7 **Abstract.** Contributing to the poor understanding of abrupt climate change is the lack of a known mechanism for a ~1470-yr
8 quasi-periodicity, leading to debates as to its existence. This oscillation is associated with the controversial Bond cycle, which
9 has been by some as stochastic resonance, and is a harmonic resonating with Heinrich, Dansgaard-Oeschger ice-rafting debris
10 events, as well as millennial-scale ENSO events in the Pacific. Suggestions of a solar link to the Bond cycle were made but
11 there is no known solar periodicity of this length. Here, statistically-significant results of a comparison between TSI
12 reconstructions based on Antarctic ¹⁰Be data and the modelled interaction of the solar and lunar cycles that produce a 1470-yr
13 cycle are presented. These results confirm the cycle's existence, its astronomical mechanism, and the major lunar role in the
14 timing of all these ice-rafting debris events. The associated data show that the occurrence of Bond events coincides with
15 maximum gravitational forcing and peak TSI, both associated with minimum Sun-Earth distance that are influenced by both
16 the perihelion and the Moon. These findings are consistent with previous suggestions by Bond and other researchers that
17 amplified gravitational and solar forcing may be involved. The results also indicate that the Moon's gravitation influences
18 patterns of cosmogenic isotopes at millennial time-scales.

19 **1 Introduction**

20 Although the mechanism of abrupt climate change is unknown, indicators exist, inferring that it may be astronomically-forced
21 (Bond et al., 2001, Braun et al., 2005, Rahmstorf, 2003). Understanding this mechanism is an important step in understanding
22 the physics of abrupt climate change. It has the capacity to inform our current understanding of Earth's cosmogenic nuclide
23 record, which is important for radiometric dating in various scientific fields. Given that climate-change modelling relies on
24 knowledge of the past to inform the future (Budyko, 1982), this astronomical mechanism is important because it influences
25 total solar irradiance (TSI) and cosmogenic nuclides upon which climate reconstruction depends. An understanding of natural
26 climate cycles is integral to understanding the nature and extent of anthropogenically-induced climate change and climate
27 sensitivity.

28
29 Here, the arguments for and against the controversial Bond cycle are presented, along with relevant background astronomical
30 and calendrical information, prior to presentation of modelling and results that reinforce the existence of an ~1470-yr quasi-
31 periodicity. Variations in Sun-Earth, Sun-Moon distances are key to producing variations in total solar irradiance (TSI), solar
32 insolation, and gravitational forcing that are associated with abrupt climate change at the millennial scale. Whilst various cycles
33 at different time scales are produced by this interaction, of particular interest is the ~209 Suess de Vries cycle (SdV) and a
34 hitherto unexplained 133-yr cycle. This astronomical mechanism also explains why tidal and solar records are synchronised in
35 the palaeoclimatic record (e.g., Bond et al., 1997) as the result of an external forcing mechanism. 'Teleconnections' between
36 hemispheric records, as mentioned by Turney et al. (2004), can also be explained by this same mechanism for the same reasons,
37 consistent with the Bipolar Seesaw theory (Broecker, 1998).

38 2 Background

39 A periodic or quasi-periodic characteristic in climate is suggestive of external forcing (Rahmstorf, 2003). The Milankovitch
40 precessional cycle is itself a quasi-periodicity that results in a constantly changing relationship between the seasons and
41 perihelion (Berger, 2009), the closest point in Earth's orbit to the Sun, over $\sim 21 \pm 2$ ky. The perihelion moves forward through
42 the year over a cycle of ~ 110 ky (Lowrie, 2007), whilst the equinox moves in retrograde motion through the year over ~ 26 ky
43 as the result of equinoctial precession. The Moon contributes two-thirds to the equinoctial precessional cycle and the Sun
44 contributes one third through gravitational forcing (Lowrie, 2007). Based on a premise that precession causes abrupt climate
45 change at higher temporal resolution than Milankovitch precession, the interaction of Earth's solar and lunar cycles was
46 examined.

47

48 Millennial-scale, cyclical ice-rafted debris (IRD) events in the North Atlantic are associated with abrupt climate change, which
49 is characterised by rapid warming then gradual cooling. These IRD events have been associated with the Dansgaard-Oeschger
50 and Bond "cycles". Dansgaard-Oeschger oscillations in atmospheric temperature are found in the Greenland ^{18}O ice-core
51 record of the glacial period, occurring at transitions from cold stadial to warm interstadial during the glacial period (Bond et
52 al., 1997, Dansgaard et al., 1993, Schulz, 2002, Wolff et al., 2010) The Bond cycle was defined as a weaker and shorter climate
53 signal permeating both the Holocene and glacial, with a mean periodicity of ~ 1470 yrs (Bond et al., 1999). Bond et al. (1999)
54 identified this quasi-periodic oscillation to which Dansgaard-Oeschger and Heinrich events appeared to be tuned, meaning that
55 the underlying Bond quasi-periodicity is a low amplitude signal that appears to be magnified at the times of Dansgaard-
56 Oeschger and Heinrich events.

57

58 Heinrich events are massive discharges of IRD into the North Atlantic that occur at occur on a 11 ± 1 ky periodicity (Bond et
59 al., 1999, Heinrich, 1988, Summerhayes, 2015) and are therefore linked to the Milankovitch precessional cycle. Both Heinrich
60 and Bond events showed clear associations with the modulation of the solar signal (Heinrich, 1988, Bond et al., 1999), the
61 former as a precessional signal. Statistically-significant coherence between cosmogenic nuclides and IRD events with inferred
62 solar frequencies of 500 yrs, 1 ky and 2 ky was established in relation to Bond events (Bond et al., 2001). However, the Bond
63 cycle is controversial and has been dismissed by some as stochastic resonance (Ditlevsen et al., 2007), although the debate is
64 clouded by a poor understanding of the physics of abrupt climate change (Ditlevsen and Ditlevsen, 2009, Banderas et al., 2015,
65 Turney, 2008). Whilst stochastic resonance is a possibility for explaining this quasi-periodicity, it is conceivable that a
66 combination of astronomical forcing factors could also produce this climate signal. Part of the problem in understanding the
67 Dansgaard-Oeschger cycle is that "detection of periodicity depends on the age scale used", the asymmetry of events, and small
68 sub-sampling of datasets (Wolff et al., 2010:2831). What has not been considered was a quasi-periodicity derived from multiple
69 contributing astronomical periodicities.

70

71 The cause of the ~ 1470 -yr pulse in ice-rafting debris (IRD) events in the North Atlantic is not known. Because no millennial-
72 scale solar periodicities were apparent, an ocean-atmosphere link through solar forcing was suggested via a combination of
73 periodicities (Bond et al., 2001, Braun et al., 2005, Schulz, 2002). Such suggestions were based on the coherence of the climate
74 signal with cosmogenic nuclides. Turney et al. (2004) also demonstrated the existence of a ~ 1490 -yr cycle in the tropical
75 Pacific that was cross-correlated with the Dansgaard-Oeschger signal in the GISP2 ice-core record, where warm phases in the
76 southern hemisphere were correlated with cold phases of Dansgaard-Oeschger events. Multiple records from around the world
77 show a quasi-periodicity of this length, indicating the signal is global, e.g., (Clement and Peterson, 2008, Darby et al., 2012,
78 van Buren, 2001).

79

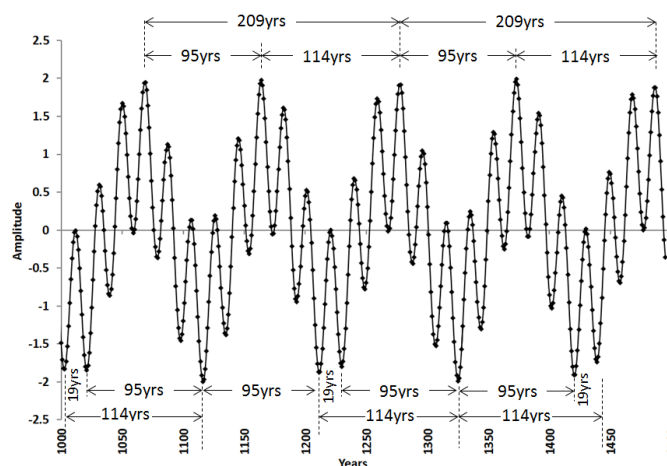

80 Rahmstorf (2003) investigated the origin and stability of millennial-scale abrupt climate change cycles and Dansgaard-
81 Oeschger events. Rather than being a cycle, he concluded that (i) this cycle was paced by an external, regular 1470-yr orbital
82 cycle such as orbital or solar forcing, and (ii) realistically, errors due to triggering and dating would contribute significantly to
83 total deviations, whilst clock errors are much smaller than estimates. Braun et al. (2005) modelled the superposition of the
84 ~210-yr SdV cycle and the 86.5-yr Gleissberg cycle to emulate a ~1470-yr cycle of freshwater forcing of the thermohaline
85 current in the North Atlantic. In Braun et al.'s (2005) model, frequencies were inferred solar frequencies but no astronomical
86 mechanism was provided.

87

88 However, the modelled superposition of Earth's solar and lunar cycles has the capacity to produce oscillations at different
89 temporal scales, including millennial and centennial scales. (Figure 1). Modelling by Kelsey et al. (2015:4915) showed that
90 the Gleissberg cycle could result from the interaction of solar and lunar cycles (Figure 1). The concept of a specific
91 astronomical mechanism behind the ~1470-yr quasi-periodicity was introduced and was seen as a high-frequency expression
92 of the Milankovitch precessional cycle. The perihelion and the Moon were identified as variables because of their causal roles
93 in precession. This model showed cyclical interaction of the perihelion with the Metonic lunation (~209 yrs). The proxy used
94 in this model for the perihelion, with a value of 103.77 yrs is simply a precise and accurate measurement of the anomalistic
95 year based on Earth's rotation-revolution relative to the perihelion [Figure S1]. As such, this proxy's occurrence at 207.54 yrs
96 in conjunction with the Metonic New Moon is indicative of increased gravitational forcing, as well as suggestive of a
97 relationship with the sunspot cycle.

98

99

100 **Figure 1: Suess de Vries and Gleissberg cycles. The modelled superposition of solar and lunar cycles reproduces the Suess de Vries**
101 **(SdV) (209 yrs) and Gleissberg cycles (95 yrs)). This model captures the interaction of Earth's perihelion with the 19-yr Metonic**
102 **lunation: a time of maximum gravitational forcing.**
103

104 Throughout Earth's climatic record, 133-yr and ~208-yr periodicities are pervasive. The 133-yr cycle is found in various
105 climatic datasets, such as tropical Atlantic cyclones and water levels (Cohen and Sweetser, 1975, Yousef, 2000); fire and
106 drought cycles (Biagioni et al., 2015, Vázquez et al., 2015, Xue et al., 2008); and Arctic and Antarctic ice core chronologies
107 (Yiou et al., 1997). The SdV cycle, is an inferred solar cycle from the cosmogenic nuclide record (Hathaway, 2010). Because
108 the SdV cycle does not appear in the sunspot record, the inference is drawn because the SdV is a multiple of the longest known
109 solar cycle (Schwabe): an ~11.4-yr cyclical variability in solar luminosity (Hathaway, 2010). In association with the sunspot
110 cycle, the Metonic lunation is also a mathematical factor in the SdV ($19 \times 11 = 209$). The Metonic cycle is a lunation that
111 occurs once every 19.0002 tropical years (O'Neil, 1975) and is used for synchronisation between solar and lunar calendars.

112 With a combination of periodicities theorised as producing the controversial Bond cycle and the existence of candidate
113 periodicities evidenced in palaeoclimatic data, research was undertaken to test an hypothesis of astronomical forcing
114 mechanism for the ~1470-yr cycle.

115 **2.1 Questioning the 1500-yr quasi-periodicity**

116 Whilst stochastic resonance is a possibility for explaining this quasi-periodicity, it is conceivable that a combination of
117 astronomical forcing factors could also produce this climate signal. What has not been considered was a quasi-periodicity
118 derived from multiple contributing periodicities. Part of the problem in understanding the Dansgaard-Oeschger cycle is that
119 “detection of periodicity depends on the age scale used”, the asymmetry of events, and small sub-sampling of datasets (Wolff
120 et al., 2010:2831). Additionally, uncertainty associated with various ice core models have been troublesome.

121
122 Alley et al. (2001) suggested that the ~1500-yr peaks in the ¹⁸O signatures from Greenland ice-cores could be potentially
123 explained by stochastic resonance within the climate system, triggered by random freshwater flux into the North Atlantic,
124 although stating that this did not constitute proof. Stochastic resonance produces a ripple effect through a system from a random
125 event, growing weaker with each periodic return. Alley et al. (2001) supported the existence of the quasi-periodicity and
126 believed that stochastic resonance model could be a contributor. They suggested that the stochastic resonance theory could be
127 tested later. In relation to the number and timing of Dansgaard-Oeschger events,

128
129 “asymmetry in Dansgaard-Oeschger oscillations causes the times of coolings to depend upon the threshold
130 to define a cooling, whereas times of warmings are less sensitive to the threshold chosen” (Alley et al., 2001:195).

131
132 Ditlevsen and Ditlevsen (2009) dismissed the ~1500-yr quasi-periodicity as random, noise-driven, and potentially stochastic
133 based on their redefinition of Dansgaard-Oeschger events. The redefinition process used by Ditlevsen et al. (2005) used
134 commonalities in the GRIP and NGRIP ice core records in an attempt to provide an objective definition (Ditlevsen et al., 2007,
135 Ditlevsen and Ditlevsen, 2009). Consequently, new events were classified and one declassified (DO9). In a later test using the
136 GISP2 record, the rejection of a strict periodicity could be achieved only by eliminating a Dansgaard-Oeschger event (DO9).
137 This DO9 event occurred at about 40 kya, which was at the edge of the period tested in these studies (11-42 kya) (Ditlevsen et
138 al., 2007). With DO9 removed, the 1470-yr cycle was then “indistinguishable” from a random event (Ditlevsen et al.,
139 2007:129). (Wolff et al., 2010) consider this matter to be unresolved.

140
141 A high band-pass filter was used to eliminate variations in the isotope record due to astronomical forcing at Milankovitch
142 scales (Ditlevsen et al., 2005, Ditlevsen et al., 2007). The low band-pass filter was selected on shared commonalities between
143 GRIP and NGRIP ice core records, which resulted in all signals of <30 yrs cyclicity being filtered out as background noise.
144 This process excluded signals generated by the Sun and Moon considered in this research. New thresholds in the isotope record
145 were also established to identify Dansgaard-Oeschger events: one high and one low. An upper threshold was established
146 through the use of stochastic resonance models that assume the signal is random and not externally forced (Ditlevsen et al.,
147 2005).

148
149 In their analysis of this quasi-periodicity from the filtered record, Ditlevsen et al. (2007) used three different model types
150 (exponential distribution, periodic, and stochastic resonance), with assumptions of randomness for the exponential model, and
151 a “perfect periodic signal” of 1470 yrs, for the periodic and stochastic resonance models. They then attempted to capture the
152 variability of the 1470±500-yr quasi-periodicity using a standard deviation of ±100 yrs. They concluded that the null hypothesis
153 of no periodicity could not be rejected, and that there was “no long-term memory in the climate system or unknown 1470-yr

154 periodic triggering of the climate shifts” (Ditlevsen et al., 2007:134). On one hand they state that statistical distribution of this
155 quasi-periodicity “implies” that the climate system has a simple no-memory process. Thereafter, this implication is specifically
156 stated as “fact” (Ditlevsen and Ditlevsen, 2009:446). Given the nature of the various ice-core records and chronologies, which
157 are complicated by chronometric uncertainties and disparities between various records, it is difficult to understand this
158 transition from implication to fact. These Ditlevsen models were not designed to deal with quasi-periodicities, using only
159 assumptions of randomness or perfect periodic beating.

160

161 Furthermore, the models used by Ditlevsen et al. (2007) have not considered the influence of some astronomical forcing factors
162 on the timing signals. An example of this is chronometric complications caused by precession, resulting from the inconstant
163 rate of the March equinox movement relative to the changing shape of Earth’s elliptical orbit. This factor must influence the
164 length of the periodicity, which is exacerbated when the time-series is sub-sampled. Precession influences both the timing and
165 strength of the climate signal due to the changing relationship between Earth’s seasonal year and changing orbital shape. When
166 considering astronomical cycles over very long periods, chronological precision is extremely important, especially because of
167 these precessional influences. Despite the use of a perfect periodicity in their exponential model, the “waiting time” between
168 Dansgaard-Oeschger events assumed by Ditlevsen et al. (2007) was 2800 yrs, which varies by 57.1 yrs to the definition
169 supplied. The stochastic resonance model is also flawed in this instance, resting on a “precise periodicity” and approximations
170 of “waiting time” (Ditlevsen et al., 2007).

171

172 Given the prerequisite of the precision assumed for dating Dansgaard-Oeschger events in their modelling experiment
173 (Ditlevsen et al., 2007), any arguments based on this premise are undermined by the cycle’s quasi-periodic nature and the fact
174 that “all palaeoecological and palaeoclimatological data come with a degree of uncertainty” (Blaauw, 2012:38). The
175 combination of periodicities suggested as the cause of the Bond and Dansgaard-Oeschger cycles (Bond et al., 1997) is unlikely
176 to result in a periodicity of a precise length, particularly if multiple factors are involved. Ditlevsen et al. (2005) acknowledged
177 a similar point, citing Paillard and Labeyriet (1994) as “only simplified models with few degrees of freedom exhibit strict
178 cyclic behaviour”. Clemens (2005) emphasises the importance of accurate chronologies, noticing that millennial-band
179 frequencies are sensitive to small changes in the modelled centennial-scale patterns on which they are based.

180

181 Other issues with the aforementioned Ditlevsen papers include the use of a monotonic function and assumptions about the
182 Gaussian form of dates based on strict periodicity (Ditlevsen et al., 2007). What has not been taken into account is the fact that
183 the radiocarbon calibration curve is not a monotonic function and the derived distribution of calendar dates for the data from
184 radiocarbon dating “is no longer Gaussian, nor is mathematically definable” (Bowman, 1990:46). For example, variations in
185 the radiocarbon curve caused by the 209-yr SdV cycle result in a radiocarbon date that can equate to more than one calendar
186 date (cf. Bowman, 1990). Calendar dates should be regarded as a range of equally likely dates, not as a central term with an
187 error margin (cf. Bowman, 1990, Dincauze, 2000).

188

189 To place the Ditlevsen dismissal of the 1500-yr quasi-periodicity as a real phenomenon in context, Alley et al. (2001:196) state
190 that “No finite data sequence ever uniquely defines the process that produced it.” This is in keeping with the notions that the
191 use of empirically-derived models risk arguments of circularity being levelled against them (cf. Henshilwood and Marean,
192 2003, Popper, 1972). The testing and development of such models require a good understanding of the data in order to
193 compensate for problems associated with the use of statistics on non-linear and non-stationary geographic data, the nature of
194 which violates statistical assumptions (Longley, 2011, Mitchell, 1999, Schulz, 2002). If the cause of the quasi-periodicity is
195 not known or understood, this makes the job even more difficult. This is a problem acknowledged by Ditlevsen and Ditlevsen

196 (2009:446): “Dansgaard-Oeschger (DO) events of rapid climate shifts in the glacial climate observed in the Greenland ice
197 cores are still not well understood.”
198
199 Referencing Ditlevsen et al. (2007) and Clemens (2005), Obrochta et al. (2012:25) dismiss the 1470-yr quasi-periodicity stating
200 that the signal is “absent from other Greenland ice cores”. The Ditlevsen arguments have already been discussed. In contrast
201 to these claims that the 1470-yr cycle is absent from Greenland ice cores, Clemens (2005) reports (i) a bifurcation of the signal
202 into 1163-yr and 1613-yr peaks in the GRIP spectrum, and (ii) spectral peaks in GISP2 (tuned to the Hulu Cave record) of
203 1190, 1490, and 1667 years. Additionally, Clemens (2005) historical perspective of this cycle highlighted that it was evident
204 throughout the last 100 ky years in the GRIP SS09 model, and strong in the 20-40ky period in GISP2. These two chronologies
205 agree well where layers are counted, but differ significantly between 40-80 kya when “age models are based on independent
206 glaciological flow models” (Clemens, 2005:522).
207
208 Whereas the GISP2 chronology is layer counted to ~51 kya (Rahmstorf, 2003), based on visual stratigraphic layers, and
209 sometimes refined using laser scattering, oxygen isotope chronology, and electrical conductivity (Meese et al., 1997); GICC05
210 is based on NGRIP records between 10-42 kya, the SS09SEA model beyond 60 kya (after reducing the SS09SEA scale by 705
211 yrs at 60 kya) and annual layer counting (42-60 kya) (Svensson et al., 2006, Wolff et al., 2010). The NGRIP chronology is
212 based on the GRIP SS09SEA model (Svensson et al., 2006), which is an ice-flow model that factors in the $^{18}\text{O}:^{16}\text{O}$ relationship
213 (Svensson et al., 2008), and with which the GICC05 model agrees well (Wolff et al., 2010); this is not surprising given that
214 GICC05 is based on both models. However, whilst the 1470-yr quasi-periodicity is evident in a number of Greenland ice cores
215 over the past 120 ky (Rahmstorf, 2003), the GICC05 modelling alters the patterns of the Dansgaard-Oeschger cycle between
216 its tie-points (Ditlevsen et al., 2007). Whilst the 1470-yr cycles are best developed in MIS3 using the GISP2 Meese/Sowers
217 model (Bond et al., 1999), Obrochta et al. (2012) found that they were best developed during MIS4, which is based on the
218 SS09SEA glaciological model.
219
220 Apart from the aforementioned arguments raised by Obrochta et al. (2012) to dismiss the existence of a 1500-yr cycle, they
221 frequently reinforced their argument with the point that no solar cycle of that length exists. However, Bond et al. (2001) found
222 coherency of IRD events in various North Atlantic deep-sea cores with cosmogenic nuclide production, specifically ^{10}Be and
223 ^{14}C , and matched these events to other records from around the world during the Holocene, including (i) ^{18}O fluctuations in a
224 well-dated-stalagmite core from Oman, (ii) advances of Scandinavian glaciers linked to dendrochronological ^{14}C variations,
225 (iii) and evidence of abrupt climate change from other sources of atmospheric, lacustrine, and oceanic variations. Obrochta et
226 al. (2012) argued that the coherency was not at 1500 yrs, but at 500, 1000, and 2000 yrs, ignoring Clemens (2005) finding of
227 spectral peaks in GRIP and GISP records close to the 1500-yr mark and within the variability of this quasi-periodicity.
228
229 These conclusions by Obrochta et al. (2012) were based on a reinterpretation of the last 70ky North Atlantic record, using only
230 one of numerous deep-sea cores (Site 609) previously used by Bond et al. (1999, 2001). Previously, VM23-81 and Site 609
231 were extended by Bond further back in the glacial (beyond 26 kya) by transferring the GISP2 timescale to the foraminiferal
232 record in these cores using tie points, and interpolating between these records. Bond also used radiocarbon ages from VM23-
233 81 to construct a calendar age model for core SU90-24 that also enabled it to be extended further back into the glacial. In
234 contrast, Obrochta et al. (2012) updated the existing chronology on Site 609, using the latest marine calibration, extended it
235 back to 31 kya BP using additional radiocarbon dates, and superimposed NGRIP’s GICC05 model further back in time. Whilst
236 Obrochta et al. (2012) imply that the whole of the GISP2 core is inferior to the NGRIP core due to thinning, this is not
237 accurately reported (cf. Svensson et al., 2006). There is generally a good match between GICC05 and GISP2 until 40kya
238 (Svensson et al., 2007), with layer thinning occurring during the early MIS3 in the GISP2 ice core (Svensson et al., 2006). Ice

239 layers are thin or absent during extreme cold (Svensson et al., 2006), which is also problematic for GICC05 (along with
240 resolution) during the glacial (Andersen et al., 2006).

241

242 Obrochta et al.'s (2012) conclusions fall short of effectively dismissing the 1500-yr quasi-periodicity. Firstly, their citation of
243 Clemens (2005) and Braun et al. (2005) was selective, and potential modification of solar forcing using heterodynes (Clemens,
244 2005) or combination tones (Braun *et al.*, 2005) was effectively overlooked in their conclusion. This oversight occurred despite
245 a statistically significant coherence between cosmogenic nuclide evidence with centennial- and millennial-scale IRD events
246 (Bond et al., 2001). Furthermore, their mathematical averaging argument that the 1500-yr cycle results from “1000 and 2000-
247 year forcing, similar to variability of inferred solar proxies” (Obrochta et al., 2012:32) provides no real solution as no known
248 solar cycle exists at either 1000-yr or 2000-yr intervals, and the longest known solar cycle is ~11.4 mean years (Hathaway,
249 2010). The question still remains as to the cause of the apparent millennial-scale variability of proxies for solar variability (*viz.*,
250 cosmogenic nuclides) and associated climate cycles. Finally, non-existence is not scientifically provable (cf. Popper, 1972).

251 3 Methods

252 Astronomical data were developed and graphed during exploratory data analysis, which mainly uses graphical techniques, to
253 gain insights into the interactive behaviour of the Sun, Moon and Earth. Additionally, a trigonometric model of the
254 superpositioned 133-yr and 207.5-yr cycles was implemented and adjusted for precession and sunspot activity. The 207.5-yr
255 cycle is associated with the anomalistic year and closely aligned to a 209-yr cycle associated with the Metonic lunation. These
256 models were compared to TSI reconstruction based on Antarctic ¹⁰Be data (Bard et al., 2007).

257 3.1 Astronomical data

258 Astronomical data for the last 5500 yrs was generated using planetarium software. Data were collected at 19-yr intervals,
259 starting with the last Metonic lunation that occurred on the same day as Earth was at perihelion (4 January 2011). In this way,
260 the Moon serves as a proxy for the tropical year, and its movement can then be measured relative to the perihelion, to which
261 the anomalistic year is referenced. The point of osculation between the interacting variables is based on the Metonic lunation
262 at perihelion, which was a solar eclipse, when the Sun is at solar zenith. This point represents maximum annual gravitational
263 influences and solar irradiance, relative to any given starting longitude on Earth. It also provides a consistent baseline of
264 measurement of TSI, solar insolation, distance and gravitation throughout time, simultaneously chronologically anchoring it
265 to multiple methods of measuring time. Data recorded included solar and lunar declinations and longitudes, right ascension,
266 lunar nodal positions, and the obliquity of the ecliptic. Declinations are measured relative to the celestial equator and longitudes
267 relative to the ecliptic. These data were recorded using Gregorian dates and Universal Time. Earth-Sun and Earth-Moon
268 distances, and lunation type were also recorded as were variances of solar and lunar declinations. NOVA provides data back
269 to ~1221 BC while SkyChart III provides the earlier results.

270 3.2 Ice core data

271 The data used for comparison to the model are TSI reconstructions based on Antarctic ice-core data from the South Pole of
272 smoothed ¹⁰Be record detailed in Bard et al. (2003-2007, Bard et al., 2007), as well as a superseded reconstruction by Yang et
273 al. (2000). These data span ~1200 yrs from 843 CE. The Bard TSI reconstruction used a 12-box numerical model to convert
274 ¹⁰Be signals in ice-cores to a synthetic radiocarbon record (Bard et al., 2007). This reconstruction of TSI was found to strongly
275 correlate with the dendrochronologically-calibrated radiocarbon record ($r=0.81$), also showing no significant lag between the
276 ¹⁰Be and radiocarbon records.

277 3.3 Model – trigonometric

278 The superpositioning of the 133-yr and 207.5-yr periodicities was modelled, using the formula:

$$f(t) = \sin((2\pi t) \cdot 133^{-1}) + \sin((2\pi t) \cdot P^{-1}) \quad (1)$$

279 where t =time elapsed (in years) since the start of the cycle and $P=207.54$ yrs as a measure of the anomalistic year. This model
280 captures the 133-yr cycle found in the astronomical data of fluctuations of Earth-Sun and Earth-Moon distance. The amplitude
281 of each contributing signal is assumed to be the same as both astronomical cycles are associated with variations in solar
282 irradiance based on changes in Earth-Sun distance. For $S = 1365 \text{ W/m}^2$ where S (mean solar irradiance), which is the value
283 used by Bard et al.(2003-2007), the result for each value in the above equation was added to this mean TSI value in the
284 normalisation process, such that:

$$f(t) = (\sin((2\pi t) \cdot 133^{-1}) + \sin((2\pi t) \cdot P^{-1})) + S \text{ (W/m}^2\text{)} \quad (2)$$

285
286 These models were chronologically-anchored at the concurrence of the Metonic lunation and the December solstice in 1183
287 BCE: a time of maximum gravitational forcing during a total solar eclipse [Figure S2] and the start of a new phase. The model
288 of the superimposed sinusoids was further normalised (feature-scaled) to the data being tested, e.g., where 1 unit of the model's
289 amplitude equals 0.7 W/m^2 (cf. Vieira et al., 2012). The value assigned to the amplitude during the normalisation process is
290 an estimate to cater for a number of factors, including annual variation in TSI during the year, such as orbital eccentricity
291 ($\pm 0.81 \text{ W/m}^2$) (Vieira et al., 2012); see also Tables S1 to S4. The model was then compared to Bard et al.'s (2007) TSI
292 reconstruction based on smoothed ^{10}Be record measured at South Pole. Statistical tests were performed (Pearson's χ^2
293 goodness-of-fit; regression analysis).

294 3.4 Justification of TSI values used in model

295 The variation in TSI is not constant through time (cf. Feulner, 2011, Vieira et al., 2012). TSI varies due to changes in Earth-
296 Sun distance and sunspot activity, and is dependent upon time of year, and strength of and temporal position within the sunspot
297 cycle. Over long stretches of time, TSI levels in any particular season will vary due to precessional drift. Additionally,
298 reconstruction of TSI values prior to recorded observations are reliant on modelling and proxy data, such as cosmogenic
299 isotopes (Feulner, 2011, Vieira et al., 2012). One study identifies a difference of $0.2\text{-}0.7 \text{ W/m}^2$ at the time of solar minima
300 between the Maunder Minimum and 2008/2009 (Feulner, 2011). During the 3 previous solar cycles to 2012, TSI varied by
301 0.12% . Although the value for differences between sunspot minima and maxima is still debated, there is currently a consensus
302 that this value is $\sim 0.12\%$ (0.001) of total insolation, equivalent to $\sim 1.6 \text{ W/m}^2$ (Friis-Christensen and Lassen, 1991, Kopp and
303 Lean, 2011, Vieira et al., 2011, Weng, 2005).

304 3.4.1 Adjustments for sunspot maxima and minima

305 For the model, TSI was increased by 0.12% during the Medieval Warm Period (high sunspot activity and auroral sightings)
306 and for relatively high sunspot activity during modern times (cf. Hathaway, 2010, Kopp and Lean, 2011, Vieira et al., 2011).
307 TSI was decreased by 0.05% and 0.1% respectively during the Maunder and Spörer Minima based on an estimated 0.7
308 W/m^2 difference between the 2008 solar minimum and the Maunder Minimum (cf. Feulner, 2011).

309 3.5 Background to chronological measurement

310 Adjustments for precession are dependent upon how time is measured so some background is important in understanding the
311 adjustments made for precession (see below). The tropical, anomalistic, and sidereal years are all based on measurements of
312 Earth's rotation relative to different starting points, which respectively are the March equinox, the perihelion, and the fixed
313 star framework. Calendars vary in their attempt to measure the seasonal or tropical year, with the relevant ones to this
314 discussion being the Julian and Gregorian calendars. Earth's tropical (seasonal year) moves slowly backwards through the

315 calendar year, with the size of the differences due to the ability of the calendar year to adapt. The perihelion moves forward
 316 through the tropical year.

317 Based on Earth's rotation [Tables 1 & 2], Figure 2 is a schematic showing the relationship of
 318 the different year types relative to the others through a cycle of 2922 yrs. It can be seen that
 319 the Gregorian calendar (G) closely mimics the tropical year (T) movement, whereas both the
 320 Julian (J) and Anomalistic (A) years are in apparent opposite motion to the tropical and
 321 Gregorian years. Thus $AG = AT - GT$; this relationship is numerically expressed in Table 2,
 322 where as part of a cycle: $0.017136^\circ = 0.0174369^\circ - 0.0003009^\circ$. Table 1 shows that the lengths
 323 of the various year types in days, and the residual of a day based on the overshoot of the
 324 rotation to the starting longitude in both days and hours. Table 2 shows the separation rates
 325 between the different year/calendar types in minutes based on values in Table 1, and also as
 326 parts of a day and hour and are based on the values in Table 1.

327 **Figure 2: Schematic of movement of different year/calendar types. The starting point is 0° of a cycle; A= anomalistic year; J=Julian**
 328 **year; G=Gregorian year; T= tropical year. The direction of Earth's rotation (west to east) is indicated by arrow R. Thus, tropical**
 329 **year is the shortest and anomalistic year is the longest, Schematic is an exaggeration of the actual movement although the proportions**
 330 **between the different year lengths is preserved.**

331 **Table 1: Different year lengths measured in days and associated surplus of Earth's rotation (day, hrs).**

Year	Days	Day	Hrs
Anomalistic	365.2596	0.259636	6.231264
Sidereal	365.2564	0.25636	6.152641
Tropical	365.2422	0.242199	5.812778
Julian	365.25	0.25	6
Gregorian	365.2425	0.2425	5.82
Mean anomal/tropical	365.2059	0.205918	6.022021
Egyptian calendar	365	0	0

332

333

334 **Table 2: Relationships between year/calendar types, rotation values, and associated cycles. These rates are shown as portions of a**
 335 **day, hour, and in minutes. The orbital scale cycle is based on the number of number of years in geographical return, which equals**
 336 **1° of orbital cycle. The period produced based on the 1461-day Olympiad is calculated from the percentage of a rotation cycle (i.e.,**
 337 **$(1+0.0174369) \times 1461=1486.48$).**

Yr type relationship	day (dec.)	Annual residual			Harmonic return (yrs)	Orbital scale cycle (yrs)	Length of cycle Julian (days, yrs)
		% day	Hrs p.a. (dec)	Deg. Long.			
Anomalistic-tropical	0.0174	1.74369%	0.4185	6.28	57.35	20,645.87	1486.48
Sidereal-tropical	0.0142	1.41609%	0.3399	5.10	70.62	25,422.04	1481.69
Julian-tropical	0.0078	0.78009%	0.1872	2.81	128.19	46,148.52	1472.40
Julian-sidereal	0.0064	0.63600%	0.1526	2.29	157.23	56,603.42	1470.29
Julian-anomalistic	0.0096	0.96360%	0.2313	3.47	103.78	37,359.90	1475.08
Anomalistic-sidereal	0.0033	0.32760%	0.0786	1.18	305.25	109,891.45	1465.79
Gregorian-tropical	0.0003	0.03009%	0.0072	0.11	3323.36	1,196,410.77	1461.44
Gregorian-sidereal	0.0139	1.38600%	0.3326	4.99	72.15	25,973.95	1481.25
Gregorian-anomalistic	0.0171	1.71360%	0.4113	6.17	58.36	21,008.40	1486.04
Gregorian-Julian	0.0075	0.75000%	0.1800	2.70	133.33	48,000.00	1471.96

338

339 As the Earth rotates at 15°/hr, the number of degrees of separation per annum (geographic longitude) between each of the year
 340 relationship types can be calculated [Table 2] and expressed as a proportion of any rotation cycle of 360°. For example, the
 341 Gregorian and anomalistic year separate at a rate of 1.71% per annum; this rate is evidenced in the astronomical data developed

342 for this project, which gives the equation of the perihelion movement through the Gregorian calendar of $y=0.0171x + 247.53$,
343 where x is measured in years and y is longitude [Figure 3]. As can be seen [Table 2], the geographical return for the Gregorian-
344 anomalistic year occurs after 58.36 yrs. This value is very close to the actual values of the anomalistic and tropical year
345 separation (57.35 yrs) as the Gregorian calendar closely mimics the natural cycle. As the tropical and anomalistic year
346 separation produces the Milankovitch precessional cycle, over ~ 57.35 yrs the precessional separation is 1° producing a cycle
347 of $\sim 20,646$ yrs ($\sim 21,008$ yrs Gregorian) [Table 2]. Similarly, the Gregorian-tropical relationship produces a cycle of ~ 3.3 ky,
348 which is the point at which the Gregorian calendar requires a further adjustment to realign with the tropical year.
349

350 **Figure 3: Longitudes of perihelion and Metonic lunation through time. This graph shows the relationship of the Metonic lunation**
351 **and perihelion to the tropical year, derived from astronomical data. Negative values on the x-axis are BCE. Date of perihelion-**
352 **December solstice conjunction at (270°) from this graph is 1308CE. The trend line equations are: $y = 0.0171x + 247.53$ (perihelion)**
353 **and $y = 0.0041x + 275.89$ (Metonic lunation).**

354 Whilst the Julian calendar is not equipped to keep pace with the tropical (seasonal) year the Gregorian calendar is well-adapted.
355 Whilst the difference between the Gregorian, tropical, and Julian years may not seem much, over large expanses of time this
356 error is cumulative. Clemens (2005) emphasises the importance of accurate chronologies, noting that millennial-band
357 frequencies are sensitive to small changes in the modelled centennial-scale patterns on which they are based.
358

359
360 Astronomical and climate data over long timespans and into the deep past are respectively recorded as Julian years, or uncal
361 BP or b2k (the latter of which are essentially Julian in nature). This is one of the reasons that these dates need to be calibrated
362 such as through absolutely dated tie-points or dendrochronology, the latter of which is a measurement of the seasonal year.
363 These chronometric systems, without calibration, do not account for either equinoctial or apsidal precession. Whilst the Julian
364 and tropical year Olympiads both contain ~ 1461 days (tropical 1460.969 days), the tropical year-Julian calendar produces an
365 ~ 1472 -yr cycle [Table 2], effectively stretching the length of the cycle by ~ 11 yrs. Other Julian relationships are in this vicinity.
366

367 This stretching of the cycle is achieved in the same manner as the difference between the sidereal and solar days, where the
368 Earth has to rotate 4 minutes further to catch up to the solar position, (cf. O'Neil, 1975) whose apparent location has changed
369 due to Earth's movement along its orbital path. The relationship can be seen in Table 3, which shows that 1 day = $1^\circ = 1$ yr.
370 Table 3 shows that after 1461 yrs the vernal point of the spring equinox occurs approximately 11.4 days earlier (as 353 days
371 is ~ 11.4 days short of a full tropical year). This relationship is further confirmed at the annual scale where the cyclical

relationships of cycles embedded in cycles (hours, days, years) for the Gregorian-anomalistic year (0.0171) [Table 2] is the same as the annual rate expressed in Figure 3 for the movement of the perihelion through the Gregorian year.

374

Table 3: Lunar relationship with IRD events and relationship between days, years, and degrees. The difference between a full Earth rotation and the tropical year is 0.24 days, which is a surplus of a full cycle. After an Olympiad (4 yrs), which is the basis of calendar corrections, nearly an extra day has accumulated, which is also equal to about 1° ecliptical longitude. Values of particular interest have been bold-faced for easy comparison. There is a cyclical interaction between the New Moon and any given starting point in the tropical year.

Yrs	Earth Rotation (°) Surplus	Cycle (°)	No. of cycles	Hrs accum	Additional time (days)	Added time (length of cycle) (Dec.)	Vernal point position relative to starting position	Diff between residual and full (days)	Lunation cycle
1	87.19	0.2422	0.00	5.81	0.2422	0.0007	0		
4	348.77	0.9688	0.00	23.25	0.9688	0.0027 days	0

380

3.6 Adjustments for precession

The intention of this exercise is to measure the movement of the perihelion relative to the tropical year, thereby capturing maximum solar forcing relative to the tropical year. However, because the Milankovitch precessional cycle results from the movement of the perihelion through the tropical year and because the astronomical data are recorded in Gregorian dates, the separation rates between the tropical and anomalistic years and Gregorian dates are highly relevant to any adjustment made to the models for precession. Adjustments to the models were therefore made for the precessional separation between the tropical and anomalistic years relative to the Gregorian calendar.

388

The data already accounts for the movement of the Gregorian-anomalistic year relationship, so an adjustment needs to be made for the differences between the tropical and Gregorian years [see Table 2]. Whilst the Bard et al. data and reconstruction begin at 843 CE, the model presented here is chronologically-anchored at 1183 BCE and must be brought into phase with the Bard data by adjusting for apsidal precession (of the perihelion), where 1183 BCE is cycle year 0. This time adjustment of the cycle number for precession, t_p , is made by adjusting time elapsed (t) in Equation 2 such that:

394

$$t_p = 1.0003009t \quad (3)$$

3.7 Statistical tests

Statistical tests were used to compare the model of superimposed astronomical cycles and the TSI reconstructions of ^{10}Be data (Bard et al., 2003-2007). Non-stationary and non-linear data violates fundamental assumptions of inferential statistics, such as those of independence (autocorrelation) and distribution and therefore presents problems for statistical analysis. However, non-parametric tests, such as the Pearson's X^2 goodness-of-fit test, are suitable for analysing non-linear and non-stationary data such as astronomical cycles and geographic data. The X^2 test, is a test against the null hypothesis of observed versus expected or predicted values, which is one of no difference. Initially, the critical X^2 value (X^2_c) is determined using an identified α value (probability) and the degrees of freedom (df). The generally accepted α value is 5% or $\alpha=0.05$, which was used here.

403 If the X^2 statistic is greater than the X^2_c , then the null hypothesis of “no difference” between the expected and observed values
404 is rejected. If the X^2 statistic is less than the X^2_c , the null hypothesis is accepted.

405

406 Despite the violations of statistical assumptions in analysing non-stationary and non-linear data, compensations can be made
407 if the nature of the data is understood (Schulz, 2002). In testing superimposed sinusoids of astronomically forced cycles against
408 sea-surface temperature data (both of which are non-linear and non-stationary), Imbrie (1985) calculated the Pearson’s
409 correlation coefficient (r) to test the strength of the relationship between a model of superimposed sinusoids and the data. In
410 the following tests upon the predictive model of superimposed sinusoids of astronomical cycles and the TSI reconstructions
411 of ^{10}Be data, X^2 and r values were calculated at each stage of the model development. As with Imbrie (1985), the data and
412 model were assumed to be stationary and independent, *contra* to the intrinsic nature of the data.

413 4 Results

414 4.1 Astronomical data

415 Earth-Sun and Earth-Moon distances revealed patterns of 133-yr cyclicality [Figure S3] that is also found in solar declination
416 data (Kelsey et al., 2015) [Figures S4, S5], which is influenced by the lunar orbit as it moves between extreme southern and
417 northern declinations. Declinations are the positions of celestial bodies measured relative to the celestial equator. The vertical
418 alignment of lunar orbital plane also straightens a little each synodic month as it “faces the Sun” (Gutzwiller, 1998). The lunar
419 gravitational influence on the Earth’s axis explains the 133-yr cycle found in solar declinations. Earth-Sun distances [Figure
420 S3] show a 133-yr cycle that flattens out as the perihelion and December solstice reach a conjunction around 1308 CE, attaining
421 a minimum distance as the perihelion and Metonic lunation form a conjunction in 2163 CE [Figures S3, S6]. Also evident in
422 Earth-Moon distances is a clear millennial-scale quasi-periodicity based on relative lunar perigee [Figure 4], when distance is
423 minimal and gravitational forcing maximal. These instances of lunar perigee occur close to Bond events (300–400, 1400, 2800,
424 4200 yrs ago) (cf. Bond et al., 1997).

425

426 **Figure 4: Earth-Moon distances based on Metonic data. A basic oscillation of 133 yrs can be seen. Millennial-scale quasi-periodicities**
427 **can also be seen and are most pronounced at perigee. B marks the occurrence of a Bond IRD event at a time of reduced Sun-Earth**
428 **distance.**

429 These 133-yr cyclical patterns can be attributed to the dance between the Earth and Moon on their orbital paths. This figure
430 shows that at each New Moon, the Earth is periodically closer to the Sun than at Full Moon. As the Moon journeys around the
431 Earth, and the Earth around the Sun, their paths create sinusoidal patterns around their common barycentre. Naturally, when
432 the New Moon occurs close to perihelion the gravitational forces are stronger and distances smaller. The physical data show
433 that during the 133-yr cycle, minimum distances between Earth and Moon correspond with minimum distances between Earth
434 and Sun; they also share the timing of maximum distances. These distances influence both gravitational force and solar
435 irradiance levels.

436 4.2 Modelling and statistical testing

438 **Figure 5: The chronologically-anchored, normalised model adjusted for both sunspot minima and maxima and precession compared**
439 **to TSI reconstructions. Each of the TSI reconstructions is shown as indicated in the legend. TSI_1 is the original Bard reconstruction**
440 **(Bard et al., 2007), uncorrected for geomagnetic modulation; TSI_2 is corrected for geomagnetic modulation, with agreement**
441 **between Bard et al., Korte and Constable (2005), and Gubbins et al. (2006); TSI_3 is corrected for geomagnetic modulation based**
442 **on the superseded record of Yang et al. (2000). The black solid line is the model.**

443
444 The model of the superimposed 133-yr and 207.5-yr periodicities produced a cycle of 1470 tropical years (1459 Julian years)
445 [Figures 5, S7]. The model bears a strong visual resemblance to the TSI reconstructions based on Antarctic ¹⁰Be; X² and
446 regression analysis serve to statistically quantify this relationship. The normalised, chronologically-anchored model, adjusted
447 for both precession and sunspot activity, shows a strong positive correlation [Figure S8] compared to the TSI reconstructions
448 from Antarctic ice core data (Bard et al., 2007). The results of the statistical tests are shown in Table 4. The X² results between
449 each of the reconstructions (TSI_1, TSI_2, TSI_3) were the same at X²=0.04 well below the critical value (X²_c = 168.61,
450 df=140 and α=0.05). Therefore, the null hypothesis of no difference between the model and each of the reconstructions cannot
451 be rejected. There is no difference between the model and the TSI reconstructions.

452

453

454

455 **Table 4: Statistical results of X^2 , r values. Variance (r^2), and significance (p) for precession and sunspot-adjusted**
 456 **model.**

Stat test/period	TSI 1			TSI 2			TSI 3		
X^2	0.04			0.04			0.05		
Correlation/variance/significance	r	r^2	p	r	r^2	p	r	r^2	p
(entire period)	0.88	0.78	0.00	0.88	0.78	0.00	0.86	0.74	0.00
843CE-1481CE	0.88	0.78	0.00	0.89	0.80	0.00	0.92	0.84	0.00
1481CE-1829CE	0.87	0.76	0.00	0.86	0.75	0.00	0.86	0.73	0.00
1829CE-1961CE	0.85	0.72	0.00	0.85	0.72	0.00	0.86	0.74	0.00

457

458 For the full range of the model, TSI_1, TSI_2, and TSI_3 scored similarly for correlation ($r=0.88$ and $r=0.86$). These r values
 459 show a strong positive correlation similar to the best results achieved by the TSI reconstructions detailed in Bard et al. (Bard
 460 et al., 2007) compared to the dendrochronologically calibrated radiocarbon record ($r=0.81$). All results are statistically
 461 significant ($p<0.05$). This result indicates that $\sim 78\%$ of the variation in TSI can be explained through the interaction of the
 462 superpositioning of the 133-yr and 207.5 year solar and lunar cycles.

463 5 Discussion

464 A 1470-yr cycle was produced by the interaction of the 133-yr cycle of reduced Earth-Sun and Earth-Moon distances with the
 465 perihelion (207.5-yr), which is closely aligned to the sunspot cycle, Metonic lunation, and SdV cycle. Modelling of the 133-
 466 yr cycle interaction with the lunar-linked 209-yr cycle similarly produced a 1474-yr cycle (1463 Julian years) [Figure S9].
 467 Statistical results from the superpositioning of the 133-yr and 207.5-yr cycles confirm the involvement of solar forcing at
 468 ~ 1470 yrs, and also identify lunar forcing as a contributor through its effects on Earth-Sun and Earth-Moon distances.

469

470 Whilst sunspots and the solar wind modulate cosmic ray flux, evidenced in Earth's cosmogenic nuclide record, it is now
 471 evident lunar gravitational forcing also shapes patterns of cosmogenic nuclides in the climate record at the millennial scale.
 472 Such results are important to radiochronology as the amplitude and shape of the climate signal are influenced by chronological
 473 models. For example, the Cariaco core (ODP1002) had an estimated calendar chronology based on correlation of visually-
 474 identified stratigraphy with GISP2 ^{18}O record (Chiu et al., 2007). The application of various other Greenland ice-core
 475 chronologies to this core altered the trends and amplitudes of the ^{14}C record.

476

477 For the SdV cycle (~ 208 yrs) that is found in the radiocarbon record, there is an inferred association with the perihelion
 478 movement (207.5 yrs), Metonic lunation cycle (209 yrs), and sunspot cycle (~ 206 yrs). A 209-yr cycle is also found in lunar
 479 declination data (Kelsey et al., 2015), which forms a sinusoidal pattern, consisting of four phases of 209 to 228 yrs [Figure
 480 S10], with a cycle of 893-912 yrs. All these factors are influenced by distance relationships, consequently impacting on both
 481 gravitation and TSI. Just as Earth's solar declination is affected by gravitation, so too is lunar declination. The 228-yr harmonic
 482 was previously identified in radiocarbon data as a "mysterious" companion signal to the SdV signal (Damon and Peristykh,
 483 2004:243) is also a phase length in the lunar declination data.

484

485 Reinforcing these radiocarbon associations is the coincidence of reduced variability in the solar declination cycle during the
 486 second millennium BCE [Figure S4], concurrent with reduced variability of the SdV cycle in radiocarbon data (cf. Stuiver et
 487 al., 1998). This reduction in both the solar declination and radiocarbon signals can be explained by the occurrence of the
 488 Metonic lunation at the December solstice during this same period. Lunar declination is constrained by the ecliptic (the lunar
 489 orbital plane is inclined at $\sim 5^\circ$ to the ecliptic). Because the solstices are the maximum southern and northern declinations, the

490 extremes of lunar declination are constrained by the turning points in solar declination. Similarly other associations between
491 frequencies found in palaeoclimatic data and astronomical features are also evident (Table S5).

492

493 The Gregorian and Julian calendars are based on the synthesis of solar and lunar cycles. Just as combined solar and lunar
494 gravitational forcing produce the Milankovitch precessional cycle ($\sim 21 \pm 2$ ky), so too is the ~ 1470 -yr cycle, which is found in
495 records globally. The ~ 1470 -yr 'cycle' can thus be seen as a high-frequency expression of the Milankovitch precessional
496 cycle. Thus millennial-scale ENSO events and North Atlantic ice-rafted debris (IRD) events can be seen as symptomatic of
497 this forcing, with variations based on physical geography. Such geographical variations also have the capacity to incorporate
498 the bipolar seesaw effect (cf. Broecker, 2003) and explain teleconnections linking northern and southern hemispheres (cf.
499 Turney et al., 2004). Effectively, the interaction between TSI, solar and lunar gravitational forces trigger responses in Earth's
500 oceans and atmospheres, such as the thermohaline current and ENSO's atmospheric transport of heat and moisture (Broecker,
501 2003).

502

503 The mean value for the Bond (1999) cycle during the Holocene and Glacial was given as 1469 ± 514 yrs; for the Holocene as
504 1374 ± 502 yrs; for the Glacial as 1476 ± 585 yrs. Whilst the Bond cycle is a quasi-periodicity, underlying both Heinrich and
505 Dansgaard-Oeschger events, the individual contributions of the Sun and Moon as well as their interactions have the capacity
506 to account for variations in the length ~ 1470 -yr quasi-periodicity. The strength of the solar signal (through the perihelion and
507 anomalistic year) varies due to a number of factors, including position of the perihelion relative to the seasonal year, the
508 precision of cyclical interaction between Earth, Sun, and Moon, as well as the interaction of the 133-yr cycle of variations in
509 distance with the perihelion.

510

511 Importantly, these IRD events and abrupt warming can also be seen to be linked directly to the lunation cycle [Table 3], as
512 days short of a full year (cyclical return). Effectively this means that the vernal point of the spring equinox has moved
513 backwards through the year relative to the calendar, fixed stars, and perihelion due to equinoctial precession. Gravitational
514 forcing is strongest at the New Moon, which occurs at ~ 29.53 -day intervals, which cyclically occurs at 5910 yrs (the same
515 oscillation as Heinrich events) (cf. Mayewski et al., 1997). This means that after 5910 yrs, the vernal equinox has moved
516 retrograde by one synodic month. Next in strength is the Full Moon, occurring ~ 14.75 days later which is linked to the
517 Dansgaard-Oeschger oscillation at 2955 yrs. The First and Third Quarter lunar phases are next in strength and are clearly
518 associated with the Bond cycle at ~ 1478 yrs. At times of solar and lunar eclipses, these events are magnified by increased
519 gravitational forcing. Essentially, the Bond cycle frequency, which underpins Dansgaard-Oeschger and Heinrich oscillations
520 cycle, is linked with the rhythmic phases of the Moon. As the New and Full Moons amplify this signal, so are Heinrich and
521 Dansgaard-Oeschger events amplifications of the Bond signal. These events would be further amplified at half the precessional
522 cycle as the New Moon come into contact with the perihelion where gravitational forcing is at a maximum.

523 **6 Conclusion**

524 Here it has been demonstrated that two cycles (133-yr and 207.5-yr), found in astronomical data (with counterparts in climate
525 cycles), together produce a ~ 1470 -yr cycle. The astronomical mechanism for this forcing is comprised of fluctuations in Earth-
526 Sun and Earth-Moon distances that affect gravity, insolation, and TSI. A comparison between TSI reconstructions (Bard et
527 al., 2007) and the model (based on astronomical data) shows a statistically-significant, strong, positive correlation ($r=0.88$,
528 $p=0$); and that there is no difference between this model and previous TSI reconstruction based on ^{10}Be from the South Pole
529 ($X^2=0.04$; $X^2_c = 168.61$, $df=140$ and $\alpha=0.05$). These results provide a new and important understanding of the physics of
530 climate change and radiochronological dating used by a variety of sciences.

531
532 This 1470-yr frequency is closely linked with Earth-Sun-Moon interaction, and offers a mechanical explanation for abrupt
533 climate change where previously none existed. The 1470-yr cycle is associated with the lunation cycle at multiple time scales.
534 The timing of these lunations at millennial scales with Heinrich, Dansgaard-Oeschger, and Bond events in the North Atlantic
535 reinforces its identity as a high-frequency expression of the Milankovitch precessional cycle; and fortifies its role in producing
536 abrupt climate change. This evidence negates previous suggestions that the ~1470-yr cycle is non-existent (Ditlevsen et al.,
537 2007), results from mathematical averaging (Obrochta et al., 2012), or that it may simply be a result of stochastic resonance
538 within Earth's climate system (Alley et al., 2001).

539 Acknowledgements

540 I thank the School of Earth and Environmental Sciences at the University of Queensland for research funding. I would also
541 like to thank Prof. Fred Menk, Prof. Patrick Moss, Prof. Peter Kershaw for their advice. There are no real or perceived conflicts
542 for the author.

543 **Author contribution:** 100%

544 **Competing interests:** None

545 **Code/Data availability:** Data is available at <https://doi.org/10.14264/uql.2019.962>

546 **Supplementary information** is available for this paper.
