## Abstract.

Boron isotopes in planktonic foraminifera are a widely used proxy to determine ancient surface seawater pH, and by extension atmospheric CO<sub>2</sub> concentration and climate forcing on geological time scales. Yet, to reconstruct absolute values for pH and CO<sub>2</sub>, we require a  $\delta^{11}\text{B}_{\text{foram-borate}}$  to pH calibration and independent determinations of ocean temperature, salinity, a second carbonate parameter, and the boron isotope composition of seawater. Although  $\delta^{11}\text{B}$ -derived records of atmospheric CO<sub>2</sub> have been shown to perform well against ice core-based CO<sub>2</sub> reconstructions, these tests have been performed at only a few locations and with limited temporal resolution. Here we present two highly resolved CO<sub>2</sub> records for the late Pleistocene from ODP Sites 999 and 871. Our  $\delta^{11}\text{B}$ -derived CO<sub>2</sub> record shows a very good agreement with the ice core CO<sub>2</sub> record with an average offset of  $13\pm 46$  (2 $\sigma$ ), and a RMSE of 26 ppm, with minor short-lived overestimations of CO<sub>2</sub> (of up to ~50 ppm) occurring during some glacial onsets. We explore potential drivers of this disagreement and conclude that partial dissolution of foraminifera has a minimal effect on the CO<sub>2</sub> offset. We also observe that the general agreement between  $\delta^{11}\text{B}$ -derived and ice core CO<sub>2</sub> is improved by optimising the  $\delta^{11}\text{B}_{\text{foram-borate}}$  calibration. Despite these minor issues a strong linear relationship between relative change in climate forcing from CO<sub>2</sub> (from ice core data) and pH change (from  $\delta^{11}\text{B}$ ) exists over the late Pleistocene, confirming that pH change is a robust proxy of climate forcing over relatively short (<1 million year) intervals. Overall, these findings demonstrate that the boron isotope proxy is a reliable indicator of CO<sub>2</sub> beyond the reach of the ice cores and can help improve determinations of climate sensitivity for ancient time intervals.

## 1- Introduction.

The boron isotope composition of ancient planktonic foraminifera shells is widely used to reconstruct past concentrations of atmospheric CO<sub>2</sub> to understand the drivers and responses of climate change over orbital and geological time scales. Unlike many environmental proxies where it is difficult to assess the accuracy of the resulting reconstructions (e.g. for sea surface temperature), the boron isotope pH/CO<sub>2</sub> proxy can directly be compared with the ice core CO<sub>2</sub> records, i.e. the West Antarctic ice sheet divide (Ahn et al., 2012), the EPICA (European Project for Ice Coring in Antarctica) dome Concordia ice core record (Siegenthaler et al., 2005; Lüthi et al., 2008; Bereiter et al., 2015), and the Vostock ice core record (Petit et al., 1999). This comparison of CO<sub>2</sub> over the last 800 kyr provides a very powerful test of proxy accuracy. Several past intervals have been studied to test the boron isotope proxy in this way

44 (Sanyal et al., 1995; Foster, 2008; Hönisch and Hemming, 2005; Henehan et al., 2013; Raitzsch et al.,  
45 2018).

46 Given the success of these comparisons, the boron isotope proxy has been used to investigate the  
47 interaction between CO<sub>2</sub>, the ocean carbon cycle and climate beyond the reach of the ice cores, such as  
48 during the Mid-Pleistocene transition (Hönisch et al., 2009; Chalk et al., 2017; Dyez et al., 2018), the  
49 Pliocene (Martinez-Boti et al., 2015, de la Vega et al., 2020), the Miocene (Foster et al., 2012; Greenop  
50 et al., 2014, Guillermic et al., 2022), the Eocene (Anagnostou et al., 2016, 2020; Harper et al., 2020),  
51 Paleocene-Eocene boundary (Penman et al., 2014; Gutjahr et al. 2017) and the Cretaceous-Palaeogene  
52 boundary (Henehan et al., 2019). Application of the boron isotope proxy is however complicated by the  
53 need for: (i) an empirical species-specific calibration of  $\delta^{11}\text{B}_{\text{foraminifera}}$  to  $\delta^{11}\text{B}_{\text{borate}}$  in the pH expression  
54 (Henehan et al., 2013, 2016, hereafter  $\delta^{11}\text{B}_{\text{foram-borate}}$  calibration), sometimes including extinct species  
55 for deep-time reconstruction; (ii)  $\delta^{11}\text{B}$  of seawater ( $\delta^{11}\text{B}_{\text{sw}}$ ), temperature and salinity in the past to  
56 calculate pH from  $\delta^{11}\text{B}$ ; and (iii) a second carbonate parameter (typically total alkalinity, dissolved  
57 inorganic carbon, DIC, or calcite saturation state) to convert pH to CO<sub>2</sub>. While these variables do not  
58 influence the magnitude of uncertainty equally in all time intervals, assessment of the boron-based  
59 reconstructions against existing ice-core records is a powerful test of the proxy's accuracy.  
60

61 Recently, Hain et al. (2018) suggested that the radiative forcing from CO<sub>2</sub> change ( $\Delta F_{\text{CO}_2}$ ) is linearly  
62 related to pH change ( $\Delta\text{pH}$ ) of equilibrated water of the low-latitude surface ocean when the CO<sub>2</sub> change  
63 occurs faster than the residence time of carbon with respect to silicate weathering (e.g., ~1 million years  
64 (Myr)). That is, glacial/interglacial CO<sub>2</sub> climate forcing could be estimated directly from reconstructed  
65  $\Delta\text{pH}$ . Given that one of the main priorities for accurate reconstructions of past CO<sub>2</sub> levels is to allow  
66 determinations of climate sensitivity, defined as the temperature response to a radiative forcing –  
67 typically a doubling of CO<sub>2</sub> with associated slow and fast feedbacks (e.g. Rohling et al., 2013, 2018) –  
68 this recognition may provide a useful shortcut. Climate forcing is a perturbation of the planet's energy  
69 balance averaged over the planet (Hansen et al., 2008) and CO<sub>2</sub> forcing,  $\Delta F_{\text{CO}_2}$  expressed in  $\text{W}\cdot\text{m}^{-2}$ , at a  
70 given time can be written as:

$$71 \quad \Delta F_{\text{CO}_2} \cong \alpha_{2\times\text{CO}_2} * \frac{\Delta \log_{10} \text{CO}_2}{\log_{10} 2} \quad (1)$$

72 where  $\alpha_{2\times\text{CO}_2}$  is the sensitivity of the radiative balance per doubling of CO<sub>2</sub>, and  $\Delta \log_{10} \text{CO}_2$  is the CO<sub>2</sub>  
73 change over time expressed in terms of how many 10-foldings of proportional (not absolute) CO<sub>2</sub>  
74 change (Hain et al., 2018).  
75

76 By considering basic equilibrium reactions of carbon species,  $\Delta \log_{10} \text{CO}_2$  can be derived and expressed  
77 as:

$$78 \quad \Delta \log_{10} \text{CO}_2 \cong \Delta \log_{10} \text{DIC} + \Delta \text{p}K_0 + \Delta \text{p}K_1 - \Delta \text{pH} \quad (2)$$

81 Hain et al. (2018) showed that the terms  $\Delta \log_{10} \text{DIC}$  and  $\Delta \text{p}K_0 + \Delta \text{p}K_1$  are small and that  $\Delta \log_{10} \text{CO}_2$  can  
82 therefore simply be expressed as :

$$83 \quad \Delta \log_{10} \text{CO}_2 \cong -\Delta \text{pH} \quad (3a)$$

$$84 \quad \Delta F_{\text{CO}_2} \cong -\frac{\log_{10} 2}{\alpha_{2\times\text{CO}_2}} \Delta \text{pH} \cong -12.3 \Delta \text{pH} \quad (3b)$$

87  
88 To assess the uncertainty of this approximate -1:1  $\Delta \log_{10} \text{CO}_2 / \Delta \text{pH}$  relationship Hain et al. (2018)  
89 considered three different end-member causes to compute the accurate  $\Delta \log_{10} \text{CO}_2 / \Delta \text{pH}$  relationship:  
90 (1) DIC addition/removal yields a slope of -1.3:1 (relative to the basic formalism), (2) CaCO<sub>3</sub>  
91 addition/removal (e.g. precipitation/dissolution, riverine input) yields a slope of -0.9:1, and (3)  
92 warming/cooling yields a slope of -1.1:1. That is, even if  $\Delta \text{pH}$  was known exactly this range of  
93 plausible slopes results in estimated  $\Delta \log_{10} \text{CO}_2$  and  $\Delta F_{\text{CO}_2}$  that are systematically biased by -10% for  
94 change caused purely by CaCO<sub>3</sub> variations or +30% for change purely caused by DIC variations

95 relative to the approximate -1:1  $\Delta\log_{10}\text{CO}_2/\Delta\text{pH}$  relationship. While introducing such structural  
96 uncertainty in the estimation of  $\Delta F_{\text{CO}_2}$  is a concern, this approach eliminates the need to assume a  
97 second carbonate system parameter and the uncertainty incurred thereby. An estimate of  $\delta^{11}\text{B}_{\text{sw}}$  is still  
98 needed to reconstruct pH based on the boron isotope proxy system (Foster and Rae, 2016) but  
99 estimated pH change (i.e.,  $\Delta\text{pH}$ ) is much less sensitive to error in assumed  $\delta^{11}\text{B}_{\text{sw}}$  than is absolute pH  
100 (Hain et al., 2018). An important caveat to estimating  $\Delta F_{\text{CO}_2}$  directly from  $\Delta\text{pH}$  is that the intercept of  
101 the  $\Delta\log_{10}\text{CO}_2/\Delta\text{pH}$  relationship can change with silicate weathering carbon cycle dynamics thought  
102 to be important on a million-year timescale, such that the approach is applicable for orbital timescale  
103 variability and short-term shifts but not for long-term trends in  $\Delta F_{\text{CO}_2}$ . Therefore, the orbital timescale  
104 ice age cycles of atmospheric  $\text{CO}_2$  reconstructed from air occluded in Antarctic ice cores offer a  
105 unique opportunity to determine the  $\Delta\log_{10}\text{CO}_2/\Delta\text{pH}$  relationship observationally and compare to  
106 theory. Furthermore, given the principal drivers of the glacial-interglacial  $\text{CO}_2$  cycles (e.g. change in  
107 water masses, sea-ice cover, the soft tissue pump, the solubility pump, the  $\text{CaCO}_3$  counter pump and  
108 the disequilibrium pump; see Sigman et al., 2010; Hain et al., 2010, 2014 for a full review), will  
109 impact the  $\Delta\log_{10}\text{CO}_2/\Delta\text{pH}$  relationship in different ways, comparing the slope of the regressed  
110  $\Delta F/\Delta\text{pH}$  line from data to theoretical endmembers (temperature, DIC,  $\text{CaCO}_3$ ) could allow the  
111 primary controlling mechanisms during Glacial-Interglacial (G-IG) cycles to be deciphered.

112  
113 In light of these recent advances, our aims here are twofold. First, we extend previous ice-core validation  
114 studies (Foster, 2008; Henehan et al. 2013; Chalk et al., 2017) and test the extent to which boron  
115 isotopes reconstruct  $\text{CO}_2$  faithfully when current methods and assumptions are applied. In contrast to  
116 most previous studies, we use two deep ocean sites and present  $\delta^{11}\text{B}$  and  $\text{CO}_2$  data at high temporal  
117 resolution (1 sample every  $\sim 3$  to 6 kyr). This enables: (i) a thorough test of the assumptions typically  
118 made including the central tenet of atmospheric  $\text{CO}_2$  proxies that surface ocean  $\text{CO}_2$  remains in  
119 equilibrium with the atmosphere over time at any given site, (ii) an evaluation of the overall uncertainty  
120 of the proxy; (iii) an evaluation of the influence of variable foraminiferal preservation on the accuracy  
121 of the  $\text{CO}_2$  reconstructed; and (iv) a refinement of a number of the input assumptions and uncertainties,  
122 including the  $\delta^{11}\text{B}_{\text{borate-foram}}$  calibration. Second, we evaluate the approach of Hain et al. (2018) and  
123 assess the robustness of pH change to not only provide insights into the magnitude of climate forcing  
124 from  $\text{CO}_2$  change, but also the ability of this approach to provide insights into the causes of  $\text{CO}_2$  change  
125 over glacial-interglacial cycles.

126

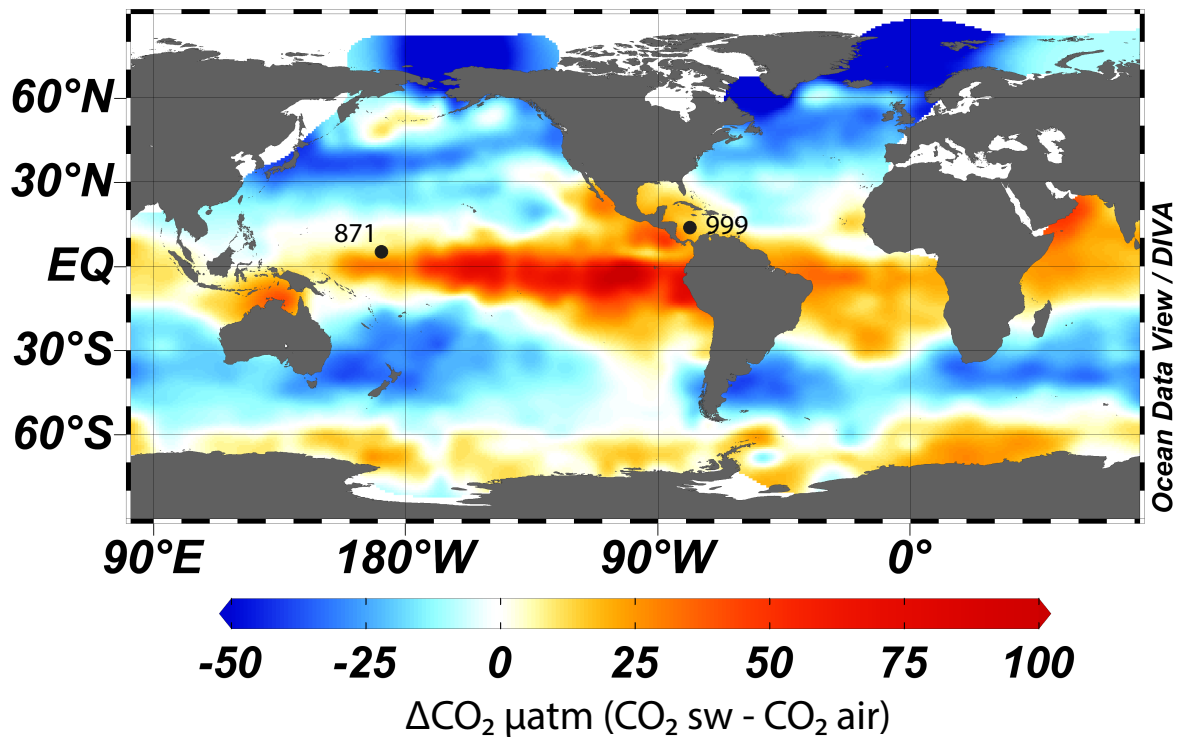

## 127 **2. Methods.**

### 128 **2.1 Core location and oceanographic setting.**

129 To accurately reconstruct atmospheric  $\text{CO}_2$  with the  $\delta^{11}\text{B}$ - $\text{CO}_2$  proxy, it is essential to measure  $\delta^{11}\text{B}$  in  
130 foraminifera from locations where the  $\text{CO}_2$  flux between the ocean and the atmosphere is in near  
131 equilibrium. We therefore target regions of the ocean where the water column is stratified and  
132 oligotrophic as these regions are most likely to attain this condition (Takahashi et al., 2009). Here,  
133 following previous studies (Foster, 2008, Henehan et al., 2013; Chalk et al., 2017), we report and add  
134 new data from ODP Site 999 (Figure 1, 12.75°N, 78.73°W, water depth 2827 m, sedimentation rate 3.7  
135 cm/ky) in the Caribbean and supplement this well studied site with samples from ODP Site 871 in the  
136 Western Pacific (5.55°N, 172.35°E, water depth 1255m, sedimentation rate  $\sim 1$  cm/ky). The sediments  
137 studied at ODP Site 871 are shallowly buried and the site today features a deep thermocline and is  
138 located off the equator, hence they are unlikely to be influenced by significant equatorial upwelling  
139 (Dyez and Ravelo, 2013, 2014). These two sites show a minor annual mean disequilibrium of +12 ppm  
140 (range  $\sim 0$  to  $\sim 30$  ppm, Takahashi et al., 2009) for ODP Site 871, and +21 ppm (Olsen et al., 2004;  
141 Foster, 2008) for ODP Site 999. These disequilibria are used to correct our  $\text{CO}_2$  data derived from  $\delta^{11}\text{B}$   
142 and are assumed to be constant throughout the entire record presented here (with an uncertainty of  $\pm 10$   
143 ppm).

144

145 Whilst we recognised that both sites have a minor disequilibrium, this is often a necessary  
 146 compromise as areas of the ocean that are in strict equilibrium with the atmosphere are often located  
 147 in the middle of oceanic gyres and tend to have deep sediments located under the lysocline, have a  
 148 low sedimentation rate and/or are outside the preferred geographic habitat of *G. ruber*. Furthermore,  
 149 we present surface  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  (site 871) and temperature (both sites) from *G. ruber* that provide  
 150 insight into the potential influence of upwelling (see section 4.2.2) at these locations. Recent Earth  
 151 System Model (IPSL-CM5A-MR) outputs (Gray and Evans, 2019) also show that relative pH  
 152 difference at our core sites between the last glacial maximum (LGM) and the pre-industrial (PI),  
 153 compared to the ocean average pH difference are close to 0, giving confidence that changes in local  
 154 disequilibrium are unlikely to drive large changes in our  $\text{CO}_2$  reconstructions (at least during the last  
 155 glacial period).

156  
 157  
 158  
 159 Figure 1. Map of air-sea  $\text{CO}_2$  disequilibrium (seawater – air) in ppm and location of ODP sites used in this study.  
 160  $\text{CO}_2$  data from Takahashi et al. (2009). The map was made with Ocean Data View (Schlitzer, 2022).

## 161 2.2 Samples.

### 162 2.2.1 Sample selection and preparation.

163 Samples of deep-sea sediment from our two study sites were taken at 6cm (~3ky) and 10cm (~6ky)  
 164 resolution at ODP 871 and 999 respectively. Around 1-2 mg of the foraminifer (between 120 and 200  
 165 individuals) from the species *Globigerinoides ruber sensu stricto white* (here after *G. ruber ss*) were  
 166 hand-picked from the size fraction 300-355  $\mu\text{m}$  for a target of 10 to 20 ng of boron. *G. ruber ss* was  
 167 chosen here because it is readily identified, is abundant throughout our chosen time interval and a  
 168  $\delta^{11}\text{B}_{\text{foram-borate}}$  calibration that accounts for vital effects is available from culture, plankton tows and core-  
 169 top samples (Henehan et al., 2013). It is also known to live in the upper surface of the ocean with a  
 170 relatively small depth range (Rebotim et al., 2017) which prevents significant influence of deeper more  
 171 remineralised  $\text{CO}_2$ -rich waters on the measured  $\delta^{11}\text{B}$ . The morphotype *G. ruber sensu lato* (hereafter  
 172 *G. ruber sl*) has slightly different morphology (Aurahs et al, 2011; Carter et al., 2017) and is thought to  
 173 live in deeper water compared to *G. ruber ss* (Wang, 2000). The morphotype *G. ruber sl* was also hand

174 separated and analysed at lower resolution at ODP 871 to monitor any change over time in morphotype  
175 differences in  $\delta^{11}\text{B}$  that could result from different habitats. For similar reasons, carbon and oxygen  
176 isotopes ( $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$ ) were also measured on *G. ruber ss* and *sl* for comparison on the whole record  
177 at ODP 871. For this, around 10 individuals of *G. ruber* per sample were picked, their shells gently  
178 broken open and mixed and then a 100  $\mu\text{g}$  aliquot of the homogenised carbonate was measured using a  
179 Thermo KIEL IV Carbonate device at the University of Southampton, Waterfront Campus. . While this  
180 number of specimens is lower than classically done for  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  analysis, it provides power for  
181 the identification of species-specific preferential diagenetic alteration, which may have occurred in the  
182 sediment and it was sometimes necessary due to the scarcity of some of the *G. ruber* spp morphotypes.  
183

#### 184 2.2.2 Age constraints.

185 Samples were taken from 1.5 to 5 metres below sea floor (mbsf) for ODP 871 and from 9 to 21 mbsf  
186 for ODP 999. Sample age at Site 871 was initially determined from sample depth using published age  
187 models (Dyez and Ravelo, 2013). At Site 999, the age was determined by developing a new  
188 *Cibicidoides wuellerstorfi* benthic  $\delta^{18}\text{O}$  record. The initial age model at Site 871 was refined by  
189 measuring  $\delta^{18}\text{O}$  on the benthic species *Uvigerina peregrina* (50  $\mu\text{g}$  of 3-5 mixed, crushed, and  
190 homogenised specimens) measured on a Thermo KIEL IV Carbonate device at the University of  
191 Southampton, Waterfront Campus. These new  $\delta^{18}\text{O}$  data (Figure 2) were then tuned to the benthic  
192  $\delta^{18}\text{O}$  LR04 stack (Lisiecki and Raymo, 2005) using Analyseries (Paillard et al., 1996). A correction of  
193 +0.47 was applied to the  $\delta^{18}\text{O}$  *Cibicidoides wuellerstorfi* at ODP Site 999 following Marchitto et al.  
194 (2014).

195

#### 196 2.2.2 Fragment counts.

197 Foraminifera fragment counts were conducted on ODP Site 871 to monitor variations in carbonate  
198 preservation. Samples were sub-sampled using a splitter (in order to maintain homogeneity) and poured  
199 onto a picking tray. The fragmentation index (FI) was calculated following the approach of Howard and  
200 Prell (1994) and Berger (1970) where percentage fragment is defined as:  
201

$$202 \quad FI = 100 * \frac{\text{number of fragments}}{\text{number of fragments} + \text{number of whole tests}} \quad (4)$$

203

204 Counts of whole intact grains and fragments of grains were conducted three times and averaged. The  
205 standard deviation ( $1\sigma$ ) of the fragmentation index is 1.69. This approach followed that used in an early  
206 study at ODP Site 999 (Schmidt et al. 2006) ensuring that the datasets between the two sites are  
207 comparable.

#### 208 2.2.3 Boron separation.

209 The hand separated foraminifera tests for boron isotope analysis were broken open, detrital clay was  
210 removed, and oxidatively cleaned and leached in a weak acid to obtain a primary carbonate signal  
211 using established methods (Barker et al., 2003). Samples were then slowly dissolved in  $\sim 100 \mu\text{l}$   
212 0.5M  $\text{HNO}_3$  added to 200  $\mu\text{l}$  of MQ water. Dissolved samples were then centrifuged for 5 minutes to  
213 separate any remaining undissolved contaminants (e.g. silicate grains, pyrite crystals) and transferred  
214 to screw top 5 ml Teflon pots for subsequent boron separation. An aliquot equivalent to 7% of each  
215 sample was kept for elemental analysis and transferred to acid cleaned plastic vials in 130  $\mu\text{l}$  0.5M  
216  $\text{HNO}_3$ . Samples were purified for boron using anion exchange column chemistry method prior to  
217 isotope analysis as described elsewhere (Foster, 2008). A total procedure blank (TPB) was conducted  
218 for each batch of samples and typically ranged from 0 to 100 pg which represents a blank contribution  
219 of up to 2.3% (for samples containing  $\sim 10\text{-}20 \text{ ng}$  of boron). Most samples had a TPB below 40 pg

220 and were not corrected. Two batches had a TPB of 70 and 100 pg for which we corrected using a  
221 long-term median TPB  $\delta^{11}\text{B}$  value of -7.27‰ from the University of Southampton. This represents a  
222  $\delta^{11}\text{B}$  correction of 0.1 to 0.7 ‰.

### 223 2.3 Analytical techniques

224 Boron isotope analyses were performed on a ThermoScientific Neptune multi collector inductively  
225 coupled plasma mass spectrometer (MC-ICPMS) with  $10^{12} \Omega$  amplifier resistors using a standard-  
226 sample bracketing routine with NIST 951 boric acid standard (following Foster et al. 2013 and Foster,  
227 2008). Elemental analysis was performed on each dissolved sample using a ThermoScientific Element  
228 inductively coupled plasma mass spectrometer (ICPMS). All analyses were carried out at the University  
229 of Southampton, Waterfront Campus (following Foster, 2008 and Henehan et al., 2015). Element to  
230 calcium ratios were measured with  $^{43}\text{Ca}$  and  $^{48}\text{Ca}$  and measured against in house mixed element  
231 standards. Elemental ratios measured included: B/Ca, Mg/Ca, Al/Ca, Mn/Ca, Sr/Ca. Based on the  
232 reproducibility of our in-house standards, the uncertainty for most elemental ratios is  $\sim 5\%$  (at 95%  
233 confidence).

### 234 2.4 Constraints on $\delta^{11}\text{B}$ -derived pH and $\text{CO}_2$ .

#### 235 2.5.1 From $\delta^{11}\text{B}$ to pH.

236 Seawater pH is related to the boron isotopic composition of dissolved borate ion by the following  
237 equation:

$$238 \quad \text{pH} = \text{p}K_B - \log \left( - \frac{\delta^{11}\text{B}_{\text{sw}} - \delta^{11}\text{B}_{\text{borate}}}{\delta^{11}\text{B}_{\text{sw}} - \alpha_B * \delta^{11}\text{B}_{\text{borate}} (\alpha_B - 1)} \right) \quad (5)$$

240 where the isotopic fractionation factor  $\alpha_B$  between  $\text{B}(\text{OH})_3$  and  $\text{B}(\text{OH})_4^-$ , is 1.0272 as determined by  
241 Klochko et al. (2006) and the  $\delta^{11}\text{B}$  of seawater is 39.61 ‰ (Foster et al., 2010) for both sites and kept  
242 constant throughout the record due to the long residence time of boron (10-20 Myrs, Lemarchand et al.  
243 2002).

244  
245  
246  
247 The sea surface temperature (SST) values necessary to calculate  $\text{p}K_B$  in equation (5) were determined  
248 at both sites using the Mg/Ca of *G. ruber* (Dyez and Ravelo, 2013) including a depth-dependent  
249 dissolution correction for each site (following Dyez and Ravelo, 2013 for Site 871 and Schmidt et al.,  
250 2006 for Site 999) and a pH correction using the iterative approach of Gray and Evans (2019) to account  
251 for the observed pH effect on Mg/Ca in *G. ruber* producing higher apparent sensitivity of Mg/Ca during  
252 glacial cycles (Gray et al., 2018).

253  
254 Mg/Ca was corrected for depth-dependent dissolution at Site 871 using the following equation (Dyez  
255 and Ravelo, 2013):

$$256 \quad \frac{\text{Mg}}{\text{Ca}} (\text{corrected}) = \frac{\text{Mg}}{\text{Ca}} (\text{measured}) + 0.26 * \text{depth} + 0.52 \quad (6a)$$

257 Mg/Ca from Site 999 was corrected following Schmidt et al. (2006):

$$258 \quad \frac{\text{Mg}}{\text{Ca}} (\text{corrected}) = \frac{\text{Mg}}{\text{Ca}} (\text{measured}) + 0.66 \quad (6b)$$

259

260 To evaluate the effect of various Mg/Ca treatment on temperature and calculated CO<sub>2</sub>, we performed  
 261 seven sensitivity tests (Table S1) with Mg/Ca-derived SST using the calibrations of: (1) Gray et al.  
 262 (2018) temperature-dependent only (global calibration), (2) Gray and Evans (2019) with a pH  
 263 correction; (3) Gray et al. (2018) temperature-dependent with Mg/Ca corrected for depth-dependent  
 264 dissolution; (4) Gray and Evans (2019) with Mg/Ca corrected for depth-dependent dissolution and pH  
 265 correction; (5,6) Anand et al. (2003) with and without a depth correction; and (6) with temperature  
 266 kept constant (26°C).

267 The differences in SST and resulting CO<sub>2</sub> can be substantial (Figure S1, Table S2): up to 6 degrees  
 268 and ~50 ppm, respectively, between the Gray et al. (2018) calibration uncorrected for pH and the  
 269 Anand et al. (2003) calibration corrected for dissolution. We have chosen the Mg/Ca treatments that  
 270 accounts for pH effect on Mg/Ca and yields the closest agreement between coretop at both sites and  
 271 modern temperature from Glodap v2 (Lauvset et al., 2022) This treatment is with a pH correction and  
 272 Mg/Ca corrected for depth-dependent dissolution. Choosing this approach is justified considering (1)  
 273 the strong offset between Anand et al. (2003) multi-species Mg/Ca-Temperature calibration and the  
 274 more recent *G. ruber* compilation of Gray et al., (2018); (2) the effect of pH correction as shown in  
 275 Gray et al., (2018) and Gray and Evans (2019); (3) the suggested influence of dissolution on Mg/Ca  
 276 (Dyez and Ravelo, 2013; Schmidt et al., 2006) and (4) the better agreement between coretop and  
 277 modern SST at each site when using a pH and depth correction (Figure S1).

278 The salinity (S) that is used in the expression of pK<sub>B</sub> is kept constant for both sites (35) due to the very  
 279 minor effect of salinity on calculated pH/CO<sub>2</sub> (1 salinity unit changes pH by 0.006 ).  
 280  
 281

## 282 2.5.2 From pH to CO<sub>2</sub>.

283 Calculating CO<sub>2</sub> from boron isotope derived pH is dependent on the determination of a second  
 284 parameter of the carbonate system. Here we use the modern value of total alkalinity (TA) at each site:  
 285 2279 and 2350 μmol/kg at ODP 871 and ODP 999, respectively (Shipboard Scientific Party, 1993;  
 286 Takahashi et al., 2009). Following Chalk et al. (2017), these values were kept constant throughout the  
 287 whole record. To account for any variations in alkalinity, a generous uniform (i.e. equal likelihood of  
 288 values within the range of uncertainty) uncertainty of 175 μmol/kg, distributed equally on either side of  
 289 the central value, is applied. This range in TA encompasses the likely range in this variable on glacial-  
 290 interglacial (e.g. Toggweiler, 1999; Hain et al., 2010; Cartapanis et al., 2018) or longer timescales  
 291 (Hönisch et al. 2009), and its adoption means the local TA record is not tied to a global sea-level record  
 292 as has been practiced previously. We avoid drawing this link because the ~+3% (+68μmol/kg)  
 293 concentration increase of solute alkalinity occurring from sea-level lowering during the last glacial  
 294 maximum may not have been the dominant driver of ocean alkalinity change (Boyle, 1988a/b; Sigman  
 295 et al., 1998; Toggweiler, 1999; Hain et al., 2010; Cartapanis et al., 2018). By assuming a uniform  
 296 distribution for TA we avoid imposing a temporal evolution to this variable because evolution of TA  
 297 through a glacial cycle is uncertain and is unlikely to be simply a function of sea-level or salinity (e.g.  
 298 Dyez et al. 2018) due to the effect of carbonate compensation.

299 The surface water CO<sub>2</sub> is then calculated as (Zeebe and Wolf-Gladrow, 2001):  
 300  
 301

$$302 \quad \text{CO}_2 = \frac{\text{TA} - \frac{K_B \cdot B_T}{K_B + [\text{H}^+]} - \frac{K_W}{[\text{H}^+]} + [\text{H}^+]}{\frac{K_1}{[\text{H}^+]} + \frac{2K_1 K_2}{[\text{H}^+]^2}} \quad (7)$$

303 where TA is the total alkalinity, K<sub>B</sub> the equilibrium constant of boron species in seawater, B<sub>T</sub> the  
 304 concentration of boron in seawater (432.6 μmol/kg, Lee et al., 2010), [H<sup>+</sup>] the concentration of H<sup>+</sup>  
 305 determined from pH = - log [H<sup>+</sup>], K<sub>W</sub> the dissociation constant of water (function of T, S and pressure),  
 306

307  $K_1$  and  $K_2$  the first and second dissociation constants of carbonic acid (function of T, S and pressure,  
 308 Luecker et al., 2000). The estimate of atmospheric  $\text{CO}_2$  includes site-specific offsets relative to  
 309 reconstructed surface water  $\text{CO}_2$  to account for observed local disequilibrium (+21 ppm and +12 ppm  
 310 at ODP Sites 999 and 871, respectively).

## 311 2.6 Uncertainty.

### 312 2.6.1 Analytical uncertainty.

313 The uncertainty on the measured  $\delta^{11}\text{B}$  is expressed as the external uncertainty which includes  
 314 instrumental error and chemical separation of the sample (see a detailed discussion in John and Adkins,  
 315 2010). This was determined empirically by long-term repeat measurements of JCp-1 subject to the same  
 316 chemical purification as our foraminiferal samples. As discussed by Rae et al. (2011) this uncertainty  
 317 is dependent on the intensity of the  $^{11}\text{B}$  signal and is expressed here by the following relationship defined  
 318 during the duration of this study at the University of Southampton (Anagnostou et al., 2019), for  $^{11}\text{B}$   
 319 intensities  $<0.54\text{V}$ :

$$320 \quad 2\sigma = 129600 e^{-212 \times [^{11}\text{B}]} + 0.3385 e^{-1.544 \times [^{11}\text{B}]} \quad (8).$$

321 where  $[^{11}\text{B}]$  is the intensity of  $^{11}\text{B}$  signal in volts. The  $\delta^{11}\text{B}$  uncertainty for  $^{11}\text{B}$  intensities  $> 0.54\text{V}$  is  
 322 0.15‰ (at 95% confidence).  
 323  
 324

### 325 2.6.2 pH and $\text{CO}_2$ uncertainty.

326 The  $\text{CO}_2$  uncertainty we report was calculated with a Monte Carlo simulation (10, 000 realisations) in  
 327 order to fully account for the uncertainty in all variables used in the calculation of pH and  $\text{CO}_2$  ( $\sigma_{\text{CO}_2}$   
 328  $\delta^{11}\text{B}$ -derived). The shape of the uncertainty distribution sampled is either normally distributed (for  
 329 temperature, salinity and  $\delta^{11}\text{B}$ ) or uniform (for alkalinity, as discussed above). The maximum  
 330 probability of all realisations was used as the central value for  $\text{CO}_2$  and an error envelope at 1 and  $2\sigma$   
 331 was calculated based on the 68% and 95% distribution of the realisations.  
 332

### 333 2.6.3 Uncertainty on the $\text{CO}_2$ offset.

334 To constrain the offset between  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  and ice core  $\text{CO}_2$ , each sediment age is compared to  
 335 the ice core  $\text{CO}_2$  record by interpolation of the record of highest resolution (in this case the  $\delta^{11}\text{B}$  record  
 336 onto the ice core compilation). To fully account for age uncertainty when interpolating the sediment  
 337 age to the well-dated ice core record, a distribution of the ice core data was calculated within the  $4\sigma$   
 338 uncertainty of the  $\delta^{11}\text{B}$  age and weighed by the respective likelihood based on the age difference  
 339 between ice core and sediment core.  
 340

341 The  $\text{CO}_2$  offset (or residual) is defined by:

$$342 \quad \text{Offset}_{\text{CO}_2} = \text{CO}_2_{\delta^{11}\text{B-derived}} - \text{CO}_2_{\text{ice}} \quad (9)$$

343 The uncertainty on this offset ( $\sigma_{\text{offset}}$ ) accounts for the uncertainty of the interpolated ice core  $\text{CO}_2$   
 344 ( $\sigma_{\text{CO}_2.\text{interpol}}$ ) and the one of the  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  ( $\sigma_{\text{CO}_2.\delta^{11}\text{B-derived}}$ ), such as :

$$345 \quad \sigma_{\text{offset}} = \sqrt{\sigma_{\text{CO}_2.\text{interpol}}^2 + \sigma_{\text{CO}_2.\delta^{11}\text{B-derived}}^2} \quad (10)$$

## 350 2.7 The relationship between $\delta^{11}\text{B}$ -derived pH and $\Delta\text{F}_{\text{CO}_2}$ .

351 The linear relationships between the relative  $\text{CO}_2$  forcing  $\Delta\text{F}_{\text{CO}_2}$  and pH are determined with a York  
352 regression (York et al., 2004) that accounts for the uncertainty in both the independent and dependent  
353 variable (i.e. x and y axes). The ice core  $\text{CO}_2$  interpolation used to calculate  $\Delta\text{F}_{\text{CO}_2}$  and uncertainty is  
354 determined as described in section 2.6.3 (Hain et al., 2018).

## 355 2.8 Optimising the *G. ruber* $\delta^{11}\text{B}$ borate-foraminifera calibration.

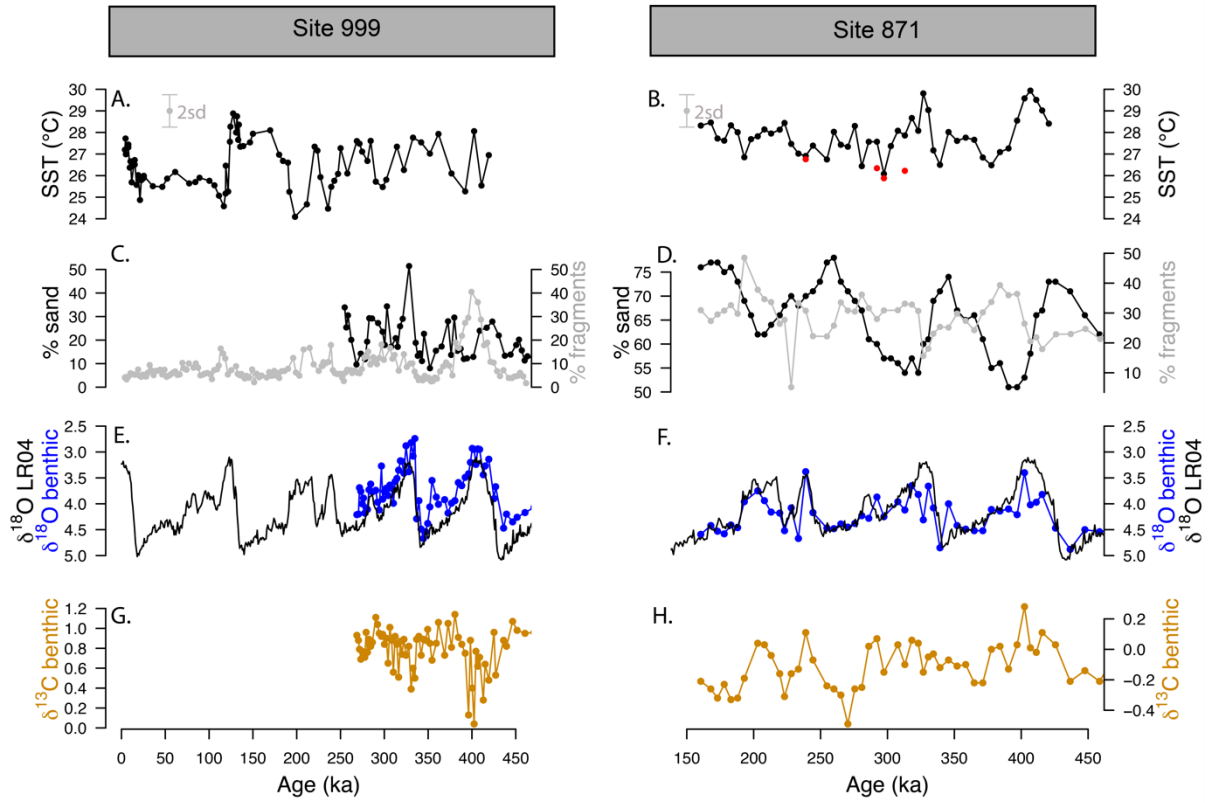

356 An optimised *G. ruber* calibration was obtained by minimising the root mean square error (RMSE) of  
357 the average offset between  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  and ice core  $\text{CO}_2$ . The steps are illustrated in Figure S2.  
358 In order to optimise the calibration, 10,000 simulations of  $\delta^{11}\text{B}_{\text{borate}}$  and  $\delta^{11}\text{B}_{\text{foraminifera}}$  from the calibration  
359 of Henehan et al. (2013) were performed within their normally distributed uncertainty ( $1\sigma$ ), from which  
360 we defined the same number of linear models each including their slope and intercept. Then, we  
361 calculate the equilibrium pH and resultant equilibrium  $\delta^{11}\text{B}_{\text{borate}}$  from ice core  $\text{CO}_2$  and the assumed  
362 constant TA at each core site. The  $\delta^{11}\text{B}_{\text{borate}}$  from the 10,000 linear models is then calculated and the  
363 difference to the ice core-derived  $\delta^{11}\text{B}_{\text{borate}}$  is determined. The linear model calibration that yields the  
364 minimum RMSE between these two borate variables defines the new  $\delta^{11}\text{B}_{\text{borate-foram}}$  calibration. To assess  
365 the effect of  $\delta^{11}\text{B}$  records from different sites we performed this exercise using the combined records  
366 (from both sites 999 and 871), 999 only and 871 only (Figure S3 ) and show that using a record from  
367 one particular site or the combination of sites yields similar  $\text{CO}_2$  offsets (Table S3) and so here we use  
368 the results from the combined sites. Unless indicated otherwise, to preserve a degree of independence,  
369 the pH results presented in this study are calculated with the published calibration (Henehan et al.,  
370 2013), and the results with the optimised calibration presented in section 4.2.6.

## 371 3 Results.

### 372 3.1 Temperature and fragment counts.

373 The SST at ODP Sites 999 and 871 show a cyclicity that agrees with the well-known glacial interglacial  
374 cycles of the late Pleistocene (Figure 2). The SST determined from *G. ruber sl* (red filled circles, Figure  
375 2B) at Site 871, show equal or cooler temperatures (by 1-2 °C) than *G. ruber ss* (black filled circles).  
376 The fragmentation index (Figure 2D) at ODP 871 range from 20 to 50 % and follow the well-  
377 documented “Pacific style” dissolution cycles (Sexton and Barker, 2012) with well-preserved carbonate  
378 (low fragments) during glacials and less well-preserved carbonates (higher fragments) during  
379 interglacials. The percentage sand typically anticorrelates with fragmentation counts at both sites,  
380 although it is less clear at ODP 999, perhaps due to the shorter record available. Fragmentation counts  
381 reach maxima at ODP 999 of 20 % during interglacials and up to 50 % during marine isotope stage MIS  
382 11 which is concomitant with the mid-Brunhes dissolution interval (MBDI, Barker et al., 2006). The  
383 fragmentation counts at ODP 871 show no substantive anomaly during the MBDI.

391 Figure 2. Mg/Ca derived temperature, coarse fraction (sand), fragmentation and benthic  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  at ODP  
392 sites 999 and 871. **A, B:** Temperature at ODP 999 (from *G. ruber ss*, black, Schmidt et al., 2006 and this study)  
393 and ODP 871 (*G. ruber ss*, black, *G. ruber sl*, red, 2sd indicated by the grey error bar). **C, D:** Fragmentation index  
394 (light grey, data from Schmidt et al. (2006) for ODP 999) and sand (black line). **E, F:** Benthic *C. wuellerstorfi* (Site  
395 999) and *U. peregrina* (Site 871)  $\delta^{18}\text{O}$  (blue) and LR04 benthic  $\delta^{18}\text{O}$  stack (black). A correction of +0.47‰ is  
396 applied to  $\delta^{18}\text{O}$  of *C. wuellerstorfi* data in order to adjust for species offset. **G, H:** Benthic *C. wuellerstorfi* (Site  
397 999) and *U. peregrina* (Site 871)  $\delta^{13}\text{C}$  (orange).

### 398 3.2 pH and CO<sub>2</sub> reconstructions.

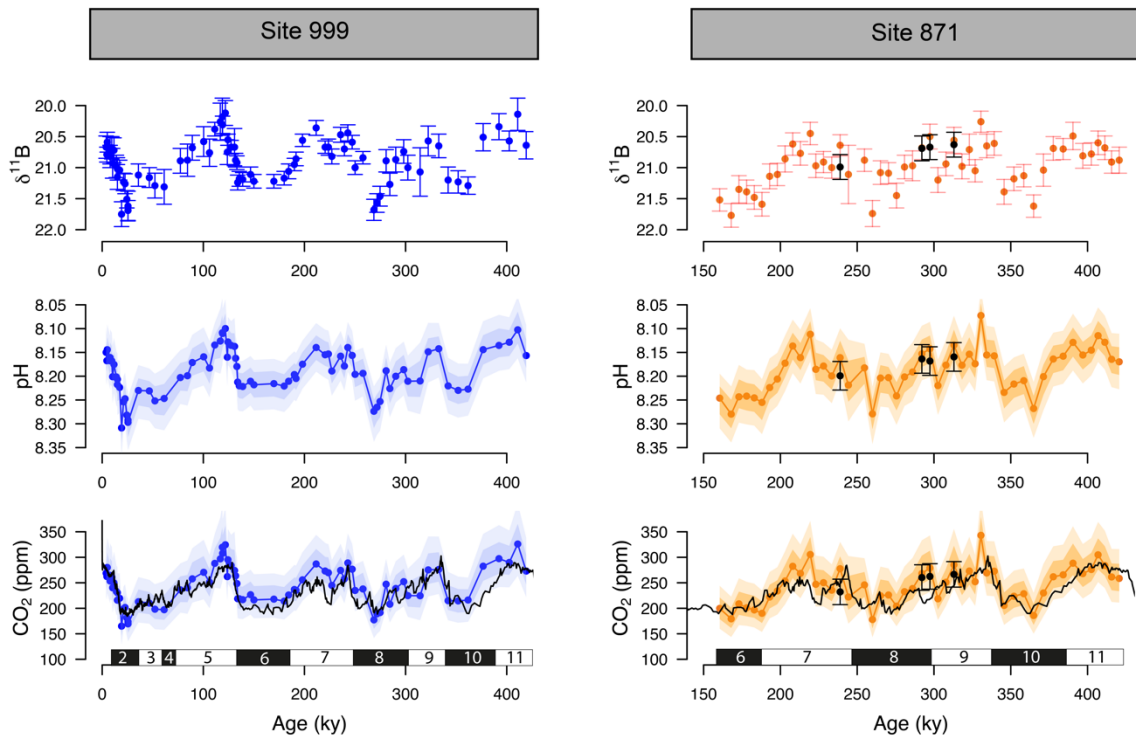

399 The  $\delta^{11}\text{B}$ , pH and  $\delta^{11}\text{B}$ -derived absolute CO<sub>2</sub> (Figure 3) from Sites 871 and 999, show clear cyclicity  
400 related to glacial-interglacial cycles. The CO<sub>2</sub> values carry an average uncertainty of  $\pm 48$  ppm and the  
401 mean offset from the ice core CO<sub>2</sub> for a combination of the two records is  $13 \pm 46$  ( $2\sigma$ ) ppm showing  
402 that there is a minor overestimation of CO<sub>2</sub> using the boron method yet it agrees on average well within  
403 uncertainty. The RMSE of the CO<sub>2</sub> offset for the combined record is 26 ppm.

404

405 Despite the overall close agreement between  $\delta^{11}\text{B}$ -derived CO<sub>2</sub> and ice core-derived CO<sub>2</sub>, each of our  
406  $\delta^{11}\text{B}$ -CO<sub>2</sub> records exhibit some short-lived intervals where the offsets from the ice core record are larger.  
407 This is further revealed by the residual CO<sub>2</sub> and the identification of the data above the upper quartile  
408 (i.e. the upper 25% of the data, Figure S4). Those data do not appear to be randomly distributed and  
409 instead occur at  $\sim 100$  ky,  $\sim 220$ -290 ky and  $\sim 390$  ky at ODP Site 999, in all three cases during the early  
410 stages of the glaciation (except for the MIS 8 glacial at 280ky, Figure S4). The mismatches with the  
411 ice core at ODP Site 871 show a similar temporal pattern occurring at  $\sim 220$  and  $\sim 300$  and  $\sim 350$ -390  
412 ky (i.e. at glacial inceptions).

413

414

415

416

417

418 Figure 3.  $\delta^{11}\text{B}$ , pH and boron-derived  $\text{CO}_2$  at site 999 and 871.  $\delta^{11}\text{B}$  of *G. ruber ss* and *sl* (top row), boron-derived  
 419 pH (middle row) and  $\text{CO}_2$  (bottom row) reconstruction from two core locations: ODP 999 (blue, this study and  
 420 published data, Foster, 2008; Henehan et al., 2013; Chalk et al., 2017) and ODP 871 (orange, this study). The  
 421 black line in the  $\text{CO}_2$  panels is the composite Antarctic ice core  $\text{CO}_2$  record (Bereiter et al., 2015). All  $\delta^{11}\text{B}$ -derived  
 422 data points are from *G. ruber ss* except black dots at ODP Site 871 measured on *G. ruber sl*. Numbers at the  
 423 bottom of the  $\text{CO}_2$  records represent marine isotope stages (black boxes for glaci-als and white boxes for  
 424 interglaci-als). Note the age scale is different between Sites 999 and 871.

425

### 426 3.3 Contrasting $\delta^{11}\text{B}$ between morphotypes.

427 Within error, the few measurements of  $\delta^{11}\text{B}$  *G. ruber sl* at ODP 871 all agree with  $\delta^{11}\text{B}$  *G. ruber ss*  
 428 (Figure 3) albeit the  $\delta^{11}\text{B}$  of *G. ruber sl* are higher than *G. ruber ss* for all 4 data pairs available. The  
 429  $\text{CO}_2$  derived from *G. ruber sl* (Figure 3) is on average 22 ppm lower than the one derived from *G. ruber*  
 430 *ss*; though the much lower resolution ( $n=4$ ) impedes a thorough comparison at this stage. The  $\delta^{18}\text{O}$  and  
 431  $\delta^{13}\text{C}$  of both morphotypes were compared for the whole records at ODP 871 (Figure S5) and a cross-  
 432 plot shows a moderate to good agreement between *G. ruber ss* and *sl* ( $r^2=0.55$  and  $0.22$  for  $\delta^{18}\text{O}$  and  
 433  $\delta^{13}\text{C}$  respectively, Figure S6). This is in contrast to other studies (e.g. Wang et al., 2000; Steinke et al.,  
 434 2005) that show  $\delta^{18}\text{O}$  in *G. ruber sl* to be systematically higher.

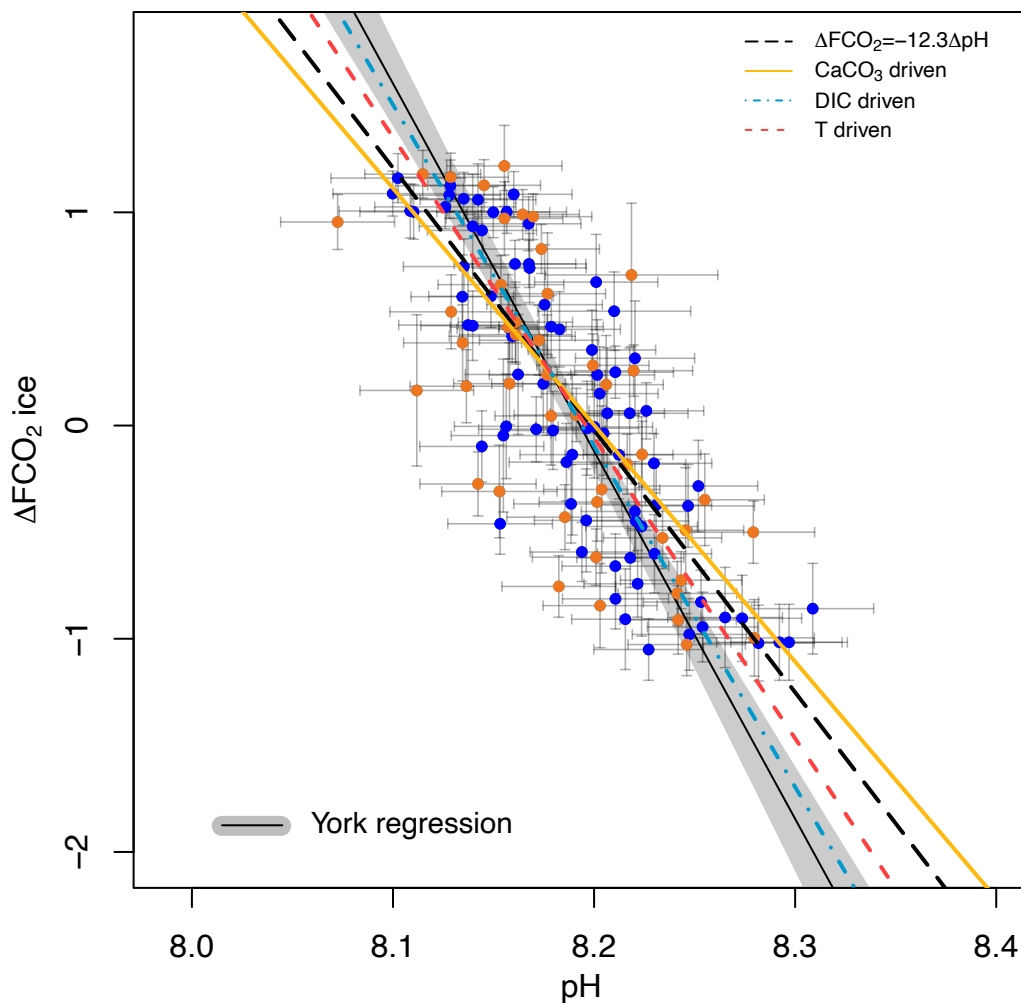

### 435 3.4 Relationship between $\delta^{11}\text{B}$ -pH and $\text{CO}_2$ forcing from the ice core.

436 A cross plot of  $\delta^{11}\text{B}$ -derived pH  $\text{CO}_2$  forcing from the ice core record for each of our marine core study  
 437 sites is shown in Figure 4 and is compared to the theoretically-derived approximate  $\Delta\text{FCO}_2/\Delta\text{pH}$   
 438 relationships as adopted by Hain et al. (2018):  $-1:1 \text{ W/m}^2$  (dashed black line);  $\text{CaCO}_3$  addition/removal  
 439 ( $-0.9:1 \text{ W/m}^2$  plain yellow line); DIC addition/removal ( $-1.3:1 \text{ W/m}^2$  dotted-dashed blue); and  
 440 warming/cooling temperature forcing ( $-1.1:1 \text{ W/m}^2$  dashed red). Our analysis includes full propagation  
 441 of uncertainty in pH, in contrast to Hain et al. (2018) who considered only the reported uncertainty of  
 442  $\delta^{11}\text{B}_{\text{borate}}$  in their validation exercise. In both cases the uncertainty in  $\Delta\text{FCO}_2$  accounts for the error in

443 interpolation arising when comparing age-uncertain  $\delta^{11}\text{B}$ -derived pH with  $\Delta F_{\text{CO}_2}$  from the well-dated  
 444 and high-resolution ice core  $\text{CO}_2$  record (see methods 2.7 and 2.6 for details). This treatment of  $\Delta F_{\text{CO}_2}$   
 445 uncertainty is dominated by the spread of ice core  $\text{CO}_2$  data points within the  $\delta^{11}\text{B}$  age uncertainty. The  
 446 data are fitted with a York-type regression (thin black line; York et al., 2004) where the grey envelope  
 447 represents the uncertainty of the linear relationship that best represents the data (i.e., the envelope is not  
 448 the prediction interval), considering the uncertainty in pH and  $\Delta F_{\text{CO}_2}$ . The regressed slope is  $\Delta F/\Delta\text{pH} =$   
 449  $-17.2 \pm 1 \text{ W/m}^2$  (-1.4:1 relative to basic formalism) and shows a good agreement with the theoretical  
 450 temperature and DIC driven relationships.

451 The effect of the uncertainty assigned to pH (fully propagated or using the measurement uncertainty of  
 452 the boron isotope) on the regressed slope is shown in Figure S7. The slope of the York regression when  
 453 using the uncertainty from  $\delta^{11}\text{B}$  only, as in Hain et al. (2018), shows a close agreement with the basic  
 454 formalism, with a slope of  $\Delta F/\Delta\text{pH} = -13.7 \pm 0.3 \text{ W/m}^2$ , (-1.1:1 relative to the basic formalism) but  
 455 with a unsatisfactory goodness of fit (mean squared weighted deviation, mswd) of 5.3, whereas  
 456 propagating the full pH uncertainty based on our iterative Monte-Carlo simulations improves goodness  
 457 of fit to  $\sim 0.9$  at a  $\Delta\log_{10}\text{CO}_2/\Delta\text{pH}$  of -1.4:1 (Figure 4).

Figure 4. Ice core based  $\Delta\text{FCO}_2$  ( $\text{CO}_2$  forcing) vs.  $\delta^{11}\text{B}$ -based pH for ODP 999 (blue filled circles, this study and published data from Foster, 2008; Henehan et al., 2013; Chalk et al., 2017) and 871 (orange filled circles). The lines show the relationship between  $\Delta\text{FCO}_2$  and pH for the simplified formalism (see method)  $\Delta\text{FCO}_2 = -12.3\Delta\text{pH}$  (black dashed line), and when driven by changes in DIC only (blue,  $\Delta\text{F}/\Delta\text{pH} = -16 \text{ W/m}^2$ ),  $\text{CaCO}_3$  (yellow,  $\Delta\text{F}/\Delta\text{pH} = -11.1 \text{ W/m}^2$ ) and temperature T (red,  $\Delta\text{F}/\Delta\text{pH} = -14.1 \text{ W/m}^2$ ). The York regressed line (black line and grey shade) falls close to the DIC-driven line (blue).

468

## 4. Discussion.

469

### 4.1 Cyclicity in foraminifera preservation.

470  
471  
472  
473  
474  
475  
476  
477  
478  
479

Percentage fragments and sand fraction ( $> 63\mu\text{m}$ ) at both studied core sites are anticorrelated and show a clear cyclicity, with better preservation of carbonates during glacial periods (Figure 2). The anticorrelation is clearer at ODP Site 871 where we have the longest record (Figure 2). Preservation in the Pacific (Farrell and Prell, 1989) show improved (poorer) preservation during glacial (interglacial) and this pattern seems to have originated after the mid Pleistocene transition (Sexton and Barker, 2012). The origin of these cycles could be a combination of enhanced ventilation during glacials in the Pacific (Sexton and Barker, 2012), or increased burial due to enhanced global alkalinity following a decrease in burial in the Atlantic (Cartapanis et al., 2018). However glacial periods seem to have been accompanied by a diminution in oxygenation in the deep Pacific (Anderson et al., 2019) that may have also impacted preservation.

490  
491  
492  
493

The observation that the fragmentation records of sites 999 and 871 covary is likely attributable to the different water masses that fill the Caribbean basin relative to the rest of the Atlantic basin. During glacials, the deep Atlantic is filled by nutrient- and carbon-rich corrosive southern sourced waters (Antarctic Bottom Water) with a reduced contribution from the less corrosive, nutrient-poor North Atlantic Deep Water (Oppo and Lehman, 1993) causing calcareous sediments in the deep Atlantic Ocean  $>2500 \text{ m}$  to be less well-preserved during glacials than interglacials. The opposite pattern of dissolution is seen in the Caribbean because shoaling of the northern sourced waters during glacials produces a mid-depth well-ventilated water mass that feeds into the Caribbean through its deepest sill ( $\sim 1900 \text{ m}$ , Johns et al., 2002). Thus the deep Caribbean is filled with less corrosive waters during glacials than interglacials improving the preservation of carbonate during glacials in a similar pattern to a Pacific styled dissolution cycle albeit in response to Atlantic circulation changes. During interglacials, the Northern sourced waters are mixed with corrosive southern sourced waters (Antarctic Intermediate Waters and upper circumpolar deep waters) leading to less well-preserved sediments.

494

### 4.2 Causes of offset between $\delta^{11}\text{B}$ -derived and ice core $\text{CO}_2$ .

495  
496  
497  
498  
499

The  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  record from both of our study sites is in very good agreement with the ice core record, with an average offset for combined both cores of  $13\pm 46 (2\sigma)$  ppm and corresponding RMSE of 26 ppm. However, the minor  $\text{CO}_2$  offsets observed in both records do not appear to be random and tend to fall during the first half of each glacial cycle (Figure S4). In order to have the highest confidence in  $\text{CO}_2$  reconstructions using  $\delta^{11}\text{B}$ , this pattern warrants further investigation (see below).

500

#### 4.2.1 Comparison between morphotypes of *G. ruber*

501  
502  
503  
504  
505  
506  
507

If as others suggested (e.g. Wang et al., 2000; Steinke et al., 2005; Numberger et al., 2009) *G. ruber sl* and *G. ruber ss* occupied different depth habitats, then inadvertent sampling of the cryptic *G. ruber sl* morphotype might conceivably produce the biases we observe between  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  and atmospheric  $\text{CO}_2$  from the ice cores. However, while our Mg/Ca-derived temperatures for *G. ruber sl* and *G. ruber ss* display variable offsets, they are within uncertainty (Figure 2) and our  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  data for the two morphotypes at ODP 871 show a good agreement with no consistent differences (Figure S5). Thus, while the water column profile of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  can be affected by factors other than

508 temperature, salinity and biological productivity (e.g, carbonate ion effect, Spero et al., 1997), overall,  
509 our data suggest that the two morphotypes we analysed shared similar depth habitat preferences.

510 Henehan et al. (2013) found that *G. ruber ss* and *sl* record similar  $\delta^{11}\text{B}$  in core-top sediments, and  
511 through necessity, used mixed morphotypes in their culture study. The  $\delta^{11}\text{B}$ -derived pH and  $\text{CO}_2$  for *G.*  
512 *ruber sl* examined here are consistently higher and lower, than *G. ruber ss* by around +0.02 pH units  
513 and -22 ppm  $\text{CO}_2$  on average, respectively (Figure 3). This is contrary to expectation if *G. ruber sl* lived  
514 in deeper more acidic waters as suggested by other studies (Wang et al., 2000; Steinke et al., 2005), but  
515 consistent with some data sets that show that the habitat of *G. ruber ss* and *sl* can vary by location and  
516 seems to be dependent on local productivity (Numberger et al., 2009). Other data sets from the Atlantic  
517 and Indian ocean nevertheless show similar Mg/Ca between both morphotypes (Gray et al., 2018). We  
518 acknowledge that the scarcity of *G. ruber sl* in our samples means that our data set for this morphotype  
519 is too small to draw firm conclusions and this warrants further investigation at other study sites.  
520 Nonetheless, the closeness of the morphotypes in terms of  $\delta^{11}\text{B}$  and depth habitat throughout our record  
521 implies any inadvertent sampling of *G. ruber sl* in the *G. ruber ss* fraction in this study and location  
522 would not significantly bias our reconstructions.

#### 523 4.2.2 *Change in upwelling and $\text{CO}_2$ disequilibrium.*

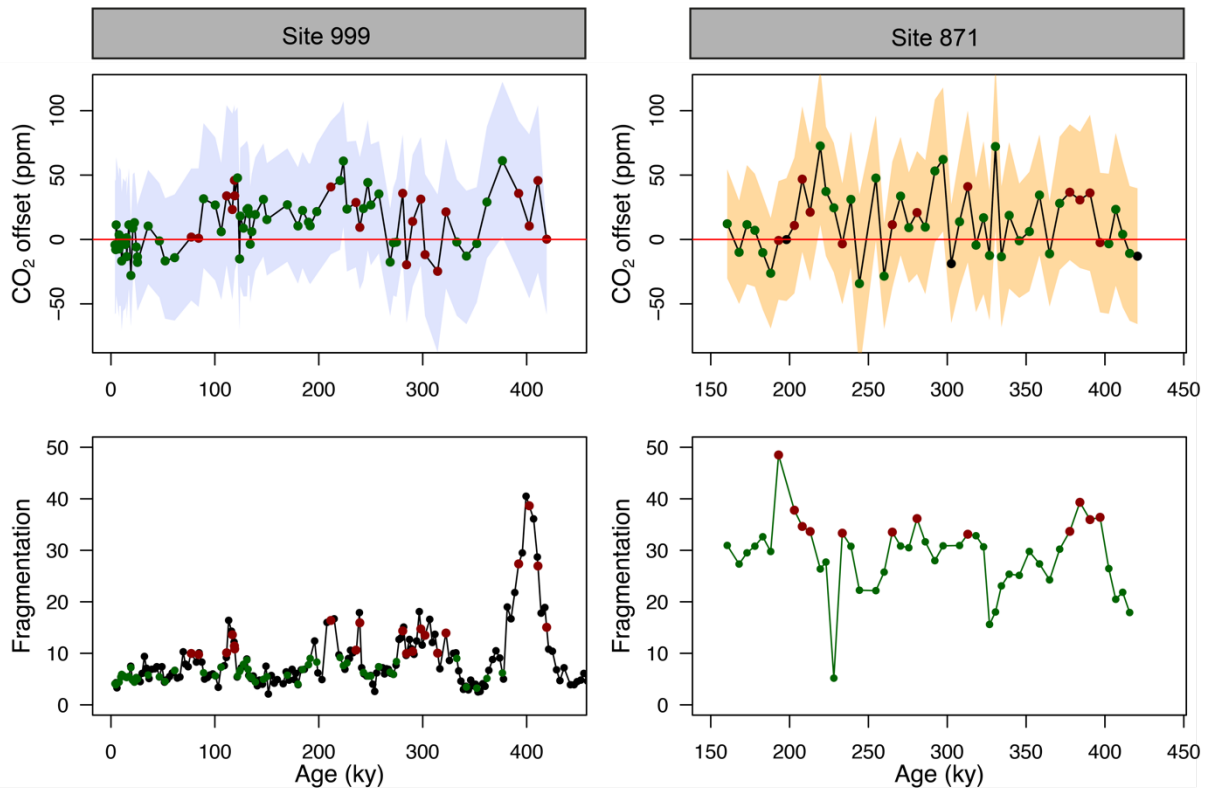

524 ODP sites 871 and 999 are both located today in stratified oligotrophic environments with a deep  
525 modern thermocline (base of the thermocline is at ~ 200 and 400 m at ODP 871 and 999, respectively;  
526 Olsen et al., 2016). It should be noted, however, that both sites are situated relatively close to regions  
527 displaying  $\Delta\text{pCO}_2 > 40$  ppm (Figure 1). However, if local upwelling occurred over the study interval,  
528 or if these areas of upwelled water expanded, we would expect these periods to be characterised by  
529 relatively low SST, high surface  $\delta^{18}\text{O}$ , and low surface  $\delta^{13}\text{C}$  due to an increased influence of deep  
530 colder and more remineralised waters. The identified anomalous intervals in residual  $\text{CO}_2$  at ODP 871  
531 (e.g at ~210, ~290 ky, Figure 5) show no particular anomaly in planktonic C and O isotopes (Figure  
532 S5 ) or in SST (Figure 2, Figure S8 ), ruling out significant variations in upwelling at that site. The  
533 Mg/Ca-derived SST record of nearby Site MD97-2140 (Figure S8) from the Western Pacific warm  
534 pool (de Garidel-Thoron et al., 2005) a location outside of the upwelling from the Pacific cold tongue,  
535 confirms this view in that the periods of high  $\text{CO}_2$  offset at Site 871 are not associated with relatively  
536 cold periods at site MD97-2140. Equally, no SST anomaly was identified at ODP 999 to be coincident  
537 with the intervals of high residual  $\text{CO}_2$ . Foster and Sexton (2014) have also reconstructed  $\text{CO}_2$  zonally  
538 across the equatorial Atlantic and the Caribbean and showed that while enhanced disequilibrium was  
539 detected in the eastern Atlantic, for the last 30 ky at least, Site 999 has remained in equilibrium with  
540 the atmosphere. This suggests the  $\text{CO}_2$  anomalies revealed in Figure 5 are not the result of enhanced  
541 local disequilibrium via sub-surface water mixing. Whilst SST is a first order constraint on upwelling,  
542 we acknowledge future constrains are needed using paired proxies of local  $\text{CO}_2$ , temperature, and  
543 productivity to evaluate changes in local  $\text{CO}_2$  fluxes.

#### 544 4.2.3 *Partial dissolution.*

545 The  $\text{CO}_2$  derived from *G. ruber*  $\delta^{11}\text{B}$  at ODP 999 and 871 appears to show, at first order at least, positive  
546  $\text{CO}_2$  offset during periods of high fragmentation (~100, ~210, ~400ky, red filled circles in Figure 5,  
547 defined by the upper 25% quantile of fragments) following a “Pacific style” dissolution cycle (better  
548 preservation and lower fragmentation during glacial periods). Periods of high fragmentation at ODP  
549 Site 999 and 871 correspond to a positive  $\text{CO}_2$  offset 65 and 75% of the time respectively, and 35 and  
550 25% of the time to a negative or no (i.e.  $\pm 10$  ppm)  $\text{CO}_2$  offset, (note that values  $\pm 10$  ppm were omitted  
551 in the criteria for positive or negative offset). We also note that almost all  $\text{CO}_2$  offsets uncertainty ( $2\sigma$ )  
552 overlap with the 0 line, hence the percentage of  $\text{CO}_2$  offset that are above or below the 0 line should be  
553 interpreted with caution.

554

555  
556  
557

558  
559  
560  
561  
562  
563  
564  
565  
566  
567

Figure 5. Top panels: CO<sub>2</sub> offset (defined as  $\text{offset} = \text{CO}_2_{\delta^{11}\text{B-derived}} - \text{CO}_2_{\text{ice}}$ ) for ODP Sites 999 (this study and Chalk et al., 2017) and 871. See text for error bars calculations. Bottom panels: fragmentation index at Site 999 (Schmidt et al., 2006) and 871 (this study). Red dots in the lower panels are the fragments above the upper quartile (and corresponding CO<sub>2</sub> in the upper panel, red dots). Green dots represent periods of low fragments below the upper quartile (and corresponding CO<sub>2</sub> in the upper panel, green dots).

568 In detail however, a cross-plot of fragment counts and CO<sub>2</sub> offset (Supplementary Figure S9) fitted with  
569 a linear regression shows no significant correlation for both core site 999 ( $r^2=0.06$ ,  $p=0.03$ ) and 871  
570 ( $r^2=0.002$ ,  $p=0.77$ ). Although it should be noted that this simple linear regression presupposes a linear  
571 relationship between the variables and does not account for the significant uncertainty in both CO<sub>2</sub>  
572 offset and fragmentation index. In particular, the CO<sub>2</sub> offset carries the uncertainty from the interpolated  
573 ice core CO<sub>2</sub> (see methods). Fragment counts at ODP 999 also come with the additional uncertainty  
574 related to the interpolation of the record of Schmidt et al. (2006), whereas fragments counts and  $\delta^{11}\text{B}$ -  
575 derived CO<sub>2</sub> at 871 are measured on the same samples. A cross-correlation function also shows no  
576 correlation between CO<sub>2</sub> offset and fragmentation (Figure S10).

577 While it seems unlikely the small offsets observed are fully explained by partial dissolution, the positive  
578 CO<sub>2</sub> offsets observed during some periods of high fragmentation index (Figure 5), are in line with trends  
579 observed in other species like *T. sacculifer* (sacc). For instance field studies observed lower  $\delta^{11}\text{B}$  in *T.*  
580 *sacculifer* for core-top samples from deeper ocean sites bathed by waters with low calcite saturation  
581 state (Hönisch and Hemming, 2004, Seki et al., 2010). Tests of *T. sacculifer* can contain a significant  
582 proportion of gametogenic calcite (ranging 30 to 75% of the weight of pregametogenic calcite, Bé,  
583 1980; Caron et al 1990) which forms at the end of the life cycle in deeper lower pH cold waters. It has  
584 been suggested that  $\delta^{11}\text{B}$  is lower in gametogenic calcite than in the primary test (Ni et al., 2007)  
585 reflecting the digestion and expulsion of symbionts (Bé et al., 1983) before gametogenesis, driving a

586 relative acidification of the micro-environment (no CO<sub>2</sub> uptake by photosynthesis) around the  
587 foraminifera (Zeebe et al. 2003; Hönisch et al., 2003; Henehan et al. 2016), and movement to deeper  
588 more acidic waters during that life-stage. It has been shown that this gametogenic calcite is more  
589 resistant to dissolution (Hemleben et al., 1989; Wycech et al., 2018) resulting in partial dissolution  
590 acting preferentially on ontogenic calcite, and driving  $\delta^{11}\text{B}$  in the residual test to lower isotopic  
591 composition.

592 However, while the decrease in  $\delta^{11}\text{B}$  in tests of *T. sacculifer* found in corrosive waters is well explained  
593 by the lighter isotopic composition of gametogenic calcite, *G. ruber* tests do not contain such  
594 gametogenic calcite (Caron et al., 1990). Hence, if the observed occasional decrease in  $\delta^{11}\text{B}$  (low pH,  
595 high CO<sub>2</sub>) was caused by partial dissolution, it needs to be explained by other processes. It should also  
596 be considered that alternative measures and proxies of dissolution (e.g. benthic B/Ca as an indicator of  
597 bottom water carbonate ion concentration) may yield more quantitative constraints on the importance  
598 of dissolution in generating our observed CO<sub>2</sub> offsets. Some studies have shown that laboratory  
599 dissolved specimens of *T. sacculifer* (Sadekov et al., 2010) and naturally dissolved specimens of *G.*  
600 *ruber* (Iwasaki et al., 2019) undergo targeted partial preferential dissolution of the shell. However,  
601 variations in intra-shell  $\delta^{11}\text{B}$  are currently unknown due to limitations in laser ablation techniques that  
602 currently impede a direct evaluation of  $\delta^{11}\text{B}$  heterogeneity in foraminifera chambers. Future studies are  
603 needed to constrain the  $\delta^{11}\text{B}$  spatial distribution in foraminiferal shells caused by potential variations in  
604  $\delta^{11}\text{B}$  from dissolution, ontogeny (e.g. Meilland et al., 2021) and/or vital effects (e.g. change in  
605 photosymbiotic activity throughout the life cycle, Lombard et al., 2009, Henehan et al., 2013, Takagi  
606 et al., 2019). In the absence of these constraints, we conclude that partial dissolution is unlikely to be a  
607 significant driver of the  $\delta^{11}\text{B}$ -CO<sub>2</sub> records we present here. Even though it was thought to be a species  
608 susceptible to dissolution (Berger, 1970), we confirm that the  $\delta^{11}\text{B}$  of *G. ruber* appears more resistant  
609 to dissolution-driven modification than *T. sacculifer*.

#### 610 4.2.4. *Effect of dissolution on Mg/Ca and calculated CO<sub>2</sub>.*

611 The direction of change of Mg/Ca with partial dissolution is towards lower ratios in partially dissolved  
612 foraminifera (e.g. Brown and Elderfield, 1996; Dekens et al., 2002; Fehrenbacher and Martin, 2014). If  
613 the Mg/Ca is impacted during periods of high fragmentation, the lower ratio would result in lower  
614 temperatures leading to lower calculated CO<sub>2</sub> values (equation 7). This effect is opposite to the  
615 occasional positive deviation of CO<sub>2</sub> observed during intervals of high fragmentation at ODP Site 999.  
616 While the weak correlation between fragmentation and CO<sub>2</sub> precludes a firm interpretation of  
617 dissolution effect, we conclude that the effect of partial dissolution on Mg/Ca ratio and resulting CO<sub>2</sub>  
618 (if any) are negligible and not responsible for the CO<sub>2</sub> offsets observed during intervals of high  
619 fragmentation.

#### 621 4.2.5. *Change in the second carbonate parameter, alkalinity.*

622 Past changes in TA are poorly constrained, although some constraints are starting to emerge for the late  
623 Quaternary (e.g. Cartapanis et al., 2018). However, since pH is directly determined by  $\delta^{11}\text{B}$ , pH defines  
624 the ratio of alkalinity to DIC (see supplementary information S11). Hence, at any given pH, any change  
625 in alkalinity must be counteracted by a change in DIC, which has the opposing effect on CO<sub>2</sub>. This is  
626 demonstrated by the tight relation between pH and CO<sub>2</sub> highlighted by our data (Figure 4). The largest  
627 residual CO<sub>2</sub> is ~50 ppm at ODP 999. To produce an effective alkalinity-driven change in CO<sub>2</sub> of this  
628 magnitude at a given pH requires an alkalinity reduction of about ~300 to 500  $\mu\text{mol/mol}$  (supplementary  
629 Figure S12 ). This is far larger than any expected change over a glacial cycle (Cartapanis et al., 2018,  
630 Hönisch et al., 2009). We therefore rule out varying TA as the cause of the minor CO<sub>2</sub> offsets observed  
631 (Figure 5).

632

633

4.2.6 Improving the  $\delta^{11}\text{B}$ -pH *G. ruber* calibration

634 A further potential cause for the minor offsets observed between  $\delta^{11}\text{B}$ -derived and ice core  $\text{CO}_2$  could  
 635 be a small inaccuracy in the calibration between  $\delta^{11}\text{B}$  of foraminifera and borate for *G. ruber* (Henehan  
 636 et al., 2013). Having the ice core data to compare with  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  offers an opportunity to explore  
 637 the effect of altering the input variables of the pH- $\text{CO}_2$  calculation to see if doing so improves the fit to  
 638 ice-core values. Note that such an exercise is for illustrative purposes only because we seek to retain  
 639 the independence offered by the  $\delta^{11}\text{B}$ -calibrated data in the context of  $\text{CO}_2$  forcing (section 4.3).  
 640 Nonetheless, in future work we suggest this calibration can be applied in tandem to the empirical  
 641 relationship of Henehan et al. (2013). The published (Henehan et al., 2013) and obtained optimised  
 642 calibration (Figure S13 ) are:

$$643 \quad \delta^{11}\text{B}_{\text{borate}} = \frac{\delta^{11}\text{B}_{\text{foram}} - 8.87(\pm 1.52)}{0.60(\pm 0.09)} \quad (\text{Henehan et al., 2013})$$

644

$$645 \quad \delta^{11}\text{B}_{\text{borate}} = \frac{\delta^{11}\text{B}_{\text{foram}} - 6.49}{0.71} \quad (\text{optimised calibration})$$

646

647 The newly calculated  $\text{CO}_2$  with the updated calibration shows an improved average  $\text{CO}_2$  offset (Figure  
 648 6) of  $-4 \pm 36$  ( $2\sigma$ ) ppm (vs  $13 \pm 46$  ( $2\sigma$ ) ppm with the calibration of Henehan et al., 2013) and an RMSE  
 649 of 18 ppm (vs. 26 ppm with the published calibration).

650

651 Figure 6. Composite  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  from both core sites 999 and 871 using the published  $\delta^{11}\text{B}_{\text{borate-foram}}$   
 652 calibration (grey points, Henehan et al., 2013) and the optimised calibration (red points). The black line is the  
 653 Antarctic composite ice core  $\text{CO}_2$  record (Bereiter et al., 2015).

654 When analysing the  $\text{CO}_2$  offset using the optimised *G. ruber* calibration and the fragmentation index  
 655 at each core location (same approach as Figure 5), we observe that intervals of high fragments

656 (defined as values above the upper quartile) are no longer preferentially associated with positive CO<sub>2</sub>  
657 offset (Figure S14). Intervals of high fragments occur 5% and 33% of the time, at Sites 999 and 871,  
658 respectively, during positive CO<sub>2</sub> offsets (and 95 and 67% of the time during negative or no offset to  
659 the ice cores).

660 This analysis shows that a small change in the borate *G. ruber* δ<sup>11</sup>B calibration is enough to improve  
661 the fit to the ice core and diminishes the apparent correlation between high fragmentation and  
662 CO<sub>2</sub> offset (Figure S14), and that uncertainty in the δ<sup>11</sup>B<sub>foram-borate</sub> calibration of Henehan et al. (2013)  
663 can – at least partly – explain the minor discrepancies we observe between δ<sup>11</sup>B-derived and ice core  
664 CO<sub>2</sub>.

### 665 4.3 Relative CO<sub>2</sub> forcing and pH.

666 Our new pH data, added to the existing compilation, show a good agreement with the formalism  
667 defined by Hain et al. (2018; Figure 4). It should be noted that CO<sub>2</sub> in this case is provided by the ice  
668 core directly and is not estimated from the δ<sup>11</sup>B-derived pH. As discussed above, because these two  
669 proxies are independent of one another, the slope of their relationship may be used to interrogate the  
670 mechanisms of CO<sub>2</sub> change. Our data fall between the CaCO<sub>3</sub> (yellow plain line) and the DIC (dotted-  
671 dashed blue line) endmembers suggesting that the CO<sub>2</sub> change observed on glacial-interglacial  
672 timescales was driven by a mix of mechanisms rather than to a single cause. This is in line with  
673 studies that require a number of mechanisms to explain glacial interglacials CO<sub>2</sub> change such as the  
674 soft tissue pump, carbonate compensation pump, solubility pump (e.g. Brovkin et al., 2007, Kohfeld  
675 and Ridgwell, 2009, Hain et al., 2010, Chalk et al., 2019, Sigman et al., 2021), and the disequilibrium  
676 pump (Eggleston and Galbraith, 2018). We note that this is a preliminary interpretation because of  
677 the sensitivity of our finding to pH uncertainty (section 3.4, Figure S7). To overcome this ambiguity  
678 in estimating past ΔF<sub>CO<sub>2</sub></sub> and to better deconvolve the driving mechanisms of glacial/interglacial CO<sub>2</sub>  
679 change, we recommend that future studies collect pH data at higher temporal resolution to examine  
680 the change in slope through a glacial cycle and strive to further quantify and reduce uncertainties  
681 related to pH determination.

682 The close agreement of the pH and ice core CO<sub>2</sub> data with the theoretical relationships has a number of  
683 consequences for the reconstruction of CO<sub>2</sub> change during periods of Earth history beyond the ice core  
684 CO<sub>2</sub> and climate records where constraints on δ<sup>11</sup>B<sub>sw</sub> and the second carbonate parameter and  
685 temperature are uncertain. The ΔpH formalism still requires an estimation of δ<sup>11</sup>B<sub>sw</sub> and temperature  
686 (for the pK<sub>B</sub> term, equation 5) however, as discussed in Hain et al. (2018), while absolute reconstruction  
687 of pH is significantly influenced by estimates of δ<sup>11</sup>B<sub>sw</sub> and temperature, reconstruction of relative pH  
688 change (ΔpH) is inherently much less sensitive to these input variables.

689 Reconstructing ΔF<sub>CO<sub>2</sub></sub> from ΔpH is ideally applicable only on relatively short timescales less than 1  
690 Myrs, when δ<sup>11</sup>B<sub>sw</sub> is likely to be invariant given the multi-million year residence time of boron in the  
691 ocean (Lemarchand et al., 2002, Greenop et al., 2017). Furthermore, to reconstruct ΔF<sub>CO<sub>2</sub></sub> (and thus  
692 climate sensitivity to CO<sub>2</sub>), the formalism can be applied as long as, in equation 2, ΔpH remains the  
693 overwhelming control. This is dependent on the residence time of carbon in the ocean with respect to  
694 silicate weathering – approximately one million years (Hain et al., 2018) such that net carbon addition  
695 to or removal from the Earth System through volcanic outgassing or silicate weathering is likely to be  
696 minor over the million-year timescale. However, during some short events, such as for instance the  
697 Palaeocene-Eocene Thermal Maximum, considerable carbon was added to the system in <200 kyr (e.g.  
698 Gutjahr et al., 2017) invalidating the formulation described in equation 2 on these intervals. We also  
699 emphasize that this formalism is only valid as long as core sites remain in equilibrium with the  
700 atmosphere.

701

#### 702 4.4 Caveats and future studies.

703 The aim of this study is to evaluate the capacity of the  $\delta^{11}\text{B}$ -pH proxy in *G. ruber* to accurately  
704 reconstruct atmospheric  $\text{CO}_2$  in the past. The overall agreement with the high confidence ice core  $\text{CO}_2$   
705 (e.g. Bereiter et al., 2015) is very promising and gives confidence to  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  reconstructions  
706 beyond the ice core record (>800 ky). We have however identified occasional, minor offsets between  
707 the two records and explored potential drivers (partial dissolution,  $\delta^{11}\text{B}$  borate-foram calibration, local  
708 air-sea disequilibrium). It is likely that the minor disagreement observed (Figure 5) has a combination  
709 of drivers and that a single mechanism is not solely responsible for the  $\text{CO}_2$  offsets observed. To confirm  
710 these trends, we recommend future work to focus on the following:

711 (1) The improved  $\delta^{11}\text{B}$  calibration approach should be tested at more core locations. We note that the  
712 improved calibration to the ice core records reported here was achieved using data from two sites. While  
713 care is taken in the choice of study site to minimize air-sea  $\text{CO}_2$  disequilibrium and sediment dissolution,  
714 the newly defined improved  $\delta^{11}\text{B}_{\text{borate-foram}}$  calibration should be seen as an exercise that is tailored to the  
715 available data in this study, and future high-resolution studies can apply the method used here (section  
716 4.2.6) to further test how the *G. ruber* calibration changes if  $\text{CO}_2$  offsets occur in a similar fashion (i.e  
717 at a particular time in each glacial cycles). We note the importance of high resolution (at least 3 ky)  
718 sampling in future studies because most  $\text{CO}_2$  offsets observed are short lived.

719 (2) A multiproxy approach is ideally needed. In particular, reliable indicators of temperature and  
720 productivity, to assess change in upwelling and foraminifera ecology. We encourage future studies to  
721 expand high resolution boron-derived  $\text{CO}_2$  record and ancillary data (C and O isotopes, proxy of  
722 carbonate preservation and bottom water corrosiveness, biological productivity) to further constrain the  
723 capacity of the boron isotope pH/ $\text{CO}_2$  proxy to generate reliable  $\text{CO}_2$  records. As more recent IODP  
724 expeditions include porewater data, constraints on bottom water conditions and degree of corrosiveness  
725 at a given site will become available to evaluate the impact on  $\delta^{11}\text{B}$  signals in foraminifera.

726 (3) Efforts should continue to decrease the analytical uncertainty associated with a  $\delta^{11}\text{B}$  measurement  
727 by MC-ICPMS because this still accounts for ~40% of the total uncertainty associated with each  $\delta^{11}\text{B}$ -  
728 derived  $\text{CO}_2$  estimate.

729 (4) We find little evidence to suggest that partial dissolution of foraminiferal tests (*G. ruber*) is a major  
730 driver of uncertainty in  $\delta^{11}\text{B}$ -derived  $\text{CO}_2$  estimates but well constrained dissolution experiments are  
731 desirable because of site-to-site differences in foraminifera taphonomy.

#### 732 733 5. Conclusion.

734 We carried out the most thorough test to date of the  $\delta^{11}\text{B}$ -pH ( $\text{CO}_2$ ) proxy by comparing new high-  
735 resolution (3 to 6 ky per sample) boron isotope-based pH and  $\text{CO}_2$  at two locations with  $\text{CO}_2$  from the  
736 ice core record. Results suggest that the boron isotope proxy is robust and suited to reconstructing  $\text{CO}_2$   
737 to a precision of  $\pm 46$  ppm ( $2\sigma$ , RMSE = 26 ppm) over this interval, with little or no systematic bias  
738 shown by a mean residual of  $13 \pm 46$  ( $2\sigma$ ) ppm. This provides high confidence to the application of the  
739 proxy beyond the reach of the ice core records.

740 Despite the overall good agreement, there are some minor short-lived  $\text{CO}_2$  offsets that appear to have  
741 some temporal structure and we explored a number of possible drivers. A visual correlation between  
742  $\text{CO}_2$  offset and fragmentation index at core site 999 is observed (Figure 5) but is not statistically  
743 significant. The effect of partial dissolution on  $\delta^{11}\text{B}$  in *G. ruber* appears to be negligible in our record,  
744 but the possible heterogeneity of  $\delta^{11}\text{B}$  within shells as well as variable susceptibility to dissolution of the  
745 different parts of the foraminifera, encourage further exploration.

746 A revised  $\delta^{11}\text{B}$  borate–foram calibration was calculated by minimising the offset between  $\delta^{11}\text{B}$ –derived  
747  $\text{CO}_2$  and ice core  $\text{CO}_2$  using published calibration (Henehan et al., 2013). While the new calibration  
748 improves the fit to the ice core records, we caution against its use to estimate  $\text{CO}_2$  given that it is no  
749 longer independent of the ice core or the assumptions we make here to calculate  $\text{CO}_2$  (i.e. that TA is  
750 constant).

751 The formalism established by Hain et al. (2018) is robust, showing that relative  $\text{CO}_2$  forcing in the past  
752 can be determined from pH change alone, even in the face of significant uncertainty in  $\delta^{11}\text{B}$  of seawater  
753 and without the need to determine a second carbonate parameter. This will not only be of great interest  
754 to determine  $\text{CO}_2$  forcing in ancient geological times where  $\delta^{11}\text{B}$  of seawater and a second carbonate  
755 parameter are poorly constrained, but the nature of the observed relationship over the last 400 kyr  
756 confirms that multiple drivers are likely responsible for glacial-interglacial  $\text{CO}_2$  change.

## 757 **6. Data availability.**

758 All raw data are provided as supplementary information.

## 759 **7. Author contribution.**

761 E.d.l.V generated boron isotope and elemental data and wrote the manuscript. E.d.l.V, T.B.C, M.P.H  
762 and G.L.F analysed the data. G.L.F, T.B.C, M.P.H and P.A.W contributed to the editing and  
763 reviewing of the manuscript. M.W, R.G and D.C generated oxygen and carbon isotope data and  
764 fragmentation index data. R.G and D.C were supervised by T.B.C and G.L.F. C.L assisted with  
765 foraminifera picking and boron isotope analysis. E.d.l.V, T.B.C and G.L.F designed the research.

## 766 **8. Competing interest.**

767 The authors declare they have no conflict of interest.

## 768 **9. Acknowledgment.**

769 We warmly thank J. Andy Milton for assistance in MC-ICPMS and ICPMS analysis, and members of  
770 the “B-team”, Agnes Michalik and Matthew Cooper for clean laboratory assistance. We thank  
771 William Gray and one anonymous reviewer for insightful comments that improved the manuscript.  
772 This work was funded by NERC grant NE/P011381/1 to GLF, PAW, TBC and MPH and by Royal  
773 Society Wolfson Awards to both GLF and PAW.
