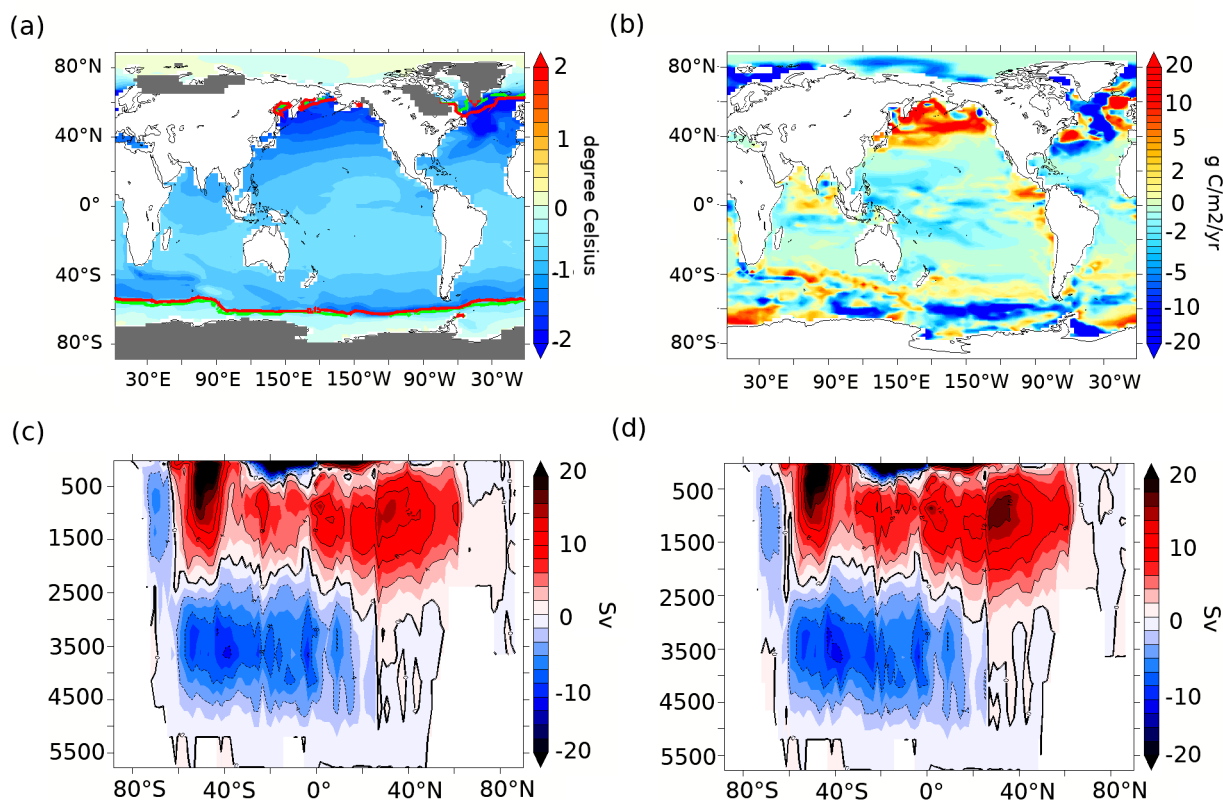

where  $P_{total}$  is the total phosphate content in the ocean.

## 3 Results

### 3.1 Simulated ocean conditions at 70 ka BP

In this section, we describe the simulated physical and biological conditions at 70 ka BP, at the onset of MIS4 (Figure 3). In our 70ka-control simulation, the globally averaged ocean temperature is  $\sim 2.8^\circ\text{C}$ , about  $0.6^\circ\text{C}$  lower than in PI-control, but  $0.9^\circ\text{C}$  higher than in a LGM simulation integrated with the same model (Saini et al., 2021). The globally averaged annual mean SST is  $17.1^\circ\text{C}$ ,  $0.8$  degrees lower than in the PI-control and  $1.1$  degrees higher than in the LGM simulation. The strongest ocean surface cooling ( $-1.45^\circ\text{C}$ ) at 70 ka BP with respect to our PI-control is simulated north of  $40^\circ\text{N}$  in the Atlantic and Pacific

**Figure 3.** (a) Annual mean SST anomalies ( $^{\circ}\text{C}$ , shading) at 70 ka BP compared to PI and 15% annual mean sea-ice concentration at PI (green line) and 70 ka BP (red line). The grey shading on land shows the extent of continental ice sheets at 70 ka BP (Abe-Ouchi et al., 2013); (b) Export production anomalies between 70 ka BP and PI at 177.5m depth ( $\text{g C m}^{-2} \text{ yr}^{-1}$ ). Global overturning streamfunction (Sv) at (c) 70 ka BP and (d) PI.

oceans, while the Southern Ocean's (south of  $30^{\circ}\text{S}$ ) annual mean SST is  $0.8^{\circ}\text{C}$  lower than in the PI-control run (Figure 3a). At 70 ka BP, the annual mean Southern Ocean sea ice edge is situated at  $55^{\circ}\text{S}$  in the South Atlantic and the South Indian Ocean,  $\sim 1$  degree further north than in the PI-control simulation, while the change is insignificant in the South Pacific sector (sea ice edge at  $\sim 62^{\circ}\text{S}$ ). The simulated AMOC strength in the 70ka-control experiment is  $\sim 14$  Sv, compared to  $\sim 17$  Sv in the PI-control. There are no significant changes in simulated Antarctic Bottom Water (AABW) formation (Figure 3c, d).

The colder conditions, more extensive sea-ice cover, and changes in the strength of the deep water masses impact marine productivity (Saini et al., 2021). Globally, NPP decreases by  $\sim 9.7\%$ , while EP decreases by  $\sim 3\%$  in our 70ka-control simulation compared to PI-control (Table 2). The simulated differences in EP in the higher northern latitudes, such as the 18% increase at 70 ka in the North Pacific (Figure 3b) can be attributed to a greater diatom and coccolithophores abundance in that region (Figure A2), while the changes in the lower latitudes are mostly due to general phytoplankton and, to a lesser extent, diazotrophs (not shown). The North Atlantic shows a complex pattern of anomalies which results in an overall decrease in NPP

and EP by 16% and 9%, respectively. In the Southern Ocean, diatoms decrease by 8% close to Antarctica in the Pacific and Indian sectors and increase in the southeast Atlantic (Figure A2a). The decrease in diatom abundance in the Pacific and Indian sectors leads to a competitive growth advantage for coccolithophores, which increase by 4.5% between 60°S and 65°S, thus leading to a poleward shift in their population in the Southern Ocean (Figure A2b). As a result of the changes in these two plankton species, Southern Ocean (south of 30°S) EP and NPP decrease by 2% and 7.5%, respectively at 70 ka. (Figure 3b).

### 3.2 Impact of changes in iron dust flux on atmospheric CO<sub>2</sub>

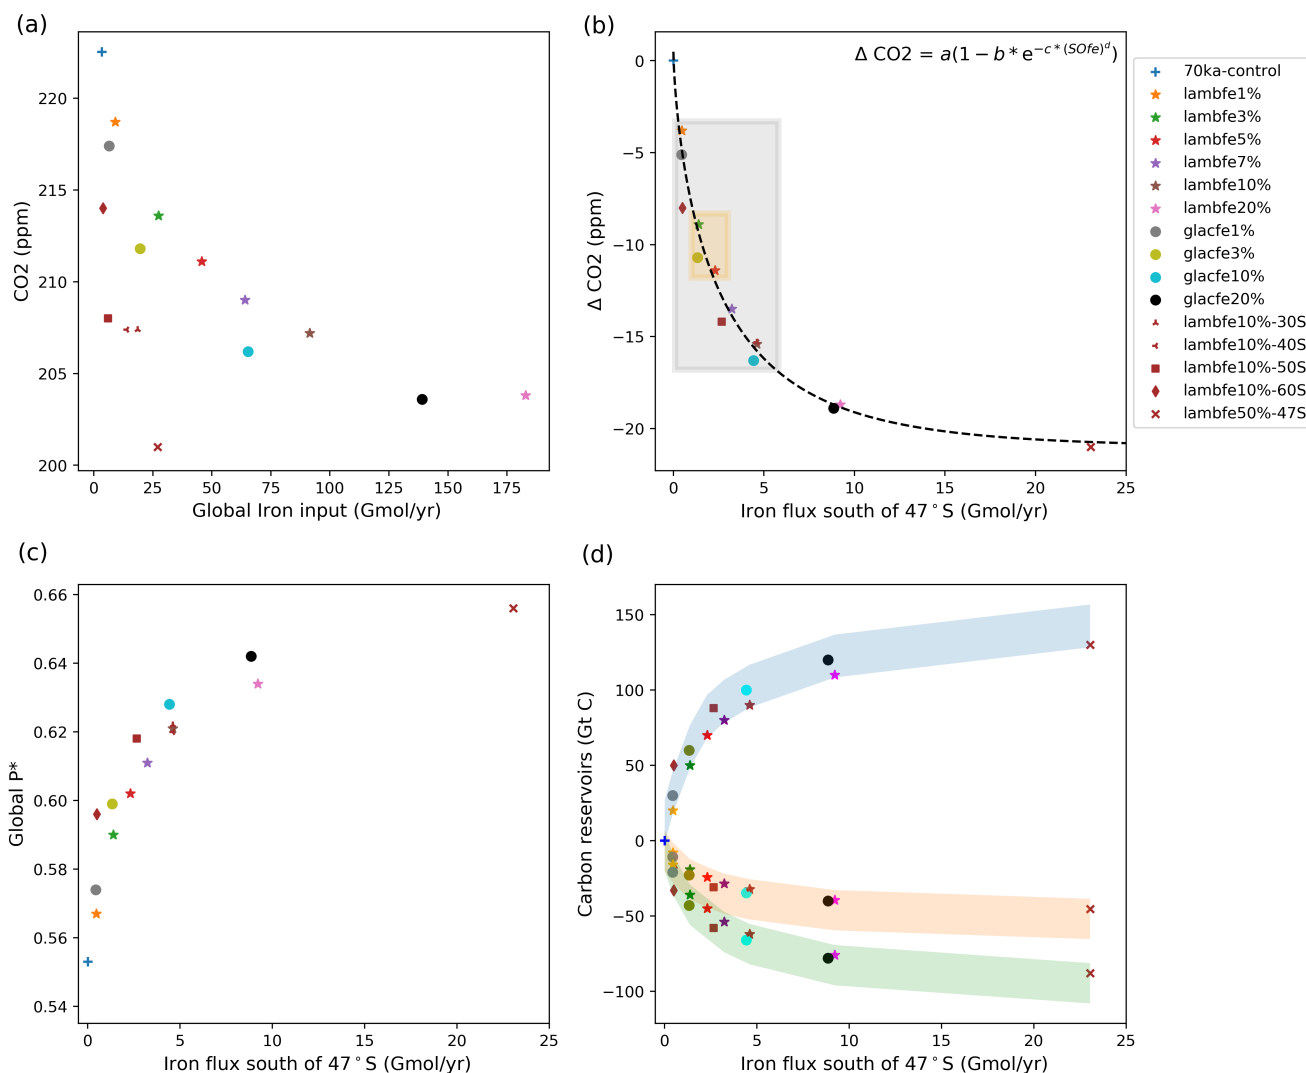

Enhanced aeolian iron input into the ocean at 70 ka BP leads to a ~4 to 19 ppm drop in atmospheric CO<sub>2</sub> concentration in our simulations, depending on the iron solubility factor (Figure 4a and b, Table 2). This change in atmospheric CO<sub>2</sub> impacts the physical conditions of the ocean only slightly in our model. As such, the global overturning circulation, mean SST and sea-ice extent are similar in most of the sensitivity experiments described below.

As the global and Southern Ocean iron input increase, the atmospheric CO<sub>2</sub> concentration decreases, but not linearly, as the efficiency of the iron fertilisation weakens with the increasing iron availability (Figure 4a,b). The patterns of aeolian iron deposition in the Southern Ocean are different for the two masks used here. Both reconstructions show an increase in the South Atlantic sector compared to PI fluxes, but they differ over the Pacific and Indian sectors, including large regions where dust deposition decreases compared to PI (Figure 2). It is therefore interesting that our experiments with similar iron input (Figure 4b, pink star and black circle) display similar efficiency in drawing down CO<sub>2</sub> regardless of the dust mask used. The glacfe mask is however slightly more efficient in drawing down atmospheric CO<sub>2</sub> which might be due to the presence of major convection sites in the Weddell Sea in our experiments.

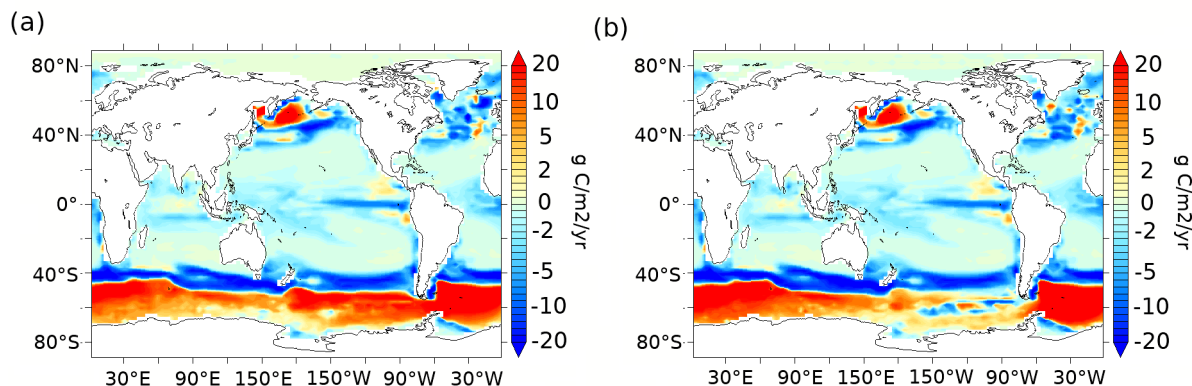

The sensitivity experiments provide additional information on the role of the Southern Ocean in our simulations. We find that experiment  $\lambda_{\text{bfe}}10\%$  is as efficient in drawing down CO<sub>2</sub> as the experiments where iron fluxes were only enhanced south of 30°S or 40°S ( $\lambda_{\text{bfe}}10\%-30\text{S}$ ,  $\lambda_{\text{bfe}}10\%-40\text{S}$ ) (Figure 4a,b). This indicates that in our experiments iron fertilization in the Southern Ocean is mainly responsible for the atmospheric CO<sub>2</sub> draw-down while fertilization elsewhere plays a negligible role. On the other hand, a 14 ppm and 8.5 ppm CO<sub>2</sub> decrease is simulated in  $\lambda_{\text{bfe}}10\%-50\text{S}$  and  $\lambda_{\text{bfe}}10\%-60\text{S}$ , respectively, compared to 15.3 ppm in  $\lambda_{\text{bfe}}10\%$ . This suggests that in our model the atmospheric CO<sub>2</sub> concentration is sensitive to enhanced aeolian iron south of 40°S.

Our experiments show that the ecosystem response north and south of ~47°S are of opposite sign (Table 2). While an increase in iron availability leads to an increase in NPP, diatom and coccolithophore abundance, and consequently EP south of ~47°S (Figures 5 and 6), the regions north of ~47°S show a significant decline in all of these parameters. The EP increase occurs south of the Antarctic polar front, where the surface nutrient concentrations are high (Figure A3). Enhanced aeolian iron input leads to a more efficient use of nutrients in that region and results in a reduction in northward transport of nutrients north of the polar front (Figure A4) which in turn leads to a decrease in EP north of ~47°S.

When fitting a relationship between atmospheric CO<sub>2</sub> and the iron flux south of 47°S, all experiments follow a similar relationship (Figure 4b):

**Figure 4.** (a) Equilibrated atmospheric CO<sub>2</sub> concentration (ppm) as a function of the globally integrated aeolian iron flux into the ocean (Gmol<sup>-1</sup>). (b) Changes in atmospheric CO<sub>2</sub> concentration (ppm) as a function of the aeolian iron flux into the Southern Ocean south of 47°S. The grey shading represents the range of likely iron solubility factors (1-10%) and the associated change in CO<sub>2</sub> concentrations (-4 to -16 ppm), while the orange shading represents our best estimate of change in CO<sub>2</sub> (-9 to -11 ppm) for 3-5% solubility factors. Note that lambfe10%, lambfe10%-30S and lambfe10%-40S overlap each other. The black curve represents the best fit and suggests a maximum CO<sub>2</sub> draw-down of ~21 ppm due to Southern Ocean iron fertilisation. (c) Global P\* as a function of aeolian iron flux into the Southern Ocean south of 47°S and (d) Globally integrated carbon reservoirs (GtC) as a function of aeolian iron flux into the Southern Ocean south of 47°S. The shadings represent ocean carbon (blue), atmospheric carbon (red) and terrestrial carbon (green).

**Figure 5.** Export production anomalies ( $\text{g C m}^{-2} \text{ yr}^{-1}$ ) at 177.5m depth for (a) lambfe3% and (b) glacfe3% compared to 70ka-control.

$$\Delta\text{CO}_2 = a(1 - b \times e^{-c \times (\text{SOfe})^d}) \quad (5)$$

where  $\Delta\text{CO}_2$  is the atmospheric  $\text{CO}_2$  anomaly in ppm compared to 70ka-control, SOfe denotes the total iron input into the Southern Ocean south of  $47^\circ\text{S}$  in  $\text{Gmolyr}^{-1}$ ,  $a = 21.01$ ,  $b = 1.02$ ,  $c = 0.485$  and  $d = 0.69$ .

We also note that the  $\text{CO}_2$  draw-down capacity levels out for high iron forcing. Both lambfe and glacfe masks with 20% iron solubility lead to a  $\sim 19$  ppm  $\text{CO}_2$  decrease. In our extreme experiment lambfe50%-47S, with an iron input south of  $47^\circ\text{S}$  almost 2.5 times higher than in lambfe20% and glacfe20%, only an additional 2ppm  $\text{CO}_2$  draw-down is simulated (Figure 4b). Our results therefore suggest that iron fertilization could have led to a maximum  $\text{CO}_2$  decrease of  $\sim 19$ -21 ppm at 70 ka.

The enhanced iron flux leads to an increase in  $P_{reg}$  in the Southern Ocean, which is subsequently transported northward at depth by AABW. As a result, the globally averaged  $P^*$ , and therefore the overall efficiency of the soft tissue pump, increases with Southern Ocean aeolian iron input (Figure 4c). As ocean circulation and ocean temperatures change only slightly in our experiments, the relationship between  $P^*$  and the resulting  $\text{CO}_2$  draw-down is almost linear (Figure A5) (Ito and Follows, 2005). However, because of the nutrient reorganization in the ocean, the resulting Southern Ocean dipole drives the reduction in iron fertilisation efficiency as the Southern Ocean aeolian iron flux increases. In experiment glacfe20% (Figure 4b, black circle), the 36% increase in EP and 24% increase in NPP south of  $\sim 47^\circ\text{S}$ , is compensated by a 40% decrease in EP and 45% decrease in NPP north of  $\sim 47^\circ\text{S}$  in the Southern Ocean, as well as a  $\sim 16\%$  decrease in both EP and NPP at low latitudes (Figure 6a,b, Table 2). The global  $P^*$  in glacfe20% and in lambfe50%-47S (Figure 4c) equal 0.64 and 0.65 respectively, suggesting a maximum efficiency of 65% in our experimental set-up. Consequently, the  $\text{CO}_2$  sink reaches saturation at high levels of iron input.

The oceanic carbon reservoir in our sensitivity experiments increases between 20 and 130 GtC depending on the iron flux scenario (Figure 4d, blue shade). The simulated decrease in atmospheric  $\text{CO}_2$ , equivalent to 8-45 GtC (Figure 4d, red shade) leads to a decrease in terrestrial photosynthesis and surface air temperatures, as well as regional changes in precipitation and

soil moisture, which together result in an overall 8 to 45 GtC decrease in terrestrial vegetation. The consequent reduction in litter fall leads to a 8-43 GtC decrease in soil carbon. Overall, the terrestrial carbon reduces by 16 to 88 GtC in our experiments (Figure 4d, green shade).

### 215 3.3 Impact of aeolian iron input on the distribution of oceanic carbon

As mentioned in the previous section, our sensitivity experiments do not show significant changes in the physical ocean conditions. However, enhanced iron input significantly impacts marine ecosystems. To understand the resulting ocean carbon changes, we start by describing changes in the simulated ecosystems for one of our sensitivity experiments, lambfe3%, compared to 70ka-control. We choose lambfe3% because earlier research shows that the lambfe Southern Ocean dust mask provides a better fit with available glacial dust flux proxy records than the glacfe mask (Saini et al., 2021). Furthermore, a solubility factor of 3% corresponds to a likely estimate of iron solubility at 70 ka (see Methods) and has also been used in previously studies (Tagliabue et al., 2014; Lambert et al., 2015; Muglia et al., 2017; Yamamoto et al., 2019). All lambfe experiments with different solubility factors show similar anomaly patterns, only the magnitude of the changes varies as a function of solubility (Figure A6).

225 A ~9 ppm drop in atmospheric CO<sub>2</sub> is simulated in experiment lambfe3% with a global increase in EP by 1.3%, and a global decrease in NPP by 6.7% (Table 2). Figure 5a shows the spatial distribution of EP anomalies at 177.5m depth between lambfe3% and the 70ka-control experiment. The higher iron supply in the Southern Ocean in lambfe3% experiment leads to a 11% increase in diatoms, particularly in the South Atlantic (Figure A2c), and a 39% increase in coccolithophores south of 47°S (Figure A2d). These ecosystem changes lead to a 23% increase in EP and 19% increase in NPP south of 47°S (Table 2, Figure 6a,b). In contrast, because of the lower nutrient availability, diatoms and coccolithophores decrease by 24% and 19%, respectively, north of 47°S (Figure 6c,d), resulting in a 25% decrease in EP and 30% decrease in NPP (Table 2, Figure 6a,b). The overall Southern Ocean EP south of 30°S increases by ~9% in the lambfe3% experiment, the NPP changes

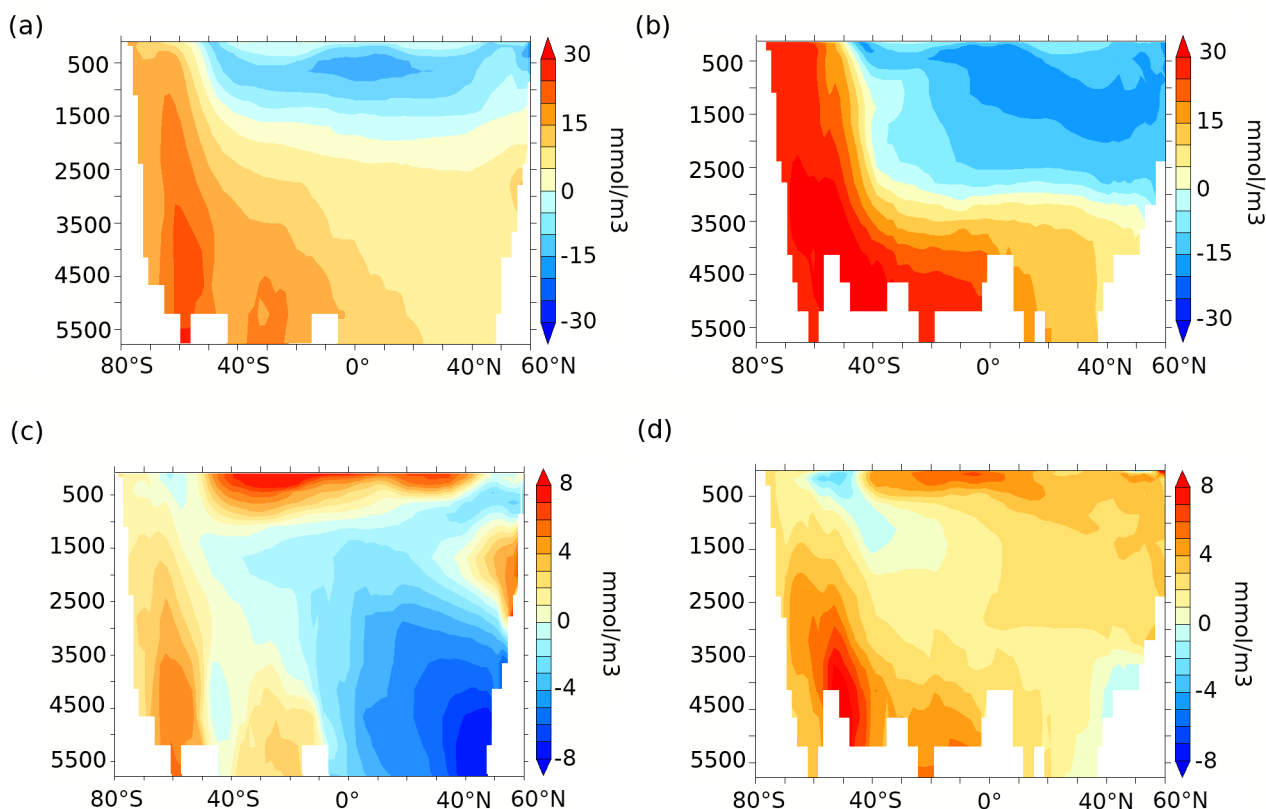

become insignificant (Table 2), and the total biological pump efficiency increases by 6.7% (Table 2). In the North Pacific (150°E:220°E;47°N:56°N), EP increases by 13%, while NPP increases by 7% due to a 82% increase in coccolithophores and  
235 58% decrease in diatoms. Both NPP and EP decrease by ~10% in the North Atlantic (60°W:0°E;47°N:56°N) where we see an overall decrease in coccolithophores by 22% and an increase in diatoms by 16%.

The increased carbon export from the surface into the deep ocean increases DIC at all depths south of 47°S. The DIC rich bottom water is advected northward and leads to a stronger vertical DIC gradient in the ocean (Figure 7a and b). While DIC increases by 25 mmol m<sup>-3</sup> in the deep Southern Ocean (south of 30°S, below 3000m), it does not increase uniformly across  
240 sectors: it increases by 22 mmol m<sup>-3</sup> in the deep Indo-Pacific sector (below 3000m, Figure 7a), and by 29 mmol m<sup>-3</sup> in the deep Atlantic sector (below 3000m, Figure 7b). The positive DIC anomalies north of 30°S are associated with AABW and its northward spread into the Atlantic and the Indo-Pacific basins, therefore leading to a 10 mmol m<sup>-3</sup> DIC increase in the deep Indo-Pacific and a 15 mmol m<sup>-3</sup> increase in the deep Atlantic sector.

In contrast, lower DIC is simulated north of 47°S in the upper Pacific ocean (above 2000m), and within the North Atlantic  
245 Deep Water (NADW) and Antarctic Intermediate Water (AAIW) pathways in the Atlantic above 3000m. Simulated changes in deep ocean oxygen concentrations are opposite to the DIC changes (not shown) indicating an increase in remineralised carbon in the deep ocean (Figure 8a,b). An increase in mixed layer alkalinity (Figure 7c and d) is simulated, partially due to the decrease in coccolithophores between 47°S-50°N (Figure 6d and A2d). As a result of these changes in surface CaCO<sub>3</sub> formation and subsequent changes in the subduction and sinking of CaCO<sub>3</sub> into deeper layers, reduced CaCO<sub>3</sub> dissolution at  
250 depth leads to lower alkalinity in the North Pacific, while higher CaCO<sub>3</sub> dissolution in the Southern Ocean and in the deep Atlantic leads to an alkalinity increase there (Figure 7c, d and Figure 8c, d).

To quantify the processes leading to changes in oceanic DIC, we decompose the changes in DIC into their remineralized, carbonate and preformed contributions (see Methods). In our 70ka-control simulation, the remineralization process leads to the generation of 131 mmol m<sup>-3</sup> C<sub>reg</sub> in the deep (≥3000m depth) Southern Ocean, which increases by 22.5 mmol m<sup>-3</sup> in  
255 lambfe3% due to higher iron influx. Changes in the carbonate pump contribute marginally to the deep Southern Ocean DIC showing an increase of 3.16 mmol m<sup>-3</sup> C<sub>CaCO<sub>3</sub></sub>, whereas the preformed DIC contribution (C<sub>pref</sub>) decreases by 0.66 mmol m<sup>-3</sup>, compared to 70ka-control. North of 30°S, C<sub>reg</sub> in lambfe3% increases by 14.7 mmol m<sup>-3</sup> in the deep Indo-Pacific basin while both C<sub>CaCO<sub>3</sub></sub> and C<sub>pref</sub> decrease by 2 mmol m<sup>-3</sup> and 2.6 mmol m<sup>-3</sup> respectively (Figure 8a, c, e). The deep Atlantic ocean shows an increase in C<sub>reg</sub> by 16.3 mmol m<sup>-3</sup> and in C<sub>CaCO<sub>3</sub></sub> by 2 mmol m<sup>-3</sup> in lambfe3% experiment, while C<sub>pref</sub>  
260 decreases by 3.2 mmol m<sup>-3</sup> (Figure 8b, d, f).

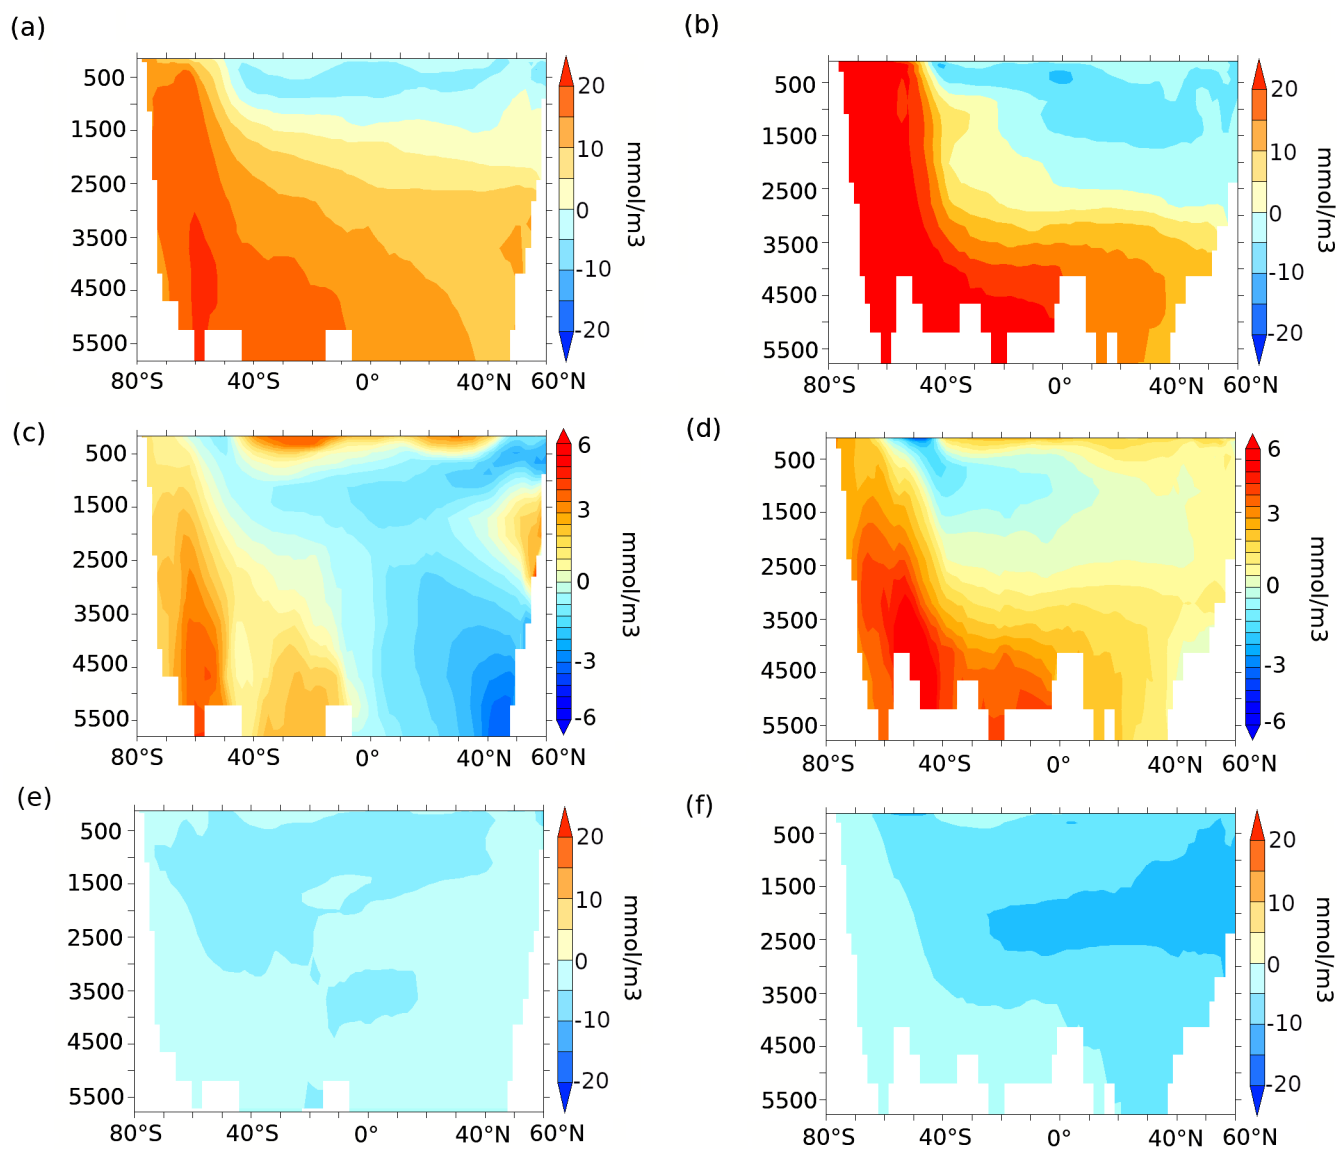

**Figure 7.** Zonally averaged DIC anomalies ( $\text{mmol m}^{-3}$ ) over (a) the Indo-Pacific and (b) Atlantic, and zonally averaged alkalinity anomalies ( $\text{mmol m}^{-3}$ ) over (c) the Indo-Pacific and (d) the Atlantic for  $\lambda_{\text{Fe}}3\%$  compared to 70ka-control.

#### 4 Discussion

In our simulations, the colder climate at 70 ka BP leads to an overall decrease in NPP and EP in compared to PI (9.7% and 3%, respectively). The changes in NPP and EP are spatially heterogeneous and sensitive to shifts in plankton distributions, changes in the length of the growing season, sea ice cover, and nutrient availability. In the Southern Ocean, the  $\sim 7.5\%$  reduction in NPP and 2% reduction in EP might be due to a shorter growing season for diatoms and coccolithophores (Saini et al., 2021), associated with a larger annual sea ice extent and lower SSTs at 70 ka BP. Both NPP and EP also decrease at low and mid latitudes.

Enhanced iron input at 70ka however alters the ecosystem and therefore NPP and EP. In the 70 ka simulation with enhanced iron input following the dust flux of Lambert et al. (2015) and imposing a 3% iron solubility ( $\lambda_{\text{Fe}}3\%$ ), a  $\sim 9\%$  increase in EP is simulated south of  $47^\circ\text{S}$  compared to the 70ka-control experiment. A 13% EP increase is also simulated in the North Pacific, while EP decreases everywhere else, partly due to reduced nutrient advection from the Southern Ocean to lower latitudes.

**Figure 8.** Zonally averaged (a, b) remineralized carbon ( $\text{mmol m}^{-3}$ ), (c, d) carbon due to calcite dissolution ( $\text{mmol m}^{-3}$ ) and (e, f) preformed carbon ( $\text{mmol m}^{-3}$ ) anomalies for  $\lambda_{bf}3\%$  compared to 70ka-control in the Indo-Pacific (left panels) and the Atlantic (right panels). Please note that the color scale is different for subpanels c and d compared to other subpanels.

Higher dust deposition in the South Pacific and the South Atlantic at 70 ka is consistent with available paleo-proxy records (Martínez-García et al., 2009, 2011, 2014; Lambert et al., 2012; Lamy et al., 2014). The EP increase in the subantarctic zone of the Atlantic and Pacific sectors, linked with the greater iron influx (stimulating higher nutrient utilization), is also consistent with available alkenone-based EP proxy records from the subantarctic Atlantic (Anderson et al., 2014; Martínez-García et al., 2014) and biogenic barium-based paleoproductivity proxies from the subantarctic Pacific (Lamy et al., 2014). Our results are also in line with the lack of ecosystem response to enhanced glacial dust in the equatorial Pacific (Costa et al., 2016). However, since proxy data for dust flux and EP is limited to only a few marine sites and ice cores, additional paleo-proxy records covering a larger area in the Southern Ocean during MIS4 are needed to better quantify iron fertilization during the glaciation. Here, we had to rely on estimates of aeolian dust deposition during MIS2, as dust deposition maps at the MIS4 onset do not exist.

Our results suggest that enhanced iron input south of the Antarctic polar front, i.e. south of  $\sim 47^{\circ}\text{S}$  (Dong et al., 2006; Giglio and Johnson, 2016), is responsible for 100% of the atmospheric  $\text{CO}_2$  drawdown. This is in agreement with the hypothesis put forward by Marinov et al. (2006), which suggests that changes in the efficiency of the biological pump in the Antarctic zone play a dominant role in  $\text{CO}_2$  drawdown. However, our results differ from Lambert et al. (2021), who find that  $\sim 30\%$  of the simulated  $\text{CO}_2$  decrease is due to enhanced aeolian iron input into the North Pacific in their simulations. While they use the same LGM dust flux, their iron input in the ocean differs from our study. Lambert et al. (2021) assume 3.5 wt% iron fraction in the aeolian dust flux, whereas we use a global map of percentage distribution of iron in dust (see Methods). More importantly, their solubility factor is not constant, but varies non linearly with the dust flux.

While the two dust masks used here suggest an increase in aeolian iron deposition in the Atlantic sector of the Southern Ocean during glacial times compared to PI, the iron input in glacial times is lower in the South Pacific compared to pre-ice, whereas it is higher in the Pacific sector. Despite these differences in spatial patterns, they both have a similar efficiency in decreasing atmospheric  $\text{CO}_2$  in our simulations. This might be due to the fact that one of the major bottom water formation sites is located in the Weddell sea in our simulations.

With no significant ocean circulation changes, changes in atmospheric  $\text{CO}_2$  are a linear function of the overall efficiency of the biological pump ( $P^*$ , Figure A5). In agreement with earlier studies (Matsumoto et al., 2002; Tagliabue et al., 2014; Lambert et al., 2015; Yamamoto et al., 2019), we find that as the efficiency of the soft tissue pump increases south of  $47^{\circ}\text{S}$ , it decreases in the lower latitudes due to reduced northward advection of surface nutrients. The increase in the vertical nutrient gradient leads to the eventual saturation of the ocean carbon uptake capacity.

We simulate a maximum of 16-18% increase in the global  $P^*$  in our experiments, leading to a maximum drop of 19-21 ppm in  $\text{CO}_2$ . The timescale of this total draw-down in our idealised simulations, i.e. without transient changes in dust, or transient changes in ice sheet volume, is  $\sim 5000$  years, which is consistent with the observed timescale of  $\text{CO}_2$  transitions during MIS4 (Bereiter et al., 2015). If we define the plausible range of the large-scale average iron solubility in the ocean to be 1 to 10% at 70 ka BP, the corresponding range of atmospheric  $\text{CO}_2$  draw-down is  $\sim 4$  to 16 ppm. More likely, large-scale solubility in the Southern Ocean at 70 ka ranged between 3 and 5%, which leads in our simulations to a  $\text{CO}_2$  decline of 9 to 11 ppm (Figure 4b).

In previous modeling studies, Tagliabue et al. (2014) obtained a 2 ppm drop in  $\text{CO}_2$  using 2% iron solubility in the Southern Ocean under PI boundary conditions, while under LGM boundary conditions, using solubility factors between 1 and 2%, a

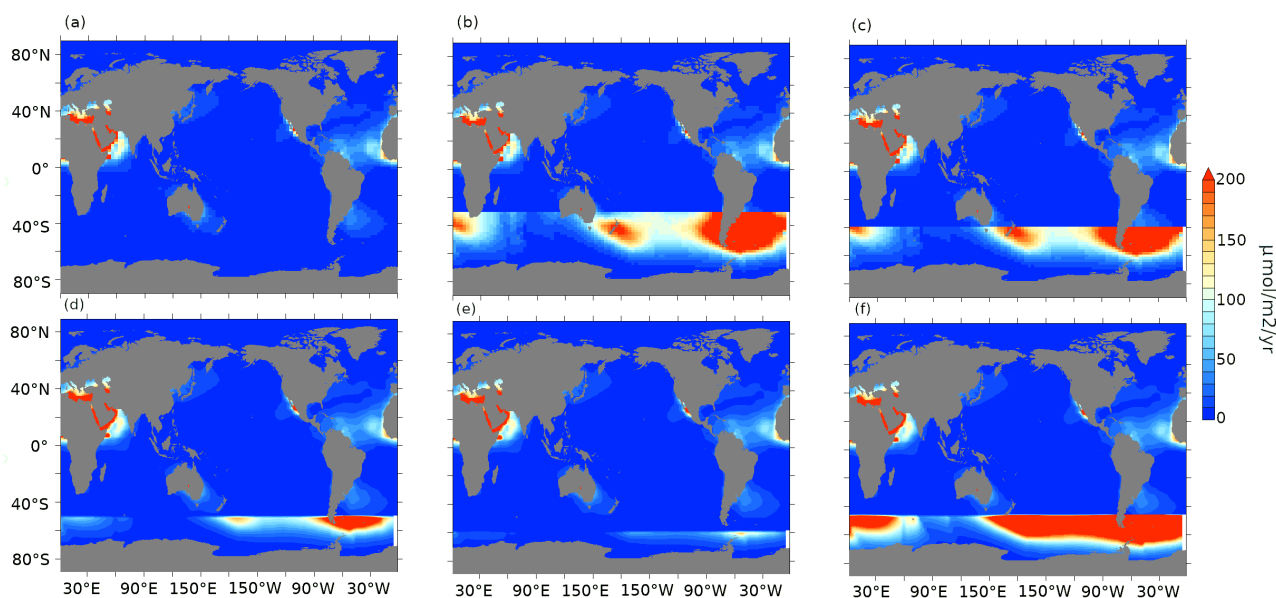

2-28 ppm drop in CO<sub>2</sub> was simulated by a range of models (Bopp et al., 2003; Tagliabue et al., 2009b; Lambert et al., 2015; Muglia et al., 2017; Yamamoto et al., 2019). Yamamoto et al. (2019) obtained a larger sensitivity than shown here, simulating a CO<sub>2</sub> reduction of 15.6 ppm and 20 ppm using iron solubility factors of 3% and 10% under LGM conditions, while a solubility of 7% with varying dust masks lead to a decrease in CO<sub>2</sub> by 12-29 ppm in Lambert et al. (2021). A 12 ppm decrease at 70 ka was simulated in a transient simulation performed with a model of intermediate complexity and using 1% solubility (Menviel et al., 2012). Clearly, better constraints on the sources of dust and its composition (Hamilton et al., 2021) are needed to better quantify past iron solubility in the Southern Ocean. Although our lowest estimate of a 4 ppm CO<sub>2</sub> reduction is in agreement with the studies mentioned above, the upper limit of 16 ppm is lower than some previous estimates (e.g. Yamamoto et al. (2019), Lambert et al. (2021)). This might be due to the comparatively larger simulated decrease in EP north of 47°S and in the equatorial Pacific in our study compared to previous ones (Yamamoto et al., 2019).

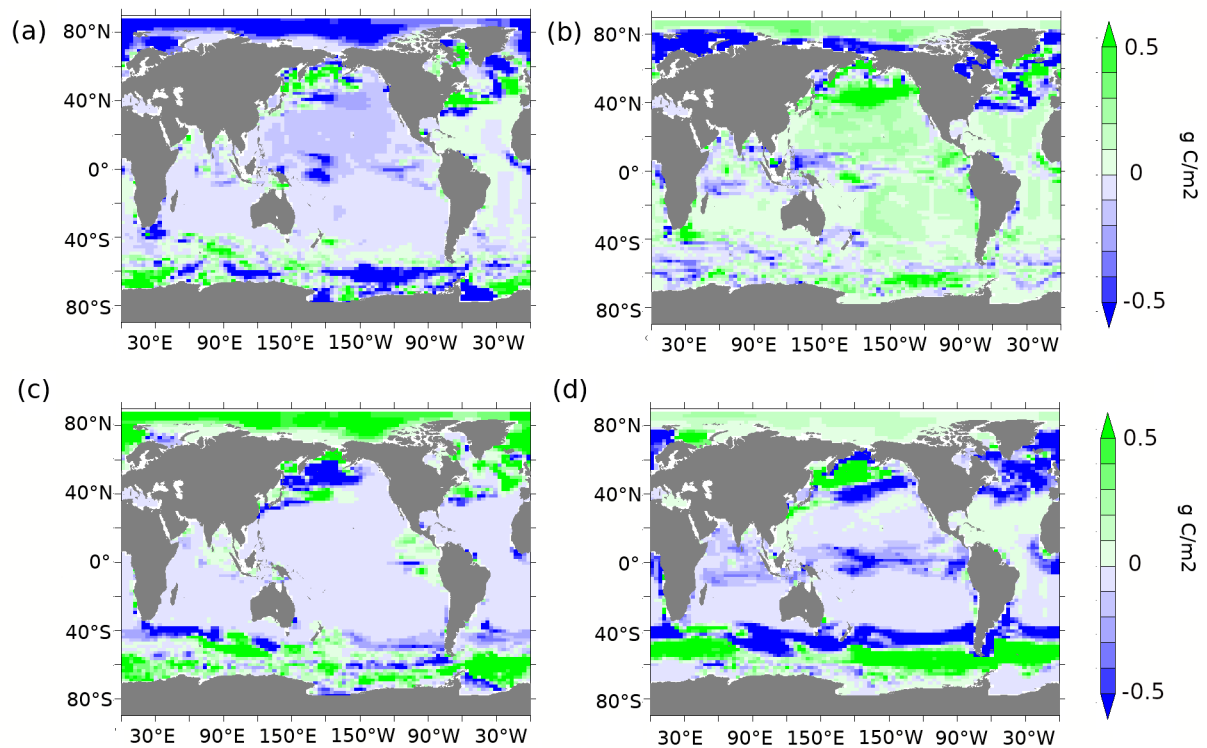

Our estimate of a 16 ppm CO<sub>2</sub> decrease with 10% iron solubility corresponds to half of the ~32 ppm CO<sub>2</sub> drop estimated for the MIS4 transition (Bereiter et al., 2015). This suggests that enhanced aeolian iron input at the MIS4 transition could have played a significant role in the CO<sub>2</sub> draw-down (Martínez-García et al., 2014; Kohfeld and Chase, 2017), but other processes must also have contributed to the CO<sub>2</sub> decline. For example, an AMOC weakening (Piotrowski et al., 2005; Wilson et al., 2015; O'Neill et al., 2021) could have enhanced ocean stratification, contributing 15-30 ppm to the CO<sub>2</sub> decrease during MIS4 (Thornalley et al., 2013; Yu et al., 2016; Menviel et al., 2017). An increase in ocean stratification at the MIS4 transition due to changes in AABW properties (Adkins, 2013) could also have increased the deep ocean carbon content (Menviel et al., 2017), thus contributing to the atmospheric CO<sub>2</sub> decline. Finally, both changes in oceanic circulation and a more efficient biological pump could have enhanced sediment calcite dissolution, thus increasing ocean alkalinity and enhancing the CO<sub>2</sub> draw-down (Boyle, 1988; Archer and Maier-Reimer, 1994; Yu et al., 2016; Kobayashi and Oka, 2018).

## 5 Conclusions

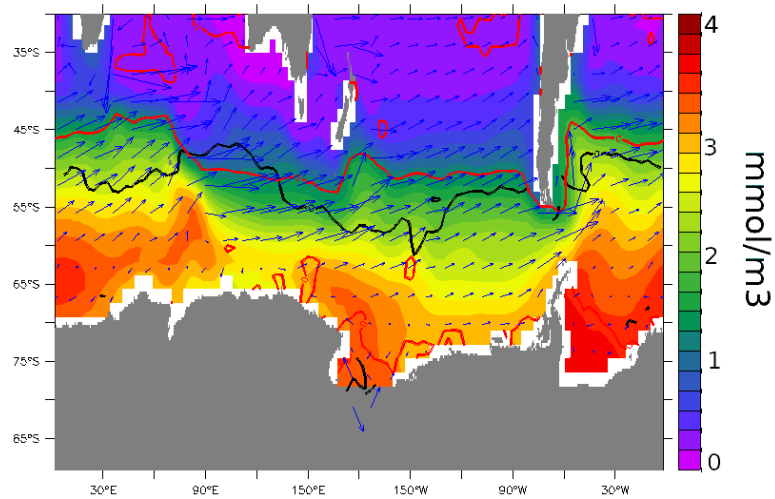

We use an Earth system model of intermediate complexity incorporating a newly developed ecosystem model to better constrain the oceanic carbon uptake due to enhanced aeolian iron fluxes at the MIS4 transition. Based on a series of 70 ka sensitivity experiments forced with two different aeolian iron flux masks and different iron solubility factors, we find that enhanced iron input south of 47°S could have led to a 4 to 16 ppm CO<sub>2</sub> decline at 70 ka BP, with a most likely range of 9 to 11 ppm. Our results suggest that the ocean's capacity to take up carbon decreases with increasing iron input because enhanced nutrient utilisation in the Antarctic zone is compensated by decreased nutrient availability at mid and low latitudes. Enhanced aeolian iron input at the MIS4 transition could thus explain up to 50% of the observed CO<sub>2</sub> drop at that time.
