**Abstract:**

14     Arctic warming and sea level change will lead to widespread permafrost thaw  
15     and subsequent mobilization. Sedimentary records of past warming events during the  
16     last glacial–interglacial transition can be used to study the conditions under which  
17     permafrost mobilization occurs, and which changes in vegetation on land are  
18     associated with such warming. The Amur and Yukon rivers discharging into the  
19     Okhotsk and Bering Seas, respectively, drain catchments that have been, or remain  
20     until today, covered by permafrost. Here we study two marine sediment cores  
21     recovered off the mouths of these rivers. We use lignin phenols as biomarkers, which  
22     are excellently suited for the reconstruction of terrestrial higher plant vegetation, and  
23     compare them with previously published lipid biomarker data.

24     We find that in the Yukon Basin, vegetation change and wetland expansion began  
25     already in the early deglaciation (ED, 14.6–19 ka BP). This timing is different from  
26     observed changes in the Okhotsk Sea reflecting input from the Amur Basin, where  
27     wetland expansion and vegetation change occurred later in the Preboreal (PB). In the  
28     two basins, angiosperm contribution and wetland extent all reached maxima during  
29     the PB, both decreasing and stabilizing after the PB. The permafrost of the Amur  
30     Basin began to become remobilized in the PB. Retreat of sea-ice coupled with  
31     increased sea-surface temperatures in the Bering Sea during the ED might have  
32     promoted early permafrost mobilization. In modern Arctic river systems, lignin and *n*-  
33     alkanes are transported from land to the ocean via different pathways, i.e., surface  
34     runoff *vs.* erosion of deeper deposits, respectively. However, accumulation rates of

35 lignin phenols and lipids are similar in our records, suggesting that under conditions  
36 of rapid sea-level rise and shelf flooding, both types of terrestrial biomarkers are  
37 delivered by the same transport pathway. This finding suggests that the fate of  
38 terrigenous organic matter in the Arctic differs both on temporal and spatial scales.

## 1. Introduction

39 Climate warming caused by anthropogenic perturbation affects the Arctic more  
40 strongly than other regions of the world. Warming climate induces environmental  
41 changes that accelerate degradation of organic matter (OM) stored in permafrost and  
42 promote greenhouse gas release (Strauss et al., 2013; Hugelius et al., 2014; Schuur et  
43 al., 2015). Permafrost, or permanently frozen ground, is soil, sediment, or rock that  
44 remains at or below 0 °C for at least two consecutive years. It occurs both on land and  
45 on the continental shelves offshore, and underlies about 22 % of the Earth's land  
46 surface (Brown et al., 2002; Wild et al., 2022). Permafrost regions around the world  
47 store twice as much carbon as is contained in the atmosphere at present (Hugelius et  
48 al., 2014; Friedlingstein et al., 2020). Across the northern circum-polar permafrost  
49 regions, the surface permafrost carbon pool (0–3 m depth) amounts to  $1035 \pm 150$  Pg  
50 (Hugelius et al., 2014). Warming climate may lead to increased mobilization of this  
51 carbon pool, while it also affects the type and extent of the vegetation cover, which in  
52 turn influences permafrost stability.

53 During the most recent interval of rapid global warming from the end of the Last  
54 Glacial Maximum (LGM) to the early Holocene (~19–11 ka BP), the climate system  
55 underwent large-scale change (Clark et al., 2012). Viau et al. (2008) found that the  
56 summer temperatures in eastern Beringia (the non-glaciated region between the  
57 Eurasian and the Laurentian ice sheet during the Late Pleistocene) during the LGM  
58 were approximately 4°C lower than the present and increased rather rapidly toward  
59 the Holocene. Sea-ice extent and distribution changed dramatically with consequences  
60 for atmospheric moisture content (Ballantyne et al., 2013) and increased heat  
61 transport from the oceans to the continental interiors (Lawrence et al., 2008). The  
62 increase of precipitation inland as a result of sea ice retreating affects the stability of  
63 permafrost in the Arctic (Vaks et al., 2020). Together with increasing air temperatures  
64 during the deglaciation, sea-ice retreat may thus have led to rising ground  
65 temperatures, active layer deepening and permafrost degradation.

66        Increased moisture due to sea ice retreat leads to heavier winter snowfall inland  
67 (Liu et al., 2012; Park et al., 2013). Menard et al. (1998) reported that groundsurface  
68 temperature was higher where ground is covered by thick snow and shrubs and trees  
69 than where it was covered by both thin snow and vegetation (moss and lichen).  
70 During the last deglacial toward the Holocene, warming ground ice melted, causing  
71 the land surface to collapse into space previously occupied by ice wedges, a process  
72 called thermokarst. This led to the formation of thermokarst lakes and thermo-  
73 erosional valleys as well as rivers, and also likely the release of carbon from thawed  
74 deposits (Walter et al., 2006; Walter Anthony et al., 2014). During millennia following  
75 the formation of thermokarst lakes, mosses and other plants grew in and around them,  
76 which may in part have offset permafrost carbon release (Walter Anthony et al., 2014;  
77 Schuur et al., 2015; Turetsky et al., 2020). Several studies suggested major deglacial  
78 changes in the vegetation of permafrost-affected areas during the last deglaciation,  
79 including the Lena River basin (Tesi et al., 2016), the Yukon Territory (Fritz et al.,  
80 2012), the Amur River basin (Seki et al., 2012), and the Sakhalin peninsula and  
81 Hokkaido (Igarashi and Zharov, 2011), the latter two bounding the Okhotsk sea to the  
82 Northwest and North. Vegetation has a profound impact on distribution and thickness  
83 of active layers, and permafrost in cold regions; for example, evidence exists that  
84 permafrost temperature in the tundra is lower than in the boreal forest in northwestern  
85 Canada (Smith et al., 1998), illustrating the strong effects of vegetation on permafrost  
86 stability. Changes in vegetation should therefore be considered when investigating  
87 permafrost stability in a changing climate.

88        Biomarker compositions, distributions, and contents in marine sediments can  
89 help to elucidate the vegetation development in adjacent land areas. Lignin is a  
90 biopolymer exclusively biosynthesized by vascular plants. The relative abundance of  
91 individual phenolic monomers varies between different plant types, and the different  
92 phenols also differ in their stability towards degradation. Ratios between different  
93 phenolic monomers are thus sensitive indicators for vegetation type and depositional  
94 history of OM originating from land plants.

95        Previous studies found that the delivery of lignin from land to the ocean is  
96 mainly controlled by surface discharge in modern Arctic river systems (Feng et al.,  
97 2013) and has the potential to provide information on surface runoff processes and  
98 wetland extent (Tesi et al., 2016; Feng et al., 2015). Long-chain *n*-alkanes (Alk) with  
99 a strong predominance of the odd carbon number homologues, as well as even-

100 numbered long-chain *n*-alkanoic acids, derived from the epicuticular waxes of  
101 vascular and aquatic plants (Eglinton and Hamilton, 1967). In contrast to lignin  
102 phenols, sedimentary records of Alk, due to their recalcitrance, likely trace terrigenous  
103 OM which has been mobilized from thawing permafrost deposits in modern Arctic  
104 river systems (Feng et al., 2013) and may be transported into the marine sediment  
105 primarily following coastal erosion during shelf flooding (Winterfeld et al., 2018).  
106 Previous studies have reconstructed the mobilization of terrigenous OM from  
107 degrading permafrost in the Okhotsk (Winterfeld et al., 2018) and Bering shelves  
108 (Meyer et al., 2019) during the last deglaciation based on long-chain *n*-alkyl lipids  
109 results. However, no records exist that combine lignin and Alk data to explore the  
110 potentially different transport of terrestrial OM archived in Arctic marine sediments  
111 during the last deglaciation.

112 Biomarker records can also be used to infer environmental conditions like sea-  
113 surface temperatures (SSTs) or sea-ice extent that influence heat and moisture  
114 transport from the ocean to the continents. A commonly used proxy for the  
115 reconstruction of SSTs is the TEX<sub>86</sub>, which relies on the relative abundance of so-  
116 called isoprenoid glycerol dialkyl glycerol tetraether lipids (GDGTs) with different  
117 numbers of cyclopentyl moieties (Schouten et al., 2002). These compounds are  
118 derived from the membranes of marine *Thaumarchaeota* and have been found to  
119 record temperature conditions of their habitat. Sea-ice reconstructions rely on the  
120 abundance of highly branched isoprenoids derived from diatoms adapted to life in  
121 sea-ice (IP<sub>25</sub>; Belt et al., 2007). GDGTs can also be used to reconstruct terrigenous  
122 input to the ocean, when the relative abundance of branched GDGTs derived mainly  
123 from soil bacteria and of isoprenoid GDGTs is quantified by the branched and  
124 isoprenoid tetraether (BIT) index (Hopmans et al., 2004).

125 In this study, we present downcore records of lignin phenols from the early  
126 deglaciation to the Holocene obtained from sediment cores from off the Amur and  
127 Yukon rivers draining permafrost drainages affected by deglacial climate change.  
128 These sites in the Okhotsk and Bering Seas, respectively, record conditions at two  
129 contrasting river-dominated continental margins in the North Pacific area. We  
130 interpret the lignin phenol records in the context of vegetation and wetland  
131 development and investigate the temporal evolution of the different pathways of  
132 terrigenous OM export to the ocean by comparing different types of terrigenous  
133 biomarker records, i.e., Alk from published studies and new lignin phenol data as well

134 as BIT index values. We further investigate new and published biomarker-based  
135 reconstructions of SST, as well as published biomarker-based sea-ice reconstructions  
136 to unravel the controls on terrigenous OM transport to the ocean from thawing  
137 permafrost landscapes.

## 2. Study area

138 The Bering Sea is located north of the Pacific Ocean (Figure 1). The Yukon River is  
139 the fourth largest river in North America in terms of annual discharge, and drains into  
140 the Bering Sea (Holmes et al., 2012). The deglacial sediments from the Bering Sea  
141 contain records both of sea-level rise-induced erosion of the vast Bering Shelf, and of  
142 runoff from the Yukon River (Kennedy et al., 2010; Meyer et al., 2019). The Yukon  
143 Basin was mostly unglaciated during the LGM, but had permafrost (Schirrmeyer et  
144 al., 2013). Although some permafrost in the Yukon Basin thawed during the last  
145 deglaciation (Meyer et al., 2019; Wang et al., 2021), most of the basin is still covered  
146 by permafrost today (Fig. 1). Arctic coastal erosion is rapid today, with average rates  
147 of erosion at  $0.5 \text{ m year}^{-1}$  (Lantuit et al., 2012; Irrgang et al., 2022). Sea level rise will  
148 lead to greater wave impact on arctic shorelines which increases the coastal erosion  
149 (Lantuit et al., 2012). [This suggests that during past times of rapid sea-level increase](#)  
150 [like in the B/A and PB periods coastal erosion was more intense than it is today](#)  
151 [\(Lambeck et al., 2014; Fig. 2, b\)](#). Coastal erosion causes a large amount of terrigenous  
152 OM to enter the ocean (Couture et al., 2018; Winterfeld et al., 2018), suggesting that  
153 during past periods of sea-level rise, similar to today or even stronger erosive forces  
154 were at play supplying vast amounts of terrigenous materials to marine sediments.  
155 Pollen records indicate there were no significant changes in vegetation pattern from  
156 the LGM to about 16 ka BP, but after about 16 ka BP, birch (one of the first trees to  
157 develop after the glacier retreated) pollen became significantly more abundant from  
158 western Alaska to the Mackenzie River (Bigelow, 2013). In the early Holocene,  
159 significant *Populus-Salix* (cottonwood-willow) woodland development occurred in  
160 interior Alaska and in the Yukon Territory (Bigelow, 2013), suggesting both  
161 increasing summer temperature and moisture. Alder grows in a warmer and wetter  
162 environment than birch, and it is a common genus in Yukon Holocene pollen records  
163 (Schweger et al., 2011). Today the catchment of the Yukon River is covered by spruce  
164 forest (20 %), grassland (40 %), shrubland (20 %), and open water and wetlands  
165 associated with the lowland areas (8 %) (Amon et al., 2012).

166 The Okhotsk Sea, a semi-enclosed marginal sea located in the west of the North  
167 Pacific, is known as the southernmost region of seasonal sea ice in the Northern  
168 Hemisphere today (Fig. 1). The continental slope off Sakhalin Island in the Okhotsk  
169 Sea receives runoff from the Amur river, the largest river catchment in East Asia. The  
170 Amur is also one of the largest rivers in the world in terms of the annual total output  
171 of dissolved OM and substantially influences the formation of seasonal sea ice  
172 (Nakatsuka et al., 2004). The river originates in the western part of Northeast China  
173 and flows east forming the border between China and Russia. The catchment of the  
174 Amur transitioned from complete permafrost coverage during the LGM  
175 (Vandenbergh et al., 2014) to almost entirely permafrost-free conditions at present.  
176 The climate of the Amur Basin today is largely determined by continental patterns  
177 from Asia, as the Asia monsoon influences the amount of precipitation from the  
178 Pacific transported to this region during the summer. Previous studies found that  
179 herbaceous plants were the predominant vegetation in the last glacial periods in the  
180 Amur Basin, and were replaced by gymnosperms during the deglaciation and  
181 Holocene (Bazarova et al., 2008; Seki et al., 2012). These authors concluded that the  
182 variations of vegetation change agree well with climate changes in East Russia with  
183 dry conditions in the last glacial followed by wetter climate in the deglaciation and  
184 early Holocene (Seki et al., 2012). Now, the vegetation of the Amur Basin belongs  
185 mostly to the Taiga zone, with larch as the most common species in the area. The  
186 upper reaches of the Amur Basin belong to the coniferous continental taiga at present.  
187 The central areas are dominated by mixed coniferous and broad-leaved forests and the  
188 coniferous larch forests are the predominant vegetation in the lower Amur Basin.

### **3. Material and methods**

#### **3.1. Sampling and age control**

189 Piston core SO202-18-3 (60.13° N, 179.44° W, water depth: 1111 m) and neighboring  
190 Kasten core SO202-18-6 (60.13° N, 179.44° W, water depth: 1107 m) were recovered  
191 from the northeastern continental slope of the Bering Sea in 2009 during R/V Sonne  
192 cruise SO202-INOPEX (Gersonde, 2012). The two cores can be treated as one  
193 composite record according to their ultrahigh-resolution micro-X-ray-fluorescence  
194 data, sediment facies analysis of laminae and radiocarbon dating results (Kuehn et al.,  
195 2014). It represents an apparently continuous sedimentary sequence dated back to the  
196 Last Glacial (~25 ka BP) (Kuehn et al., 2014). Selected samples from core SO202-18-

197 6 ( $n = 20$ , 10–589 cm core depth, 6.23–12.65 ka BP) and from core SO202-18-3 ( $n =$   
198 29, 447–1423 cm core depth, 12.99–24.1 ka BP) with an average temporal resolution  
199 of ~510 years were analyzed for lignin-derived phenol contents.

200 The 23.7 m-long piston core SO178-13-6 (52.73° N, 144.71° E) was collected  
201 from the Sakhalin margin in the Okhotsk Sea during the expedition SO178-KOMEX  
202 with R/V Sonne (Dullo et al., 2004) (Fig. 1) with the lowermost interval  
203 corresponding to ~17.5 ka (Max et al., 2014). Selected samples ( $n = 51$ , 100–2340 cm  
204 core depth, 1.11–17.27 ka BP) from core SO178-13-6 were analyzed for lignin-  
205 derived phenol contents with an average temporal resolution of ~340 years.

206 Radiocarbon-based age models for the two cores are from Kuehn et al. (2014) for  
207 core SO202-18-3/6 and Lembke-Jene et al. (2017) for core SO178-13-6. The time  
208 interval covered by the records will be subdivided into five intervals, the early  
209 deglaciation (ED; 19–14.6 ka BP), the B/A (14.6–12.9 ka BP), the Younger Dryas  
210 (YD; 12.9–11.5 ka BP), the Pre-Boreal (PB, 11.5–9 ka BP) and the Holocene (<9 ka  
211 BP).

### 3.2. Laboratory analyses

212 The extraction of lignin phenols was carried out based on the method of Goñi and  
213 Montgomery (2000a) and as described in Sun et al. (2017). Dried samples were  
214 oxidized with CuO (~500 mg) and ~50 mg ferrous ammonium sulfate in 12.5 ml 2N  
215 NaOH under anoxic conditions. The oxidation was conducted with a CEM MARS5  
216 microwave accelerated reaction system at 150 °C for 90 min. After oxidation, known  
217 amounts of recovery standards (ethyl vanillin and trans-cinnamic acid) were added to  
218 the oxidation products. The alkaline supernatant was acidified to pH 1 with 37 % HCl.  
219 The reaction products were subsequently recovered by two successive extractions  
220 with ethyl acetate. The combined ethyl acetate extracts were evaporated under a  
221 stream of nitrogen, then re-dissolved in 400 µl pyridine. Prior to injection into the gas  
222 chromatograph-mass spectrometer (GC-MS), an aliquot (30 µl) was derivatized with  
223 30 µl bis-trimethylsilyl-trifluoroacetamide (BSTFA) + 1 % trimethylchlorosilane  
224 (TMCS) (60 °C, 30 min). An Agilent 6850 GC coupled to an Agilent 5975C VL MSD  
225 quadrupole MS operating in electron impact ionization (70 eV) and full-scan ( $m/z$  50–  
226 600) mode was used for analysis. The source temperature of the MS was set to 230 °C  
227 and the quadrupole to 150 °C. The GC was equipped with a DB-1 MS column (30 m  
228 × 0.25 mm i.d., film thickness 0.25 µm). Helium was used as carrier gas at a constant

229 flow rate of 1.2 ml min<sup>-1</sup>. Samples were injected in splitless mode in a split/splitless  
230 injector (S/SL) held at 280 °C. The temperature of the GC-MS column was  
231 programmed from 100 °C (initially held for 8 min.), ramped by 4 °C min<sup>-1</sup> to 220 °C,  
232 then by 10 °C min<sup>-1</sup> to 300°C with a final hold time of 5 min.

233 Eight lignin-derived phenols were analyzed in this study. They can be classified  
234 into three groups according to their plant sources and structures:

235 1. Vanillyl phenols (V) consisting of vanillin (Vl), acetovanillone (Vn) and  
236 vanillic acid (Vd).

237 2. Syringyl phenols (S), comprising syringaldehyde (Sl), acetosyringone (Sn)  
238 and syringic acid (Sd).

239 3. Cinnamyl phenols (C) that include *p*-coumaric acid (*p*-Cd) and ferulic acid  
240 (Fd).

241 Vanillyl phenols can be found in all vascular plants, syringyl phenols exist only  
242 in angiosperms. Cinnamyl phenols are exclusively present in non-woody tissues of  
243 vascular plants. Therefore, the S/V and C/V ratios can be used to distinguish lignin  
244 between woody and non-woody tissues of angiosperms and gymnosperms (Hedges  
245 and Mann, 1979) (Fig. 4). Since S and C phenols are more easily degraded than V  
246 phenols during lignin degradation, these two ratios can also be impacted by the  
247 degradation degree of lignin (Hedges et al., 1988; Otto and Simpson, 2006) (Fig. 4).  
248 Microbial degradation of lignin increase the relative abundance of phenolic acids of V  
249 and S phenols, the ratios of vanillic acid to vanillin (Ad/Al)<sub>v</sub> and syringic acid to  
250 syringaldehyde (Ad/Al)<sub>s</sub> are commonly used to reconstruct the degradation degree of  
251 lignin (Ertel and Hedges, 1985; Hedges et al., 1988; Otto and Simpson, 2006) (Fig. 4).

252 Besides, we also included some other oxidation products that do not necessarily  
253 originate from lignin, such as 3,5-dihydroxybenzoic acid (3,5Bd) and para-  
254 hydroxybenzenes (P) like *p*-hydroxybenzaldehyde (Pl), *p*-hydroxybenzophenone (Pn),  
255 and *p*-hydroxybenzoic acid (Pd). Unlike lignin-derived phenols (V, S, and C), 3,5Bd  
256 is absent in plant tissues, but most enriched in peat (Goñi et al., 2000b; Amon et al.,  
257 2012). The 3,5Bd/V ratio can be used as a tracer for wetland extent and to determine  
258 the degree of degradation for terrigenous OM (Fig. 4).

259 These compounds were identified based on retention time and mass spectra.  
260 Quantification was achieved by peak areas of the respective compounds and using  
261 individual 5-point response factor equations obtained from mixtures of commercially  
262 available standards analyzed periodically. The yields of Pl, Vl and Sl were corrected

263 by the recovery rate of ethyl vanillin and the recovery rate of trans-cinnamic acid was  
264 applied to correct the yield of other lignin-derived compounds and 3,5Bd (Goñi et al.,  
265 2000a, b). The standard deviation was determined from repeated measurements of a  
266 laboratory internal standard sediment extract ( $n = 12$ ) and for the carbon-normalized  
267 concentration of the sum of the 8 lignin phenols ( $\Delta 8$ , mg 100mg<sup>-1</sup> OC) equals 0.31.

268 Mass accumulation rates (MAR) of vascular plant-derived lignin phenols were  
269 calculated as follows:

270  $\text{MAR} = \text{SR} \times \rho$ , (Eq. 1)

271  $\text{MAR-lignin} = \text{MAR} \times \Sigma 8 \div 100$  (Eq. 2)

272 where MAR is the mass accumulation rate in g cm<sup>-2</sup> a<sup>-1</sup>, SR is the sedimentation  
273 rate in cm a<sup>-1</sup>, and  $\rho$  is the dry bulk density in g cm<sup>-3</sup>. MAR-lignin is the mass  
274 accumulation rate of lignin (mg cm<sup>-2</sup> a<sup>-1</sup>).  $\Sigma 8$  represents the content of the 8 lignin  
275 phenols in mg 10g<sup>-1</sup> dry sediment.

276 According to previous studies, the odd-numbered *n*-alkanes in the range of C<sub>23</sub> to  
277 C<sub>33</sub> are almost exclusively terrigenous (Eglinton and Hamilton, 1967; Otto and  
278 Simpson, 2005). Therefore, we can use the mid to long chain length (high molecular  
279 weight, HMW) Alk to reflect the contribution of terrigenous OM. Lignin MARs were  
280 compared to published MARs of HMW Alk from the Okhotsk Sea (Winterfeld et al.,  
281 2018) and the Bering Sea (Meyer et al., 2019). The MARs of HMW Alk from the  
282 Bering Sea were recalculated from the published data (Meyer et al., 2019) in order to  
283 compare the results of the two sediment cores. The HMW Alk quantified for the  
284 Bering and Okhotsk Sea sediment cores are C<sub>23</sub>, C<sub>25</sub>, C<sub>27</sub>, C<sub>29</sub>, C<sub>31</sub> and C<sub>33</sub> (Fig. 2).

285 Alkanes also have been shown to provide a second marker for wetland extent via  
286 the Paq index (Ficken et al., 2000). It represents the relative proportion of mid-chain  
287 length Alk (C<sub>23</sub> and C<sub>25</sub>) to long-chain Alk (C<sub>29</sub> and C<sub>31</sub>). The Paq ratios shown in our  
288 manuscript have been published by others. The Paq ratio of SO202-18-3/6 core was  
289 published by Meyer et al. (2019). The Paq ratio of SO178-13-6 core was published by  
290 Winterfeld et al. (2018). We also cited the Paq ratio of the XP07-C9 core (Seki et al.,  
291 2012), which was retrieved from the Okhotsk Sea (Fig. 1).

292 We further report here the relative abundances of isoprenoid GDGT lipids. These  
293 data were obtained together with the same total lipid extracts that were used for Alk  
294 data published by Meyer et al. (2019). The isoprenoid GDGTs were determined using  
295 the methodology described in Meyer et al. (2016). In brief, the internal standard of

296 GDGTs (C<sub>46</sub>-GDGT) was added to known amounts of dry sediment, and total lipid  
297 extracts were obtained by ultrasonication with dichloromethane:methanol = 9:1  
298 (vol/vol), 3 times. After extraction and saponification, neutral compounds (including  
299 GDGTs) were recovered with *n*-hexane. Different compound classes were separated  
300 by 1% deactivated SiO<sub>2</sub> column chromatography. Polar compounds (including  
301 GDGTs) were eluted with methanol:dichloromethane = 1:1 (vol/vol). Afterward they  
302 were dissolved in hexane:isopropanol = 99:1 (vol/vol) and filtered with a  
303 polytetrafluoroethylene filter (0.45  $\mu$ m pore size). Samples were brought to a  
304 concentration of 2  $\mu$ g  $\mu$ l<sup>-1</sup> prior to GDGT analysis. GDGTs were analyzed by high-  
305 performance liquid chromatography and a single quadrupole mass spectrometer (see  
306 Meyer et al. (2017) for more details).

307 The TEX<sub>86</sub> index can be used as a SST proxy (Schouten et al., 2002), with the  
308 modified version TEX<sub>86</sub><sup>L</sup> being applicable in settings where SST is below 15 °C (Kim  
309 et al. 2010). The regional calibration of SST and TEX<sub>86</sub><sup>L</sup> is based on Seki et al.  
310 (2014a).

311  $\text{TEX}_{86}^L = \log (\text{GDGT-2} / (\text{GDGT-1} + \text{GDGT-2} + \text{GDGT-3}))$  (Eq. 3)

312  $\text{SST} = 27.2 \times \text{TEX}_{86}^L + 21.8$  (Eq. 4)

313 The GDGT-1, GDGT-2, and GDGT-3 are isoprenoid tetraether lipids with 1, 2,  
314 and 3 cyclopentane rings, which were detected by a single quadrupole mass  
315 spectrometer. The MS detector was set for selected-ion monitoring of the following  
316 ( $M + H$ )<sup>+</sup> ions: m/z 1300.3 (GDGT-1), 1298.3 (GDGT-2), 1296.3 (GDGT-3) (Meyer  
317 et al., 2016). SST is the sea surface temperature in °C.

318 The BIT index proxy is based on the abundance ratio of branched GDGTs to  
319 isoprenoid GDGTs (Hopmans et al., 2004); higher BIT values suggest more  
320 contributions from terrestrial soil OM (Weijers et al., 2006; Fig. 3). The BIT index is  
321 calculated as  $\text{BIT} = (\text{GDGT-I} + \text{GDGT-II} + \text{GDGT-III}) / (\text{GDGT-I} + \text{GDGT-II} +$   
322  $\text{GDGT-III} + \text{GDGT-IV})$ . GDGT-I, GDGT-II, and GDGT-III refer to the concentration  
323 of branched GDGT, GDGT-IV refers to the concentration of isoprenoid GDGT  
324 (crenarchaeol). The MS detector was set for selected-ion monitoring of the following  
325 ( $M + H$ )<sup>+</sup> ions: m/z 1022 (GDGT-I), 1036 (GDGT-II), 1050 (GDGT-III), and 1292.3  
326 (GDGT-IV) (Meyer et al., 2016).

## 4. Results

### 4.1. Lignin concentrations and MARs

327 Lignin phenol concentrations were 0.19–1.43 mg 100mg<sup>-1</sup> OC (Λ8) or 0.20–1.07 mg  
328 10g<sup>-1</sup> sediment (Σ8) in the Bering Sea sediments and 0.32–1.29 mg 100mg<sup>-1</sup> OC or  
329 0.40–2.16 mg 10g<sup>-1</sup> sediment in the Okhotsk Sea record. Overall, the MAR of lignin  
330 is lower in the Bering Sea than in the Okhotsk Sea (Fig. 2c, d). During the ED, the  
331 lignin MAR began to increase in the Bering Sea sediment and kept increasing until it  
332 reached a maximum (17.70 µg cm<sup>-2</sup> a<sup>-1</sup>) at the B/A-YD transition (Fig. 2c). After the  
333 B/A, the lignin MAR started to decrease in the Bering Sea until the onset of the YD.  
334 The lignin MAR in the Bering Sea reached a more pronounced but short maximum  
335 (20.61 µg cm<sup>-2</sup> a<sup>-1</sup>) at the YD-PB transition, followed by a decrease to the Holocene.  
336 The lignin MAR in the Okhotsk Sea is more variable than in the Bering Sea record  
337 (Fig. 2d). The lignin MAR shows an initial maximum in the B/A, but reaches a more  
338 pronounced second peak (31.16 µg cm<sup>-2</sup> a<sup>-1</sup>) in the early PB. Similar to the Bering Sea,  
339 the lignin MAR decreased after about 11 ka BP and into the Holocene, however, the  
340 lignin MAR in the Okhotsk Sea sediment featured a rather broad maximum between  
341 B/A and early Holocene.

342 Deglacial changes in the MARs of HMW Alk have previously been reported for  
343 the same cores (Meyer et al., 2019; Winterfeld et al., 2018). The MAR of lignin and  
344 HMW Alk changed mostly synchronously in the Bering Sea, but in the Okhotsk Sea,  
345 the increase in lignin MAR occurred later than in Alk MAR, and notably also later  
346 than in the Bering Sea (Fig. 2c, d). Alk MAR in the Okhotsk Sea featured two similar  
347 maxima in the B/A and during the YD-PB transition, while the lignin MAR maximum  
348 in the B/A is less pronounced than that at the YD-PB transition. Lignin MAR are  
349 more variable than Alk MARs between 10 and 7.8 ka BP.

#### 4.2. Sea surface temperature in the Bering Sea (BIT and TEX<sub>86</sub><sup>L</sup>)

350 Most BIT values in the Bering Sea are below the commonly assumed threshold value  
351 of 0.3 (Fig. 3, 1c), above which SST reconstructions are potentially biased by  
352 terrigenous isoGDGTs (Weijers et al., 2006). We are confident that in our study area,  
353 marine-derived GDGTs dominate over terrigenous GDGTs, suggesting that TEX<sub>86</sub><sup>L</sup> is  
354 not biased by terrigenous input.

355 The SST estimates derived from the TEX<sub>86</sub><sup>L</sup> index are shown in Fig. 3, 1c. The  
356 deglacial evolution of the TEX<sub>86</sub><sup>L</sup>-derived SST shows an overall warming, from ~4.5  
357 at 23.4 ka BP to 10.8 °C at 12.0 ka BP. The SST in the Bering Sea remained rather  
358 constant during the LGM and the ED. The onset of the B/A is characterized by an

359 abrupt temperature increase of  $\sim 2$  °C, followed by a decrease at the end of the B/A. At  
360 the end of the YD, the SST abruptly increased by  $\sim 2$  °C, while staying rather constant  
361 from 11.5 ka BP to 10 ka BP. At the end of PB, the SST decreased slowly by 1°C  
362 from 10.5 to 9.0 ka BP. During the Holocene, the SST ranged between 8.0 °C and  
363 9.7 °C.

#### 4.3. Lignin source and degradation indicators

364 Vegetation development can be assessed using the S/V (angiosperm *vs.* gymnosperm)  
365 and C/V ratios (woody tissues *vs.* non-woody tissues) (Hedges and Mann, 1979). The  
366 3,5Bd/V and Paq ratios can be used to indicate the change of wetland extent in the  
367 study area (Goñi et al., 2000b; Amon et al., 2012). Similar to  $(Ad/Al)_s$  and  $(Ad/Al)_v$   
368 ratios, S/V, C/V, and 3,5Bd/V ratios are also affected by degradation processes (Ertel  
369 and Hedges, 1985; Hedges et al., 1988; Otto and Simpson, 2006).

370 The S/V and C/V ratios yielded values of 0.36–0.86 and 0.11–0.46 in the Bering  
371 Sea (Fig. 4, Ia, b), while slightly higher ratios of 0.41–0.92 and 0.19–0.70 were  
372 obtained in the Okhotsk Sea (Fig. 4, IIa, b). The standard deviations for S/V and C/V  
373 are 0.08 and 0.10, respectively. In the Bering Sea, the S/V ratios began to increase  
374 from 18 ka BP and kept increasing until it reached a maximum in the transition of the  
375 YD to the PB. The change of C/V values was not as obvious as S/V values, but it also  
376 reached its maximum at YD-PB transition. Subsequently, S/V and C/V ratios  
377 decreased during the Holocene and reached minima at the top of the core.

378 In the Okhotsk Sea, the S/V values increase slowly from the ED to PB, but the  
379 C/V ratios do not display an obvious increase over the same time, except for a  
380 maximum in C/V ratios around 15 ka BP. Minimum values were found in the ED and  
381 values remained rather low before the YD-PB transition. After reaching maxima in  
382 the PB, S/V and C/V ratios decreased during the Holocene, stabilizing at a higher  
383 level than during the ED.

384 In the Bering Sea, the 3,5Bd/V ratio ranged from 0.09 to 0.20 (Fig. 4, Id)  
385 (standard deviation: 0.02). From the end of LGM to the YD, the 3,5Bd/V ratio  
386 decreased slowly, but began to increase and reached a small local maximum at the  
387 YD-PB transition. During the Holocene, the 3,5Bd/V ratio decreased again and  
388 reached the lowest values near the top of the core.

389 The 3,5Bd/V ratios in the core from the Okhotsk Sea range from 0.10 to 0.23  
390 (Fig. 4, IIId) (standard deviation: 0.02). The values were rather uniform throughout the

391 record, with the exception of a maximum during the PB, and the ratio remained rather  
392 stable afterwards.

393 The  $(Ad/Al)_s$  and  $(Ad/Al)_v$  ratios ranged from 0.19 to 0.80 (standard deviation:  
394 0.24) and 0.51 to 1.04 (standard deviation: 0.26), respectively, in the Bering Sea (Fig.  
395 4, Ie, f). Maxima in  $(Ad/Al)_s$  and  $(Ad/Al)_v$  were reached in the Holocene and YD. The  
396 Ad/Al ratio in the Bering Sea showed low values during the PB and increased towards  
397 the early Holocene, when highest values of Ad/Al were obtained.

398 In the Okhotsk Sea, the  $(Ad/Al)_s$  and  $(Ad/Al)_v$  ratios are overall similar and  
399 range from 0.30 to 0.79 (standard deviation: 0.24) and from 0.22 to 0.89 (standard  
400 deviation: 0.26), respectively (Fig 4, IIe, f). The  $(Ad/Al)_v$  ratio decreased slowly until  
401 10.5 ka BP when the biomarker MARs reached maxima. All minima and maxima in  
402 both indices occurred in the PB. Throughout the rest of the Holocene, Ad/Al values  
403 remained rather constant.

## 5. Discussion

### 5.1. Terrigenous OM mobilization during the last deglaciation

404 Permafrost remobilization has a strong impact on local topography, vegetation, and  
405 OM fate (Feng et al., 2013; Walter Anthony et al., 2014). We observed distinct MAR  
406 peaks of terrigenous biomarkers in both sediment cores, but the temporal evolution of  
407 MARs and the relative magnitude of change differ between the sites.

408 In the Bering Sea, lignin MAR began to increase at  $\sim$ 17.5 ka BP, which coincides  
409 with the onset of sea level rise (Fig. 2). Wang et al. (2021) found that the Alaskan  
410 mountain glaciers and Laurentide and Cordilleran ice sheets reached their maximum  
411 extent from 20 ka BP to 16.5 ka BP, suggesting permafrost of the Yukon Basin may  
412 not have begun to be remobilized during this time. The Yukon River discharge did not  
413 increase until 16.5 ka BP (Wang et al., 2021), the terrigenous OM transported by  
414 surface runoff thus may not have increased at  $\sim$ 17.5 ka BP. Keskitalo et al. (2017)  
415 found that the OM flux accumulated on the East Siberian Shelf during the PB-  
416 Holocene transition was high and these OM were characterized by high S/V (0.28–  
417 0.90, mean value is 0.50) and C/V values (0.19–0.60, mean value is 0.35) (Fig. 5).  
418 These authors suggested the Ice Complex Deposit (ICD) as a significant source of  
419 OM in the East Siberian Sea during this time. Previous studies indicated that ICD  
420 samples yield relatively high S/V and C/V ratios ranging from 0.47 to 1.01, and from  
421 0.03 to 0.82, indicating the OM is likely to stem from grass-like material typical of

422 tundra or steppe biome (Schirrmeyer et al., 2013; Tesi et al., 2014; Winterfeld et al.,  
423 2015). The S/V (0.50–0.75, mean value is 0.62) and C/V (0.22–0.36, mean value is  
424 0.28) values of the Bering Sea sediment core from 24 ka BP to 17.5 ka BP are high  
425 (Fig. 4, I), which may indicate that this terrestrial OM is likewise derived from the  
426 ICD. The organic-rich ICD on the coasts of the Bering Sea might have been inundated  
427 or eroded by rising sea level in the ED, which may contribute to the lignin MAR in  
428 the Bering Sea at ~17.5 ka BP.

429 HMW Alk accumulation in the Bering Shelf started to increase around 16.5 ka  
430 BP (Fig. 2), which coincides with the beginning retreat of Alaskan glaciers (Dyke,  
431 2004). The glacial meltwaters drained through the Yukon River and enhanced fluvial  
432 discharge to the Bering Sea (Wang et al., 2021). The ICD in Alaska and Beringia  
433 might have started to be remobilized at ~16.5 ka BP (Meyer et al., 2019; Wang et al.,  
434 2021), subsequently enhancing the MAR of ICD-derived OM off the Bering Shelf.  
435 Thus, the increased S/V, C/V, and Paq values near 17.5 ka BP (Fig. 4, Ia–c) lend  
436 support to the notion that permafrost of the Yukon Basin may have begun to be  
437 remobilized in the ED.

438 Retreat of sea ice will increase the SST, and open waters increase the moisture  
439 content of the atmosphere, so the transport of heat from the ocean via atmospheric  
440 pathways to continental interiors increases (Ballantyne et al., 2013; Vaks et al., 2020).  
441 Praetorius et al. (2015) found that SST warming commenced around 16.5 ka BP (core  
442 85JC, Fig. 3, If) in the northern Gulf of Alaska, and Méheust et al. (2018) observed  
443 rising SST of the northeast Pacific by ~1.5 °C near 16 ka BP (core SO202-27-6, Fig. 3,  
444 Ie) which agrees with our  $\text{TEX}_{86}^{\text{L}}$ -SST record (core SO202-18-3/6, Fig. 3, Ic). The  
445 same authors reconstructed sea-ice extent based on the  $\text{IP}_{25}$  proxy to decrease from  
446 around 16 ka BP in the Northeast Pacific (Fig. 3, Ie). Jones et al. (2020) reported that  
447 the sea ice in the Bering Sea is highly sensitive to small changes in winter insolation  
448 and atmospheric  $\text{CO}_2$ . Further evidence for regional climate warming in the hinterland  
449 of Alaska is provided by the Brooks Range glacial melting during a time of  
450 widespread cooling in the Northern Hemisphere (Dyke, 2004; Wang et al., 2021).  
451 Combined evidence from SST and sea-ice reconstructions as well as records of glacial  
452 melting thus suggest that the permafrost of the Yukon Basin may have begun to be  
453 remobilized at ~16 ka BP.

454 In the B/A, all biomarker fluxes increased and reached short maxima (Fig. 2c, d).  
455 The rate of sea level rise also reached a maximum since the LGM. If Alk had been

456 transported to the ocean primarily through coastal erosion, as is the case with the  
457 modern Arctic river transport systems (Feng et al., 2013), then Alk MAR would have  
458 been at its maximum, but it was not. Warming may have caused widespread  
459 permafrost thaw in the Yukon Basin in the B/A. At this time, SST increased, sea-ice  
460 cover decreased (Méheust et al., 2018), and an increase in river discharge was  
461 reconstructed (Wang et al., 2021), which may have fostered diatom bloom events  
462 (Kuehn et al., 2014; Fig. 2).

463 Increased S/V, and decreased  $(Ad/Al)_{s,v}$  in the B/A, suggesting that the OM  
464 deposited in the Bering Sea during the B/A may have been derived from ICD. Similar  
465 to our findings, Martens et al. (2019) found relatively high lignin fluxes in the  
466 Chukchi Sea during the B/A (Fig. 2e) and showed that lignin deposited during this  
467 period was poorly degraded. The authors interpreted this degradation state as  
468 permafrost OM from ICD being the dominant source. The relative contribution of  
469 ICD and the main pathway of transportation (abrupt thaw or gradual thaw on land)  
470 cannot be deduced from our data alone. Further analyses may reveal possible ICD  
471 contributions to lignin exported to the marine realm during this interval.

472 During the YD-PB transition, the Northern Hemisphere experienced an abrupt  
473 temperature increase, the maxima of biomarker MAR (Fig. 2c) indicate that the  
474 permafrost remobilization in the Yukon Basin reached a peak at this time. The Yukon  
475 River discharge increased during the PB (Wang et al., 2021) which can also promote  
476 lignin flux. Evidence for widespread permafrost decomposition and wetland  
477 expansion at the same time has been reported from the Bering Sea (Meyer et al.,  
478 2019), the Siberian-Arctic (Tesi et al., 2016; Martens et al., 2020), and eastern  
479 Beringia (Kaufman et al., 2015). Bering Sea sediments deposited during the time  
480 intervals of lignin MAR peaks were laminated (Fig. 2c), indicating increased export  
481 productivity and terrigenous OM supply may have promoted anoxic conditions during  
482 the YD-PB transition (Kuehn et al., 2014).

483 The rate of sea level change was lower during the PB than that in the B/A, but  
484 the MARs of Alk and lignin reached maxima, and the discharge of the Yukon also  
485 increased from the B/A to the PB. Therefore, both coastal erosion and surface runoff  
486 may affect the transport of Alk and lignin from land to ocean in the Yukon Basin  
487 during the last deglaciation.

488 Different from the Bering Sea records, lignin MAR did not yet increase in the  
489 Okhotsk Sea during the ED (Fig. 2d), except for a short peak at the transition from the

490 ED to the B/A. The discharge of the Amur River was low, but the MAR of lignin  
491 increased at the transition from the ED to the B/A when the rate of sea level change  
492 was rapid. At the same time, the Alk MAR did not change significantly (Fig. 2). This  
493 suggests that both lignin MARs in Okhotsk Sea sediment are affected by coastal  
494 erosion during the last deglaciation.

495 SSTs were higher in the Northeast Pacific and the Bering Sea than in the  
496 Northwest Pacific and Okhotsk Sea during the ED, and the IP<sub>25</sub> value was relatively  
497 high in the Okhotsk Sea (Fig. 3, IIc), indicating the sea ice of the Okhotsk Sea did not  
498 begin to retreat in the ED (Lo et al., 2018). Caissie et al. (2010) found that the first  
499 detectable concentration of alkenones in the Bering Sea sediment at 16.7 ka BP  
500 occurred earlier than in the Okhotsk Sea, although the Bering Sea is located further  
501 north than the Okhotsk Sea. As a result of prevailing sea-ice cover, the permafrost of  
502 the Amur Basin may have remained stable in the ED (Vaks et al., 2013, 2020;  
503 Winterfeld et al., 2018; Meyer et al., 2019).

504 The rate of sea-level change reached a peak during MWP-1A (Fig. 2d) which  
505 likely also caused an increase in the rate of coastal erosion. Thus, the increased  
506 biomarker MAR during the B/A (Fig. 2) may be attributed largely to coastal erosion.  
507 This suggests that both types of biomarkers are supplied via the same erosive process  
508 during the B/A, in contrast to findings from the modern-day Arctic.

509 From the YD to the PB, the Northern Hemisphere experienced an abrupt  
510 temperature increase and the SST of the North Pacific increased significantly (Max et  
511 al., 2012; Riethdorf et al., 2013; Méheust et al., 2016, 2018; Meyer et al., 2016, 2017).  
512 All biomarker MARs in the Okhotsk Sea increased and reached maxima in the YD-  
513 PB transition. The permafrost of the Amur Basin may have begun to be remobilized  
514 coevally with previously reported periods of stalagmite growth starting after the PB in  
515 the south of Siberia, which indicates the decay of permafrost and opening of water  
516 conduits into the caves (Vaks et al. 2013, 2020). A pronounced lignin flux maximum  
517 occurred during MWP-1B, coinciding with a period of enhanced discharge from the  
518 Amur River. This implies that hinterland permafrost thawing played a more important  
519 role in the land-ocean OM transport during the later deglaciation, which may have had  
520 an impact on the oxygen content and nutrient concentration in the Okhotsk Sea  
521 Intermediate Water in the MWP-1B (Lembke-Jene et al., 2017).

522 MARs decrease drastically after maxima in both the Okhotsk and Bering Seas  
523 (Fig. 2c, d). The Amur Basin was completely covered with permafrost during the

524 LGM (Vandenbergh et al., 2014) and almost all of the permafrost was lost until today  
525 as a result of permafrost mobilization today. Thus, the contribution of permafrost OM  
526 from the Amur Basin to the marine sediment began to decrease in the early Holocene  
527 in agreement with the results of Seki et al. (2012).

528 In summary, the permafrost of the Amur Basin began to be remobilized in the PB  
529 later than in the Yukon Basin. We suggest that this was caused by decreased sea ice or  
530 increased SST in the Bering Sea during the ED, while the Okhotsk Sea remained ice-  
531 covered. We found that during the last deglaciation, lignin and Alk were supplied  
532 from land to the ocean via the same combined processes in the Yukon and Amur  
533 Basins, including surface runoff and coastal erosion.

## 5.2. Vegetation changes in the two river basins

### 5.2.1. Yukon River Basin

534 As the climate warmed during the transition from the LGM to the ED, moisture  
535 increased and an increasing number of thermokarst lakes developed in Alaska,  
536 especially after about 16–14 ka BP (Bigelow, 2013; Walter et al., 2007). We observe  
537 an increase in S/V ratios from the ED to the B/A, indicating increasing contributions  
538 of angiosperms around this time, extending into the B/A (Fig. 4, Ia). The S/V and C/V  
539 ratios are also influenced by the degradation of lignin, with increasing ratios  
540 suggesting a lower degradation state (Hedges et al., 1988; Otto and Simpson, 2006),  
541 but there is no parallel decrease in the more commonly used degradation indicator, i.e.,  
542 the Ad/Al ratios, at the same time (Fig. 4, Ie, f). As the permafrost had begun to be  
543 remobilized in the Yukon Basin during the ED, the S/V suggests that the cover of  
544 angiosperms in this basin increased.

545 During the transition of ED-B/A, the rate of sea level change was rapid, implying  
546 that the distance of our study site to the river mouth must have changed. The degree  
547 of OM degradation, however, did not change significantly at the same time (Fig. 4, e,  
548 f). Reports that the degradation degree of Lena River-derived OM and surface  
549 sediments of Buor Khaya Bay are similar (Winterfeld et al., 2015) suggest that the  
550 oxidative degradation of lignin occurred mainly on land, in agreement with our results.  
551 We thus posit that transport within the ocean that might have increased in distance and  
552 duration in response to the sea level change may only have a limited impact on OM  
553 degradation in the Bering Sea. The S/V and C/V can thus be regarded to mainly  
554 reflect vegetation development in the transition of ED-B/A. Anderson et al. (2003)  
555 also found birch pollen becoming significantly more prevalent after about 16 ka BP

556 from western Alaska to the Mackenzie River, suggesting that these regions were  
557 characterized by glacier retreating and more favorable climatic conditions. Coevally,  
558 the Paq index (Fig. 4, Ic) shows an increase, indicating wetland expansion.

559 There is evidence that herb-dominated tundra was replaced by *Betula-Salix*  
560 (birch-willow) shrub tundra around Trout Lake (the northern Yukon) during the B/A  
561 (Fritz et al., 2012) as the climate warmed and became more humid than during the ED.  
562 In line with these observations, our C/V ratios indicate that the contribution of non-  
563 woody plant tissues was lower in the B/A than in the ED (Fig. 4, Ib).

564 After the B/A, the summer temperatures during the YD dropped by ~1.5 °C  
565 (Fritz et al., 2012), thus cold-adapted non-arboreal plants briefly increased in  
566 abundance (Fritz et al., 2012). The S/V ratios indicate that the non-woody angiosperm  
567 plants' contribution reached a maximum in the Yukon Basin during the YD-PB  
568 transition (Fig. 4, Ia). The MARs of biomarkers in the Bering Sea also reached  
569 maxima during this transition (Fig. 2, c). Since the opening of the Bering Strait (~11  
570 ka BP, Jakobsson et al., 2017), a trend of increase in *Betula* (birch) was observed in  
571 eastern Beringia (Fritz et al., 2012; Kaufman et al., 2015) which indicates a  
572 progressively more maritime climate developing in response to changes in the marine  
573 environment (Igarashi and Zharov, 2011). Vegetation resuscitation and permafrost  
574 remobilization both contribute to the biomarker MARs (Fig. 2, c). The BIT values  
575 higher than 0.3 from 13 ka BP to 10.5 ka BP (Fig. 3, Ic) further support this  
576 interpretation while at the same time indicating that in these intervals,  $TEX_{86}^L$  cannot  
577 be used to reflect the sea surface temperature change during this interval. Additionally,  
578 the intensification of oxygen minimum zones in the Bering Sea during the B/A (Fig.  
579 2c) may be related to the increase in surface runoff (freshwater and OM fluxes; Kuehn  
580 et al., 2014).

581 Since vegetation responds to changes in both temperature and moisture,  
582 significant *Populus/Salix* (cottonwood/willow) woodland development occurred in  
583 interior Alaska and the Yukon Territory during the early Holocene (Anderson et al.,  
584 2003). However, the expansion of these angiosperm plants is not reflected in our S/V  
585 record (Fig. 4, Ia), the interpretation of S/V ratios may be complicated by the  
586 influence of degradation processes during the early Holocene. Pollen assemblages  
587 from northern Siberian soils have shown that woody plants occurred only after the  
588 onset of the Holocene (Binney et al., 2009), which agrees with a decrease in the C/V  
589 ratios since the early PB into the early Holocene (Fig. 4, Ib).

590 We compare our S/V and C/V ratios with published values from sediment cores,  
591 surface sediments and suspended materials in the Arctic and subarctic (Fig. 5). Such  
592 plots can help to identify the main types of plant tissues the lignin phenols are derived  
593 from, and enable the detection of potential degradation effects.

594 The S/V and C/V ratios from our Bering Sea core compare favorably with those  
595 from a core recovered from the Chukchi shelf covering parts of the B/A and the YD as  
596 well as the late Holocene (Martens et al., 2019) (Fig. 5). This may suggest that a  
597 similar type of vegetation prevailed across much of Beringia. After the opening of the  
598 Bering Strait, Pacific waters flowed into the Chukchi Sea, and it is conceivable that  
599 the terrestrial material transported to the Bering Sea by the Yukon River may have  
600 been in part transported into the Chukchi Sea. The top of our core dates to the early  
601 Holocene, a period that was characterized by more widespread broad-leaf angiosperm  
602 vegetation than today, which might explain the offset between our early Holocene S/V  
603 and C/V ratios and those reported for Yukon River surface sediment (S/V: 0.28, C/V:  
604 0.14) (Feng et al., 2015) and dissolved organic carbon in the Yukon (S/V: 0.47, C/V:  
605 0.14) (Amon et al., 2012) at present. Degradation of lignin in sediments may explain  
606 some of the discrepancies between sediment data and S/V and C/V ratios reported  
607 from suspended materials collected in the modern Lena River (Fig. 5). As the Amur  
608 River catchment is dominated by gymnosperms at present (Seki et al. 2014b), the S/V  
609 ratios of the Amur River and Okhotsk Sea surface sediments (Seki et al., 2014b) are  
610 lower than in the Bering Sea core (Fig. 5).

611 The highest values of the 3,5Bd/V ratio correlate with the enhanced degradation  
612 of lignin phenols around 17.5 ka BP (Fig. 4, Id). This suggests that degraded OM is  
613 the dominant source of the lignin phenols at this time, in agreement with previous  
614 studies (Meyer et al., 2016, 2019). Global melt water pulses according to Lambeck et  
615 al. (2014) occurred during the following periods: MWP-1A from 14.6 to 14.0 ka BP  
616 and MWP-1B from 11.5 to 10.5 ka BP. The 3,5Bd/V and (Ad/Al)<sub>s</sub> ratios decreased  
617 slowly from the ED to the MWP-1A, which indicates that the change in 3,5Bd/V  
618 values from the LGM to the early B/A reflects a variable degree of OM degradation,  
619 rather than expansion of wetlands or peatlands. The 3,5Bd/V also featured a short  
620 maximum during the late YD and early PB when the 3,5Bd/V signal is likely  
621 dominantly ascribed to increases in wetland or peatland sources, as there is no parallel  
622 maximum in Ad/Al ratios (Fig. 4, Id, e, f).

623 This pattern of 3.5 Bd/V change is not in agreement with the Paq ratio  
624 determined for the same core earlier (Meyer et al., 2019), although both proxies may  
625 reflect wetland expansion (Goñi et al., 2000b; Amon et al., 2012). The temporal  
626 evolution of Paq is similar to that of S/V and C/V, where Paq began to increase in the  
627 ED and reached its maximum in the YD-PB transition (Fig. 4, 1c), indicating that the  
628 proxies are influenced to some extent by degradation.

629 The Ad/Al ratios decreased when the biomarker MAR peaked during MWP-1B  
630 (Fig. 4, IIe, f) which may correspond to better preservation during rapid burial, or  
631 higher contribution of ICD OM and fresh angiosperm debris. This better preservation,  
632 is in agreement with previous studies (Anderson et al., 2003; Meyer et al., 2019).  
633 Kuehn et al. (2014) found that increases in biological export production and  
634 remineralization of OM in the Bering Sea during the B/A and PB reduced oxygen  
635 concentration to below 0.1 ml L<sup>-1</sup> and caused the occurrence of laminated sediments  
636 (Fig. 2c). This anoxic condition in the Bering Sea during the B/A and PB also slowed  
637 down rates of OM decomposition and increased the accumulation of OM.

638 In summary, our data together with published evidence indicate that in the Yukon  
639 Basin, vegetation change and wetland expansion began in the ED. Angiosperm plant  
640 contribution and wetland extent all reached their maxima during the PB, both  
641 decreasing and stabilizing at lower levels after the PB. During the PB, terrigenous  
642 OM appeared least degraded, suggesting rapid supply and burial of rather well-  
643 preserved terrigenous OM.

### 5.1.2. Amur River Basin

644 The lowest contribution of non-woody angiosperms as indicated by low S/V and C/V  
645 ratios occurred at 16.6 ka BP (Fig. 4, IIa, b). Subsequently, both ratios increased and  
646 reached maxima during the PB, suggesting the expansion of angiosperms and non-  
647 woody tissues contributing substantially to lignin. After the PB, the S/V decreased  
648 rapidly and remained stable during the Holocene, while the C/V ratio showed a  
649 second maximum at 9.2 ka BP suggesting an increasing contribution of non-woody  
650 angiosperms in the PB (Fig. 4, IIa, b). In agreement with our data, published lipid  
651 records provide evidence that the vegetation in the Amur Basin did not change  
652 significantly in the ED (Seki et al., 2012). Winterfeld et al. (2018) found a general  
653 synchronicity of Amur River discharge and the northward extent of monsoon  
654 precipitation in the early Holocene. Climate warming associated with high moisture

655 supply allowed the expansion of birch-alder forests in the Amur Basin in the PB  
656 (Bazarova et al., 2008; Igarashi and Zharov, 2011).

657 C/V and S/V ratios indicate that the contribution of non-woody gymnosperm  
658 tissue was higher in the early than in the later deglaciation (Fig. 6), similar to what has  
659 been reported from East Siberian Shelf records (Keskitalo et al., 2017). The YD caused  
660 only minor vegetation changes in the East Asian hinterland (Igarashi and Zharov,  
661 2011). Our lignin records for this period are in agreement with previous studies that  
662 indicated that the Lower Amur River basin mainly featured shrub birch-alder forests  
663 and rare *Pinus* (Bazarova et al., 2008; Seki et al., 2012).

664 Non-woody angiosperm plant contributions to the Okhotsk Sea sediment  
665 strongly increased during the PB (Fig. 4, IIa, b), when the summer insolation and  
666 regional temperatures reached the highest values since the LGM. Significant  
667 vegetation changes in the Amur Basin thus started in the PB period, temporally offset  
668 from the Yukon Basin, and the contribution of angiosperms from 14.6 ka BP to 9 ka  
669 BP appears to be higher than during the ED (Fig. 6). Bazarova et al. (2008) reported  
670 based on pollen analyses that a turning point in vegetation development in the Amur  
671 Basin occurred at a boundary of 10 ka BP. The Middle Amur depression registered the  
672 first appearance of broad-leaved species of pollen and a prevalence of spores over  
673 arboreal pollen at that time (Bazarova et al., 2008). The C/V ratio did not decrease as  
674 rapidly as the S/V ratio after the peak and showed a second maximum at ~9 ka BP.  
675 Some pollen of *Picea* (such as *P. glauca* and *P. mariana*) yield exceptionally high  
676 amounts of cinnamyl phenols (Hu et al., 1999), which may have affected the C/V ratio  
677 as the end member of woody/non-woody tissues. An et al. (2000) concluded that lakes  
678 were deepest and most extensive around 10 ka BP in northeastern China (the upper  
679 Amur basin), and 3,5Bd/V and Paq values reached maxima at the same time (Fig. 4,  
680 IIc, c) suggesting wetland extent peaked during the PB. Therefore, wetland plants that  
681 have broad leaves, such as sedges, may also have a positive influence on the C/V ratio.

682 The S/V and C/V data from the Holocene part of our core do not agree with  
683 published values for the Okhotsk Sea and Amur River surface sediments (Fig. 6).  
684 During the past 250 years, vegetation was marked by significant rises of  
685 gymnosperms, such as pines, combined with the reduction in the swamp area and a  
686 large increase in fire activity (Seki et al., 2014b), likely resulting in higher  
687 contributions of gymnosperm to the surface sediment while these changes are not  
688 resolved in the samples analyzed for our record.

689 The 3,5Bd/V and Paq ratios of the Okhotsk Sea both display relatively high  
690 values during the PB (Fig. 4, II<sup>d</sup>, c). Seki et al. (2012) found high Paq values during  
691 the PB in a nearby sediment core XP07-C9, and the values in their core were higher  
692 than in ours (Fig. 4, II<sup>c</sup>). Spores of Sphagnum show a distinct peak during the PB  
693 (Morley et al., 1991), reflecting an expansion of mesic and boggy habitats. Our  
694 records together with published evidence thus suggest that permafrost destabilization  
695 and wetland expansion in the Amur Basin occurred only at the beginning of the PB,  
696 while those processes were initiated much earlier in the Yukon basin.

697 The Ad/Al values were decreasing until 10.5 ka BP and reached minima during  
698 the PB (Fig. 4e, f), indicating that low temperatures on land on the one hand, and  
699 rapid burial in marine sediments during shelf flooding and coastal erosion during  
700 MWP-1B on the other hand, contributed to the Ad/Al signals. The 1 ka averages of  
701 the S/V, C/V ratios show similar minima as the Ad/Al ratios from the ED to the PB  
702 (Fig. 4II), suggesting that degradation processes exert a strong control on the S/V and  
703 C/V ratios during a time when vegetation did not change in the Amur Basin. In the  
704 course of climate amelioration from around 11.6 ka BP (Tarasov et al, 2009), the rates  
705 of vegetation development, wetland expansion and Amur River discharge (Fig. 2f) all  
706 displayed maxima in the PB. Generally, higher Ad/Al values in the later part of the PB  
707 suggest that fluvial runoff supplied more degraded lignin. Aerobic degradation of OM  
708 in soils by fungi has also been shown to increase Ad/Al values (Goñi et al., 1993).  
709 Since the oxidative degradation occurred mainly on land (Winterfeld et al., 2015), and  
710 lateral transport is likely short, this increased degradation is unlikely to occur in the  
711 ocean. The Okhotsk Sea shelf is narrower than the Bering Shelf and Siberian shelves,  
712 the lateral shelf transport times (i.e., the cumulative time a particle spends in  
713 sedimentation-resuspension cycles) of the Okhotsk shelf are therefore likely to be  
714 much shorter than what has been reported for the Laptev Shelf (Bröder et al., 2018),  
715 further supporting our interpretation.

716 The rate of sea level change in the Bering Sea (Manley, 2002) is slower than the  
717 global average rate (Lambeck et al., 2014). The effect of sea level change on the  
718 degradation process of terrestrial OM in the Bering Sea is limited. We are not aware  
719 of a published local reconstruction of sea level change for the Okhotsk Sea from 20 ka  
720 BP to the present, but we suggest that, since the shelf of the Okhotsk Sea is narrower  
721 than that of the Bering Sea, the effect of sea level change on the Okhotsk shelf may be  
722 neglected. Pre-aged OM and young OM can be transported from land to the marine

723 sediments in a variety of ways, such as coastal erosion and surface runoff, but the  
724 relative contribution of different carbon pools could not be quantified by lignin and  
725 Alk fluxes or other parameters (S/V, C/V, 3,5Bd/V, Ad/Al, and Paq), as they appear to  
726 be transported through the same pathways during the last deglaciation. Further  
727 investigation using compound-specific radiocarbon analysis is needed to quantify the  
728 contribution of different carbon pools in marine sediments.

729 In summary, our records indicate that in the Amur Basin vegetation change and  
730 wetland expansion began during the PB and in the early Holocene, in agreement with  
731 previous paleo-vegetation studies. This timing is different from observed changes in  
732 the Yukon Basin. However, similar to the Yukon Basin, the wetland extent and non-  
733 woody angiosperm contribution were reduced and stabilized after the PB in the Amur  
734 Basin. The increased vegetation and wetland indices, as well as increased degradation  
735 of lignin in the Okhotsk Sea sediment at the end of the PB, may be related to changes  
736 in the source of OM (shelf and coastal erosion *vs.* river transported material).

### **Conclusions:**

737 By analyzing mass accumulation rates of terrigenous biomarkers in sediments from  
738 the Bering and Okhotsk Seas, we provide the first downcore records of lignin from  
739 the Yukon and Amur Basins covering the early deglaciation to the Holocene. We find  
740 that vegetation changed earlier in the Yukon than in the Amur Basin. Although S/V,  
741 C/V and 3,5Bd/V ratios can reflect vegetation change and wetland development, the  
742 degradation state of lignin strongly overprints these proxy signals and should be  
743 considered as a function of temperature, transport distance and burial rate. Similar to  
744 changes in vegetation, we observe that degradation and remobilization of permafrost  
745 of the Yukon Basin also occurred earlier than in the Amur Basin. Sea-ice extent and  
746 SSTs of adjacent ocean areas might have had a strong influence on the timing of  
747 hinterland permafrost mobilization. Our study reveals that lignin transported by  
748 surface runoff may account for significant proportions of lignin during inland  
749 warming, but the export of lignin and lipids do not always occur via different  
750 pathways, as both biomarker groups can be contributed from rapidly eroding deep  
751 deposits during phases of rapid permafrost thaw. In contrast to modern day evidence  
752 suggesting different pathways for lipid and lignin biomarker transport, our records  
753 imply that during glacial peaks of permafrost decomposition, lipids and lignin might  
754 have been delivered to the ocean by identical processes, *i.e.*, runoff and erosion.

755 **Authors' contributions**

756 MC measured and compiled lignin data, and wrote the manuscript with the help of all  
757 co-authors. JH was responsible for all biomarker analyses. LLJ and RT provided  
758 samples. VM carried out sea surface temperature measurements of SO202-18-3/6.  
759 GM designed the study. All authors participated in the discussion of results and  
760 conclusions and contributed to the final version of the paper.

761 **Competing interests**

762 The authors declare that they have no conflict of interest.

763 **Acknowledgments**

764 We thank the masters and crews of R/V Sonne for their professional support during  
765 cruises SO202 (INOPEX) and SO178 (KOMEX). Hartmut Kuehn is acknowledged  
766 for providing total organic carbon and dry bulk density data of site SO202-18-3/6.  
767 Mengli Cao thanks the China Scholarship Council (CSC) and POLMAR- Helmholtz  
768 Graduate School for Polar and Marine Research for additional support. We are also  
769 grateful to the laboratory and computer staff at Alfred Wegener Institute. The  
770 biomarker data generated in this study are accessible at the database Pangaea:  
771 <https://doi.org/10.1594/PANGAEA.948376>.

1124  
1125 **Figure 1.** Study area. Red dots indicate locations of sediment cores investigated in this study;  
1126 black dots denote cores described in previous studies. 1: site MD01-2414 (Lattaud et al., 2019;  
1127 Lo et al., 2018). 2: site XP07-C9 (Seki et al., 2012). 3: site LV28-4-4 (Winterfeld et al., 2018).  
1127 4: site XP98-PC-2 (Seki et al., 2014a).

1128 **Figure 2.** Proxy records of terrestrial organic matter supply and environmental records of  
 1129 deglacial changes. (a) Greenland NGRIP  $\delta^{18}\text{O}$  (Rasmussen et al., 2008). (b) Global rate of  
 1130 sea-level change (Lambeck et al., 2014). (c) MAR of lignin phenols (blue) and HMW Alk  
 1131 (black; Meyer et al., 2019) from core SO202-18-3/6. (d) MAR of lignin phenols (blue) and  
 1132 HMW Alk (black; Winterfeld et al., 2018) from core SO178-13-6. Pin marks at the top of (c)  
 1133 and (d) show age control points, the accelerator mass spectrometry  $^{14}\text{C}$  dates for SO202-18-  
 1134 3/6 (Kuehn et al., 2014) and SO178-13-6 (Max et al., 2012). Brown bars in panel c indicate  
 1135 laminated/layered (anoxic) core sections (Kuehn et al., 2014). (e) Lignin flux from core 4-  
 1136 PC1 (Chukchi Sea, Martens et al., 2019). (f) Accumulation rate of chlorophycean freshwater  
 1137 algae *Pediastrum* spp. from core LV28-4-4 (Winterfeld et al., 2018). Blue boxes represent the  
 1138 cold spells the early deglaciation (ED) and Younger Dryas (YD), orange boxes are for the  
 1139 warm phases Bølling-Allerød (B/A) and Pre-Boreal (PB). Gray boxes highlight the periods of  
 1140 melt water pulse 1A (MWP-1A) and 1B (MWP-1B).

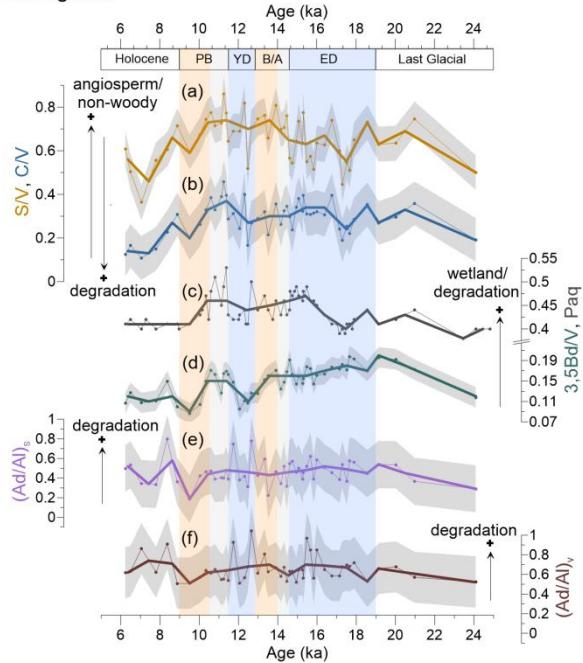

1141 **Figure 3.** Records of sea surface temperature (SST) and sea ice ( $IP_{25}$ ) in the Bering Sea and  
1142 Northeast Pacific, and Okhotsk Sea and Northwest Pacific during the past 25 ka. (a) NGRIP-  
1143  $\delta^{18}\text{O}$  from Greenland (Rasmussen et al., 2008). (b) MAR of biomarkers.

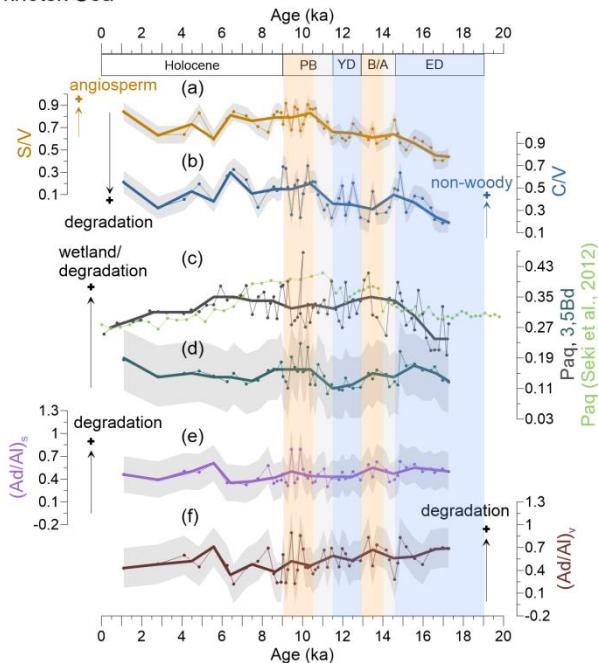

1144 I: (c) The green line reflects SST ( $TEX_{86}^L$ ), and the purple line shows the BIT from this study,  
1145 SO202-18-3/6. The orange line denotes the  $IP_{25}$  obtained for this core by Méheust et al.  
1146 (2018). (d) SST and  $IP_{25}$  for core SO202-2-114KL (Max et al., 2012; Méheust et al., 2016). (e)  
1147 SST and  $IP_{25}$  for core SO202-27-6 in the Northeast Pacific (Méheust et al., 2018). (f) SST for  
1148 core 85JC (Praetorius et al., 2015).

1149 II: (c) SST and  $IP_{25}$  of the core MD01-2414 in the Okhotsk Sea (Lattaud et al., 2019; Lo et al.,  
1150 2018). (d) SST for core XP98-PC-2 (Seki et al., 2014a). (e) SST and  $IP_{25}$  for core SO201-2-  
1151 12KL in the Northwest Pacific (Max et al., 2012; Méheust et al., 2016). (f) SST and  $IP_{25}$  for  
1152 core SO202-07-6 (Méheust et al., 2018). The units of the SST and  $IP_{25}$  are  $^{\circ}\text{C}$  and  $\mu\text{g g}^{-1}$   
1153 sediment, respectively. Blue boxes represent intervals with prevailing colder climate  
1154 conditions during the early deglaciation (ED) and Younger Dryas (YD), orange boxes are for  
1155 the warm phases Bølling-Allerød (B/A) and Preboreal (PB). Gray boxes highlight the periods  
1156 of melt water pulse 1A (MWP-1A) and 1B (MWP-1B).

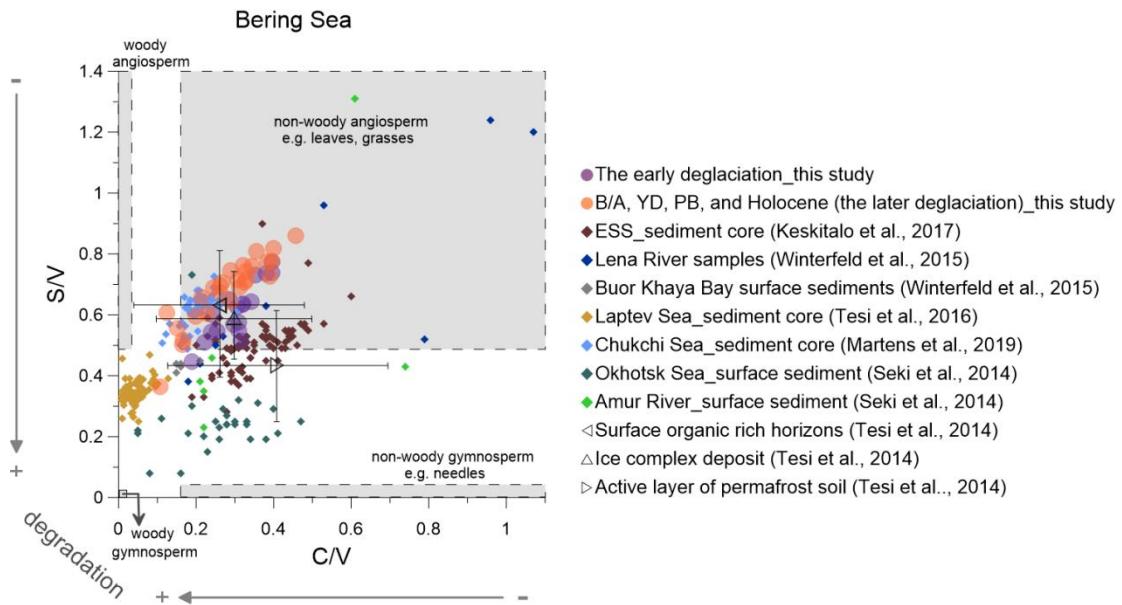

I. Bering Sea

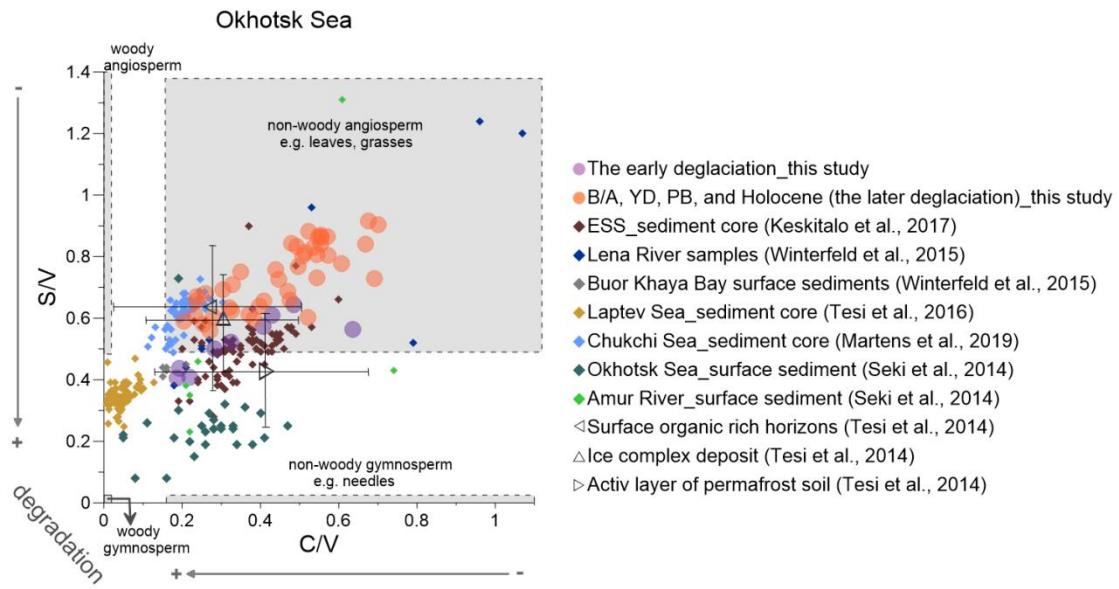

II. Okhotsk Sea

1157 **Figure 4.** Records of lignin and non-lignin phenol indices compared with the Paq index in  
1158 Bering and Okhotsk Sea sediments. (a and b): S/V and C/V ratios reflect the vegetation  
1159 change and/or degree of lignin degradation in the respective river basins. (c and d): 3,5Bd/V  
1160 and Paq ratios represent the wetland extent or degree of degradation in the respective  
1161 catchments. In panel II showing records from the Okhotsk Sea, the light green line represents  
1162 the Paq of a nearby core, XP07-C9 (Seki et al., 2012). (e and f): The Ad/Al can reflect the  
1163 degradation of lignin phenols. Grey shaded areas illustrate the uncertainty of these indices.  
1164 Bold lines are the 1 ka averages of the corresponding indices. Blue boxes represent the cold  
1165 spells the early deglaciation (ED) and Younger Dryas (YD), orange boxes are for the warm  
1166 phases Bølling-Allerød (B/A) and Pre-Boreal (PB). Gray boxes highlight the periods of melt  
1167 water pulse 1A (MWP-1A) and 1B (MWP-1B).

1168 **Figure 5.** Lignin indicators of terrigenous material in the Bering sediment (solid circles)  
1169 compared with previously studied (Martens et al., 2019; Keskitalo et al., 2017; Tesi et al.,  
1170 2016; Seki et al., 2014a; Winterfeld et al., 2015). The early deglaciation is from 19 to 14.6 ka  
1171 BP and after the early deglaciation is the later deglaciation. The dark triangles represent the  
1172 ratio of S/V and C/V from surface soils, Ice Complex deposits and active layer permafrost  
1173 (Tesi et al., 2014). ESS is short for the East Siberian Shelf.

1174 **Figure 6.** Lignin indicators of terrigenous material in the Okhotsk Sea sediment (solid circles)  
1175 compared with previously studied (Martens et al., 2019; Keskitalo et al., 2017; Tesi et al.,  
1176 2016; Seki et al., 2014a; Winterfeld et al., 2015). The early deglaciation is from 19 to 14.6 ka  
1177 BP and after the early deglaciation is the later deglaciation. The dark triangles represent the  
1178 ratio of S/V and C/V from surface soils, Ice Complex deposits and active layer permafrost  
1179 (Tesi et al., 2014). ESS is short for the East Siberian Shelf.
