18 **Abstract:** The economic and environmental impacts of persistent droughts in East
19 Asia are of growing concern, and therefore it is important to study the cyclicity and
20 causes of these regional droughts. The self-calibrating Palmer Drought Severity Index
21 (scPDSI) has been extensively employed to describe the severity of regional drought,
22 and several PDSI reconstructions based on tree rings have been produced. We
23 compiled a tree-ring chronology for Hailar pine (*Pinus sylvestris* var. *Mongolica*)
24 from two sites in the Hailar region in the Upper Heilongjiang (Amur) River Basin.
25 Analysis of the climate response revealed that scPDSI was the primary factor limiting

26 tree ring growth from May to July. The mean May to July scPDSI in the Hailar region
27 since 1796 was reconstructed from the tree-ring width chronology. The results of
28 spatial correlation analysis revealed that the reconstructed scPDSI in this region
29 responded significantly to climate change. Analysis of the synoptic climatology
30 indicated that the drought in the Upper Heilongjiang (Amur) River Basin is closely
31 related to ENSO and the Silk Road teleconnection. The results of atmospheric water
32 cycle analysis show that water vapor transport processes are the dominant factor in
33 the development of drought in this region.

35 Severe drought; Moisture recycling

36 **1. Introduction**

37 Drought—accompanied by persistent high temperatures and below-average
38 precipitation over intervals of months to years—is of growing concern. As a natural
39 disaster, the frequency and duration of drought have increased as global warming has
40 intensified. The impact of drought on human well-being and economic productivity is
41 also increasing, given that drought severely threatens food and water security (Lesk et
42 al. 2016; Trenberth et al. 2014; Wang et al. 2016; Chen et al. 2022). Due to regional
43 water shortages, droughts frequently wreak havoc on agriculture and the quality of
44 life in northeast Asia. Hence, understanding the variability of drought in this region
45 and its causal mechanisms is essential for both drought prediction and the formulation
46 of disaster response strategies (Li et al. 2019; Yuan and Wood 2013).

47 However, only short-duration instrumental records of drought variability are

48 available for northeast Asia, most of them from the 1950s onwards. However, this
49 deficiency can be addressed via proxy paleoclimate records, such as tree-ring widths
50 (Fritts, 1991). With their high annual precision and extensive coverage, tree rings
51 have been used as a reliable proxy for reconstructing historical climatic and
52 hydrological changes (Cook et al. 2016; Chen et al. 2021; Pearson et al. 2020). Hailar
53 is located in the Upper Heilongjiang (Amur) River Basin, in the woodland-steppe
54 interface of northeast Asia, part of the eastern edge of the Hulunbuir grasslands, a
55 region highly susceptible to climatic and environmental changes and that has
56 experienced drought over the past few decades (Zhang et al. 1997; Wang et al. 2010;
57 Bao et al. 2015; Chen et al. 2012). Drought reconstructions based on tree-ring widths
58 can potentially make a valuable contribution to regional planning and ecological
59 conservation in this region. Over the past two decades, several studies based on
60 tree-ring width have been conducted in Northeast Asia (Cook et al. 2010; Bao et al.
61 2015; Chen et al. 2012; Liu et al. 2016; Chen et al. 2022, Zhao et al. 2023). However,
62 there is a requirement to focus research efforts on the agro-pastoral zone located in the
63 western region of the northeast Asia. This area is characterized by a delicate
64 ecological balance and high climate susceptibility, making it imperative to enhance
65 our comprehension of drought patterns and underlying mechanisms.

66 Severe drought events are a serious problem in northern China, especially since the
67 late 1970s, when the weakening of the East Asian Summer Monsoon (EASM)
68 contributed to the 'southern flooding and northern drought' climatic pattern, with
69 frequent intense drought events in the north (Wang, 2002; Yu et al. 2004; Ding et al.

70 2009). Regarding the climatic mechanisms responsible for the northeast Asia drought,
71 it has been suggested that variations in the Pacific Ocean interdecadal oscillation
72 (PDO) and in Arctic Ocean sea-ice cover have contributed to an interdecadal decrease
73 in precipitation in northeast Asia, leading to drought (Han et al. 2015). It has also been
74 suggested that the global distribution of sea surface temperature and ENSO events are
75 closely linked to summer precipitation in northeast Asia, thus explaining the summer
76 drought mechanism in the northeast Asia from an interannual perspective (Han et al.
77 2017). Winter NAO has also been shown to impact the interannual variability of
78 summer drought events in northeast Asia (Fu and Zeng, 2005). Anticyclonic
79 circulation anomalies can often trigger extreme and prolonged drought events. Such
80 anomalies always occur as a major product of specific remote teleconnection patterns,
81 called stationary wave patterns (Schubert et al. 2014). Several steady wave models
82 have been shown to generate extreme drought events, with the 2014 summer drought
83 in northern China attributed to the European Union pattern. It has also been confirmed
84 that the Silk Road, Pacific-Japanese, and European Union models caused the
85 July–August 2014 drought in north and northeastern China (Wang and He, 2015;
86 Wang et al. 2017; Xu et al. 2017). While many of the above studies describe water
87 vapor flux anomalies during periods of extreme drought, our understanding of the role
88 of water vapor derived from local evaporation and advective transport is limited.
89 Quantifying the contribution of advected water vapor transport and precipitation
90 circulation processes to precipitation is essential for understanding the water vapor
91 cycle and anticipating the intensity of severe drought episodes (Findell and Eltahir,

92 2003; Guan et al. 2022).

93 The objectives of the present study are: (1) to reconstruct the scPDSI of the Hailar
94 region and to analyze changes in the temporal variations of regional drought; (2) to
95 determine the atmospheric circulation mechanisms generating extreme drought events;
96 and (3) to analyze the contribution of advective water vapor transport and local
97 evaporation to precipitation during droughts, and to determine their leading causes.

98 **2. Materials and Methods**

99 **2.1 Study area**

100 Tree-ring sampling sites NEGC (119°36' E, 47°58' N, 600-700m a.s.l.) and MGET
101 (119°24' E, 47°59' N, 1100-1200 m a.s.l.) are located in the Upper Heilongjiang
102 (Amur) River Basin (Fig. 1). The region lies within the arid and semi-arid region of
103 Northeast China (NEC), on the eastern edge of the Hulunbeier steppe and close to the
104 western slopes of the Greater Khingan Range. This region has a continental and
105 monsoonal climate (Bao et al. 2012). Due to the incursion of high-latitude cold and
106 dry air masses in winter and of warm and moist air masses from low-latitude areas in
107 summer, the climate tends to alternate between cold and dry in winter and warm and
108 humid in summer. The average annual temperature is around -0.9 °C and the average
109 yearly precipitation is ~382.8 mm (Fig. 2a). December–January is the coldest period,
110 with sparse rainfall, while June–August is the hottest period when precipitation is
111 abundant (Fig. 2b). Thus, the climate is generally cold and dry. The grassland in this
112 region is undergoing severe desertification and degradation in response to global and
113 regional climate change (Zhang et al. 2011).

2.2 Tree-ring data

The dominant tree species in the Hailar region is Hailar pine (*Pinus sylvestris* var. *Mongolica*), which was sampled for tree-ring analysis. Both sites were located at the upper tree line, on steep slopes with thin soils. Information about the sampling sites is given in Table 1. Samples were taken from breast height using a 10-mm diameter incremental borer. Forty cores were collected from 20 trees at sampling site NEGC, and 63 cores were collected from 33 trees at sampling site MGET. In the laboratory, the core samples were dried, mounted and successively sanded with 320- and 600-grit sandpaper until the tree-ring widths were visible, and were then imaged using a high-precision scanner. Tree-ring width data were measured using CooRecorder 9.4 software, and the data quality was checked by cross-matching using the quality control program COFFCHA (Holmes, 1983). The ARSTAN procedure was then used to remove non-climatic influences on the tree-ring width data, due to age and growth, using exponential detrending. This procedure resulted in a standardized chronology of tree-ring widths (STD), a chronology of differences (RES), and an autoregressive chronology (ARS). The individual detrended chronologies from the two sites were combined to produce a new RC chronology using a robust averaging method (Cook, 1985). The STD chronology was selected to retain high and low-frequency variations based on the considerations of subsequent analyses. The data series were truncated according to thresholds of at least $EPS > 0.85$ and 6 (3 trees) for the expressed population signal and sample size, respectively, resulting in a reliable reconstruction for the period of 1796–2020.

2.3 Climate data and statistical methods

136
137 Monthly instrumental climate data from Hailar meteorological station (49°15' E,
138 119°42' N, 650 m a.s.l.), affiliated to the National Meteorological Administration of
139 China, including monthly mean temperature and monthly total precipitation, were
140 obtained for the period of 1951–2020. Monthly mean runoff data from Khabarovsk
141 Hydrological Station on the lower Heilongjiang River were used to analyze the
142 response of the reconstructed scPDSI to runoff variations. The locations of the
143 meteorological and hydrological stations are shown in Fig. 2a. scPDSI gridded
144 climate data of CRU TS 4.06 from the Climate Research Unit (CRU) of the
145 University of East Anglia were also used in this study (Harris et al. 2014). SPSS 22.0
146 was used to assess the correlation coefficient of the climate signals contained in the
147 three chronologies for the individual months from July of the previous year to
148 September of the current year. Based on the results of this correlation coefficient
149 analysis, several seasonal climate combinations from July of the last year to
150 September of the current year were filtered, and the seasonal climate combinations
151 with the highest correlation were selected for climate reconstruction, using
152 one-dimensional linear regression. A split calibration-verification test was used to test
153 the reliability of the reconstructed models, dividing the period of 1951–2020 into
154 independent calibration and validation periods. The main parameters assessed were
155 the correlation coefficient (R), explained variance (R^2), efficiency coefficient (CE),
156 error reduction value (RE), sign test (ST1), and the first-order difference sign test
157 (ST2) (Cook and Kairiukstis, 2013). In this study, after 15-year low-pass filtering,

158 intervals of more than 10 years below/above the mean of the reconstructed series were
159 defined as dry/wet periods, and the years below or above 1.5 times the standard
160 deviation of the series mean were defined as extreme dry/wet years. The
161 quasi-periodic characteristics of the reconstructed scPDSI were analyzed using
162 Multitaper spectral analysis (MTM) (Mann and Lees, 1996). Spatial correlation maps
163 were generated between the reconstructed scPDSI series and the grid data, including
164 precipitation and scPDSI data from CRU TS 4.06, and runoff grid point data from
165 G-RUN (Harris et al. 2014; Ghiggi et al. 2021).

166 **2.4 Land-atmosphere water balance**

167 The Brubaker binary model has been used to quantify the contribution of external
168 water vapor transport and local evaporative water vapor to precipitation, based on the
169 atmospheric water vapor balance (Brubaker et al. 1993). The water vapor equation for
170 the vertical integration per unit area can be expressed as follows (Brubaker et al. 1993;
171 Guo et al. 2018):

$$\frac{\partial Q}{\partial t} = - \left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y} \right) + E - P, \quad (1)$$

172 Where Q is the vertically integrated water vapor concentration; F_u and F_v are the
173 vertically integrated latitudinal and meridional water vapor fluxes, respectively; and E
174 and P are the vertically integrated land evaporation and rainfall, respectively.

175 Compared to the magnitude of the water vapor flux, the vertically integrated water
176 vapor content varies very little over time and is insignificant on longer timescales
177 (Burde and Zangvil, 2001). Thus, the left side of equation (1) is 0. In addition, the

178 water vapor balance equation for the external water vapor transport term is as follows
 179 (Guo et al. 2018; Zhao and Zhou, 2021; Li et al. 2020):

$$-\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) = P_a \quad (2)$$

180 Where F_u^a and F_v^a represent the vertically integrated latitudinal and longitudinal
 181 water vapor transport from external inputs, respectively. Assuming P , E and P_a are
 182 constant within the study area during the interval of concern (Burde and Zangvil,
 183 2001). Assuming that externally imported water vapor and locally evaporated water
 184 vapor are well mixed over the study area, and that the proportions of evaporated and
 185 advected water vapor contribute equally to the development of precipitation and
 186 moisture fluxes. Using the above assumptions and the Gaussian scattering
 187 assumptions, equations (1) and (2) can be applied to a region of area A (in m), as
 188 follows:

$$-\left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y}\right) |A = F_{in} - F_{out} = (P - E)A \quad (3)$$

$$-\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) |A = F_{in} - F_{out-a} = P_a A \quad (4)$$

189 Here, $-\left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y}\right) |A$ and $-\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) |A$ represent the total water vapour
 190 irradiation dispersion in the targeted region and the irradiation dispersion of externally
 191 transported water vapor, respectively; F_{out} and F_{out-a} represent the total water
 192 vapour leaving the calculated area and the part of the external input water vapour
 193 flowing away from the calculated area again, respectively; and F_{in} represents the
 194 total water vapor transported to the targeted area from outside. This enables an
 195 estimate to be made of the contribution of external moisture transport and local land
 196 surface evaporation to precipitation, as follows (Guo et al. 2018; Li et al. 2020):

$$r = \frac{P_a}{P} = \frac{2F_{in}}{2F_{in} + EA} \quad (5)$$

$$\rho = 1 - \frac{P_a}{P} = \frac{EA}{2F_{in} + EA} \quad (6)$$

197 Where r and ρ are the contributions to precipitation from external water vapor
198 transport and local land surface evaporation, respectively, and ρ is the precipitation
199 recirculation rate.

200 The Brubaker binary model water vapor transport process is based mainly on
201 advection terms, which can be applied to calculate the precipitation recirculation rates
202 in the study area. Give that the calculation of these precipitation recirculation rates
203 depends on the size of the selected area, the study area was enlarged (42.5–52.5°
204 N,115–125° E) for the purpose of calculation.

205 **3. Results**

206 **3.1 scPDSI reconstruction**

207 All the tree ring chronologies show a high mean sensitivity and standard
208 deviation, typical of trees growing in arid and semi-arid regions, due to the location of
209 the Hailar region. The high inter-series correlation coefficient suggests that our
210 tree-ring width chronology reliably captures several standard climate signals. The
211 EPS of the RC chronology passed the test for signal strength ($EPS > 0.85$) after 1796
212 (Table 2 and Fig. 3). The tree-ring width series has a significant negative correlation
213 with temperature, a significant positive correlation with precipitation, and a
214 significant positive correlation with scPDSI, according to the climate response results
215 ($p < 0.05$) (Fig. 4a, b). Screening for seasonal combinations of temperature,
216 precipitation, and scPDSI revealed the strongest correlation coefficient between the

217 RC tree ring width chronology and meant scPDSI from May to July ($r = 0.645$, $p <$
218 0.01). Accordingly, we reconstructed the May to July scPDSI for the Hailar region
219 since 1796 CE, using the following equation (Fig. 4d):

$$Y = 3.681X - 4.146 \quad (7)$$

$$(n = 70, r = 0.645, R^2 = 41.6\%, R_{adj}^2 = 40.7\%, F = 48.385, p < 0.01)$$

220 Where Y is the mean reconstructed scPDSI for May to July, and X is the tree ring
221 width index from the composite chronology.

222 In equation (7), the correlation between the mean May–July scPDSI and the
223 tree-ring width index over the period of 1951–2020 is 0.645, with the tree-ring width
224 index explaining 41.6% (40.7% after adjustment for the degrees of freedom) of the
225 mean scPDSI variance, $F = 48.385$ and $p < 0.01$. Except for several anomalously high
226 values, the reconstructed mean scPDSI values agree well with the instrumental data
227 (Fig. 4c). The first-order differencing correlation coefficient is 0.571. The split
228 calibration-verification test results show that the reconstruction model has good
229 reliability and stability, with values of RE and CE > 0.20 . The sign and first-order
230 difference sign tests are significant at the 0.05 level (Table 3). These results suggest
231 that our scPDSI reconstruction has reliably recorded climate signals.

232 **3.2 Characteristics of the scPDSI reconstruction**

233 Our scPDSI reconstructions reveal oscillations between drier and wetter conditions
234 in the Hailar region during 1796–2020 CE (Fig. 4e). Dry/wet periods after 15-year
235 low-pass filtering were continuously below/above the long-term mean for more than
236 10 years. Four dry periods (1809–1819, 1829–1878, 1937–1950, 1990–2012), and

237 five wet periods (1796-1808, 1879-1900, 1910-1936, 1951-1963, 1970-1989) are
238 evident in the record. A data value < 1.5 times the standard deviation of the long-term
239 mean is defined as an extreme drought year, and such years occurred in 1779, 1826,
240 1837, 1840, 1842, 1857, 1864, 1866, 1951, 1996 and 2007. The curves also show an
241 increase following lower values in the 1870s, and a clear decreasing trend in the last
242 10 years, which is consistent with the instrumental observations (Fig. 4e). The results
243 of the MTM analysis revealed periodicities of 2–8.1 years (Fig. 5). The results of
244 spatial correlation analysis revealed a strong positive correlation between the
245 reconstructed scPDSI series on the scale of the upper basin of the Heilongjiang (Amur)
246 River and the gridded scPDSI, total rainfall, and runoff, from May to July (Fig. 6a, b).
247 After obtaining the mean series of the gridded data, good correlation coefficients were
248 obtained between the reconstructed scPDSI and the regional mean of the gridded data,
249 with $r = 0.57$ ($p < 0.01$), and $r = 0.35$ ($p < 0.01$), with CRU scPDSI and CRU
250 precipitation, respectively (Fig. 6a, b, c). The correlation coefficients between
251 reconstructed scPDSI and G-RUN runoff and runoff from the Khabarovsk
252 Hydrological Station runoff were $r = 0.34$ ($p < 0.01$) and $r = 0.36$ ($p < 0.01$),
253 respectively (Fig. 6d). These results indicate that our scPDSI reconstructions reliably
254 reflect the regional drought characteristics and changes in runoff in the Upper
255 Heilongjiang (Amur) River Basin.

256 **4. Discussion**

257 **4.1 Climate–tree ring growth relationships and temporal variations** 258 **in regional drought**

259 The positive correlation between tree-ring width and rainfall and the negative
260 correlation with temperature indicate that the increase in the circumference of *P.*
261 *sylvestris* var. *Mongolica* in the Hailar area is described by a humidity-sensitive
262 growth model. Temperature is much a greater stressor for tree growth in arid and
263 semi-arid regions than precipitation (Bao et al. 2015; Fang et al. 2010; Sun et al.
264 2012). The higher correlation coefficients between temperature and the tree-ring
265 indices in our dataset indicate that the radial expansion of *P. sylvestris* var.
266 *Mongolica* in the Hailar region is mainly influenced by soil moisture conditions
267 modulated by temperature variations (Fig. 4a). Compared with precipitation alone,
268 PDSI better reflects changes in soil moisture caused by precipitation and temperature
269 stress on the radial growth of trees. The PDSI during the growing season from May to
270 July also shows the highest correlation with scPDSI ($r = 0.645$, $p < 0.01$) (Fig. 4c).
271 The radial growth of *P. sylvestris* var. *Mongolica* is mainly determined by the control
272 of soil moisture by precipitation (Song et al. 2015). However, in semiarid areas, the
273 increasing temperature during the growing season accelerates the evaporation of soil
274 moisture and enhances plant transpiration, and thus the soil moisture supply is
275 insufficient for tree growth (Shang et al. 2012). In contrast, temperatures above a
276 certain threshold during the growth season can adversely affect tree growth because
277 the decrease in the net photosynthetic rate and excessive temperatures will lead to
278 more severe drought stress (D'arrigo et al. 2004).

279 The reconstructed scPDSI reveals ten extreme drought years during 1796–2000,
280 seven of which can be identified in historical documents (Zhang, 2004; Liu and Wen,

281 2008). (Table 4). The historical literature includes detailed descriptions of drought
282 events; for example, 1951 was a drought year throughout Inner Mongolia—one of a
283 series of relatively severe droughts—when the lack of rainfall in summer and autumn
284 was more severe than in spring. Numerous seedlings of crop plants in Hulunbuir were
285 killed by the drought and the grain yield of the entire region was significantly reduced
286 (Liu and Wen, 2008). In 1996, a severe drought affected the north-central part of Inner
287 Mongolia in early summer (Liu and Wen, 2008). Our reconstruction captures several
288 extreme drought events in the past decade. The intense heat in NEC during
289 July–August 2016 resulted in severe crop yield reductions and economic losses
290 amounting to \$15.61 billion (Li et al. 2018). In 2017, the Northeast China (NEC)
291 region encountered an exceptionally severe spring and summer drought event (Zeng
292 et al. 2019). This event had a significant impact on the cultivated area in eastern Inner
293 Mongolia. Notably, the crop failure extent and ensuing economic losses ranked as the
294 second highest since 2012. The drought affected an area of 74.3×10^4 km² across the
295 region, with the western Hulunbuir area experiencing primarily moderately intense
296 drought (Zhang et al. 2017).

297 **4.2 Synoptic meteorological analysis of severe drought**

298 To explore the climatic drivers of the extreme drought events, we screened the
299 wettest and driest decades from 1891 to 2020. SST changes in the previous winter are
300 critical for precipitation in East Asia in the following year (Juneng and Tangang,
301 2005), and thus we selected the winter SST from December of the previous year to
302 January of the current year to analyze the respective decadal SST anomalies. The

303 results indicate that during wet years, SST has the negative ENSO phase pattern,
304 while in dry years, it has the positive ENSO phase pattern (Fig. 7a, b). The
305 reconstructed scPDSI also has the same 2–5 year cycle as ENSO (Fig. 5), suggesting
306 that ENSO may have contributed to drought in the Upper Heilongjiang (Amur) River
307 Basin. The wettest decade and the driest decade from 1950 to 2020 were also selected
308 for climatological analysis, which revealed the following relationships. During the
309 wet years, the SST in the preceding winter had the negative ENSO phase pattern, the
310 SST in the eastern equatorial Pacific decreased, and the western Pacific warm pool
311 and the Walker circulation intensified. At the same time, the western Pacific
312 subtropical high pressure weakened and shifted northward, the Mongolian high
313 pressure weakened significantly (Fig. 8a), the anomalous cyclone in the wet years
314 corresponded to a cold anomaly (Fig. 8c), and the major rainfall band in May–July
315 (MJJ) shifted northward. This scenario caused an anomalous increase in precipitation
316 in the Upper Heilongjiang (Amur) River Basin during the selected wet years. In dry
317 years, the SST in the preceding winter had an ENSO positive phase pattern, the SST
318 difference between the western and eastern equatorial Pacific decreased, the
319 latitudinal Walker circulation weakened, the western Pacific subtropical high pressure
320 strengthens and shifted southward compared to normal. These events result in weak
321 East Asian summer winds and a significantly more intense Mongolian high (Fig. 8b).
322 The anomalous cyclone in dry years corresponds to a warm anomaly (Fig. 8d), and
323 the anticyclone corresponds to a warm anomaly (Fig. 8d), which is controlled by an
324 eccentric northerly component that favors cold air transport from high latitudes to the

325 northeast during dry years. This results in anomalous descending motion and a
326 southward shift of the main rain and wind belts, leading to drought (Fig. 8f).

327 Several additional studies have found that Nino3 SST has a significant negative
328 correlation with precipitation in North China (Wang 2002, Yu et al. 2004), and the
329 negative correlation between rainfall and ENSO in northern China is associated with
330 anomalous cyclones over East Asia (Wu, Hu et al. 2003). These findings exhibit
331 congruence with the outcomes derived from our analytical examinations. In summary,
332 the large-scale ocean-atmosphere-land circulation system is a critical driver of
333 drought development in the Upper Heilongjiang (Amur) River Basin.

334 **4.3 Atmospheric water cycle during drought years**

335 Based on NCEP-NCAR reanalysis 1 data (Kalnay et al. 1996), we quantified the
336 meteorological conditions and atmospheric hydrological cycle anomalies in the Hailar
337 region during May–July of the driest decade of 1950–2020, based on the
338 reconstructed scPDSI. The total climatic precipitation for May–July of 1950–2020
339 was 27.0×10^6 kg/s, while the total precipitation for May–July in a drought year was
340 23.0×10^6 kg/s, a decrease of 14.8%. The external advective input (F_{in}) under
341 climatic conditions was 230.9×10^6 kg/s, compared to 211.4×10^6 kg/s during the dry
342 year, with an 8.4% reduction in external advective input during the drought.
343 Evaporation (E) was 30.7×10^6 kg/s under these climatic conditions, and 29.5×10^6
344 kg/s during dry years, with a 3.9% reduction in evaporation during the drought.
345 Precipitation formed by external advective input (P_a) under these climatic conditions
346 was 25.3×10^6 kg/s, contributing 93.8% to precipitation, and precipitation formed by

347 evaporation (P_e) was 1.7×10^6 kg/s, with a precipitation recirculation rate of 6.2%.
348 Precipitation formed by external advection input (P_a) during the dry year was $21.4 \times$
349 10^6 kg/s, contributing 93.5% to precipitation, and precipitation formed by evaporation
350 (P_e) was 1.5×10^6 kg/s, with the precipitation recirculation rate of 6.5% (Fig. 9b).
351 During the dry year, total precipitation decreased by 14.8% compared to the climatic
352 mean, and the external advective input of water vapor decreased significantly (8.4%),
353 resulting in a 15.4% decrease in precipitation formed from the external advective
354 input of water vapor, with little change in evaporation and precipitation formed by
355 evaporation. These results suggest that the drought in the Upper Heilongjiang (Amur)
356 Basin is mainly caused by a reduction in the external advective water vapor input
357 rather than by anomalies in the precipitation cycle. Synthetic anomalies in the whole
358 layer water vapor fluxes and precipitation rates also indicate a decrease in advective
359 water vapor transport and precipitation during the drought (Fig. 9a). These results
360 indicate that variations in the process of moisture transport play a pivotal role in the
361 formation of drought in the Upper Heilongjiang (Amur) River Basin.

362 **5. Conclusion**

363 We built a composite tree-ring chronology for two sampling sites in the Hailar
364 region. Based on this chronology, we reconstructed the monthly mean scPDSI for
365 May–July in the Upper Heilongjiang (Amur) Basin since 1796. the reconstructed
366 sequence comprises more than 220 years of wet and dry variations in the Upper
367 Heilongjiang (Amur) River Basin, which experienced four consecutive dry periods
368 and five consecutive wet periods, since 1796 CE, with a significant 2-8-year

369 cyclicity. The drought reconstruction accurately captured the recent trends in dry/wet
370 variability and it reflects drought variability across a large area.

371 Our synoptic climatological analysis of extreme drought years suggests that the
372 dry/wet variability in the Upper Heilongjiang (Amur) River Basin is related to several
373 large-scale climate stresses and atmospheric circulation patterns (the ENSO and Silk
374 Road models), and that one of the critical drivers of drought development in the
375 Upper Heilongjiang (Amur) River Basin is the large-scale ocean-atmosphere-land
376 circulation system. Our atmospheric water circulation analysis suggests that the cause
377 of drought is primarily a reduction in advective water vapor transport, rather than
378 precipitation circulation processes, which further implies that atmospheric circulation
379 systems control wet/dry variability in the Upper Heilongjiang (Amur) River Basin.

380 Our drought reconstruction has several shortcomings since it is based on only two
381 sample sites, and it spans a relatively short interval (230 years), and represents only a
382 very small region. Therefore, it is essential to systematically compile additional tree
383 ring-based climate records from this region to provide drought reconstructions on a
384 large spatial scale, which may help characterize the spatio-temporal variability and
385 impact mechanisms of drought within NEC.

559 **Tables**

560 **Table 1.** Information about the tree-ring sampling sites in the Upper Amur
561 (Heilongjiang) River Basin.

Site code	Lat. (N)	long. (E)	Elevation (m)	Sample	Slope inclination	Exposure	Species
MGET	121°49'	46°42'	1120	63/33	5°-20°	0.2	<i>P sylvestris</i> var. <i>Mongolica</i>
NEGC	118°44'	49°12'	1540	40/20	10°-20°	0.3	<i>P sylvestris</i> var. <i>Mongolica</i>
RC				103/53			<i>P sylvestris</i> var. <i>Mongolica</i>

562 **Table 2.** Statistical properties of the tree-ring width chronologies from the Upper
563 Amur (Heilongjiang) River Bas

Statistic	MGET	NEGC	RC
Mean sensitivity	0.285	0.367	0.307
Standard deviation	0.198	0.21	0.19
Mean correlation between the trees	0.658	0.723	0.653
Signal to noise ratio (SNR)	86.651	60.15	26.063
Variance of the first eigenvector (%)	58.6	66.4	38.6

564 **Table 3.** Results of verification and calibration tests for the scPDSI reconstruction.

Statistical procedure	Calibration (1951-1985)	Verification (1986-2020)	Calibration (1986-2020)	Verification (1951-1985)	Full calibration (1951-2020)
R	0.727	0.611	0.661	0.611	0.645
r ²	0.529	0.374	0.436	0.374	0.416
RE		0.357		0.491	
CE		0.378		0.566	
Sign test		24+/11-		23+/12-	
First-order sign test		22+/12-		22+/12-	

565

566

567 **Table 4.** Comparisons between the reconstructed scPDSI and documented climatic
568 events.

Year	PDSI ₅₋₇	Local historical documents
------	---------------------	----------------------------

1779	-2.93	Famine in Taiyuan and Baotou
1837	-2.31	Drought in Qiqihaer
1842	-2.62	Drought in Baotou
1857	-2.28	Drought in Baotou and the Qingshuihe river
1866	-2.79	Drought in Hulunbuir
1951	-3.01	Inner Mongolia region drought, decrease I in Hulunbuir grain production
1996	-2.23	Drought in North Central Inner Mongolia in early summer

Figure 3. Chronologies of the two tree-rings records (MGET and NEGC) and the RC from the Upper Amur (Heilongjiang) River Basin. The thick black curve illustrates the 15-year low-pass filtered curve of the tree-ring width index. The inter-series correlation (Rbar) and the EPS are shown in the lowermost panel.

604 **Figure 4.** (a) Correlation coefficients between the tree-ring chronologies and monthly
 605 total precipitation and mean temperature. (b) Correlation coefficients between the RC
 606 tree-ring chronologies and monthly mean scPDSI of the CRU. Correlations are
 607 calculated from the previous June to the current September over the time period of
 608 1951–2020 (* represent the 95% significance level, and ** represents the 99%
 609 significance level). (c) Comparison between the instrumental and reconstructed mean
 610 May–July scPDSI for the Hailar region during 1951–2020. (d) One-dimensional
 611 linear regression fits for the May to July scPDSI for 1796–2020. (e) Reconstructed
 612 mean May–July scPDSI and its 15-year low-pass filtered version since 1796 CE. The
 613 horizontal central line represents the average reconstructed scPDSI. The horizontal
 614 dotted lines represent ± 1 SD and ± 1.5 SD on a mean value basis.

620 **Figure 5.** MTM spectral density of the drought reconstruction. The dashed curves
 621 represent the 95% (red) and 99% (blue) significance levels, respectively.

622

623

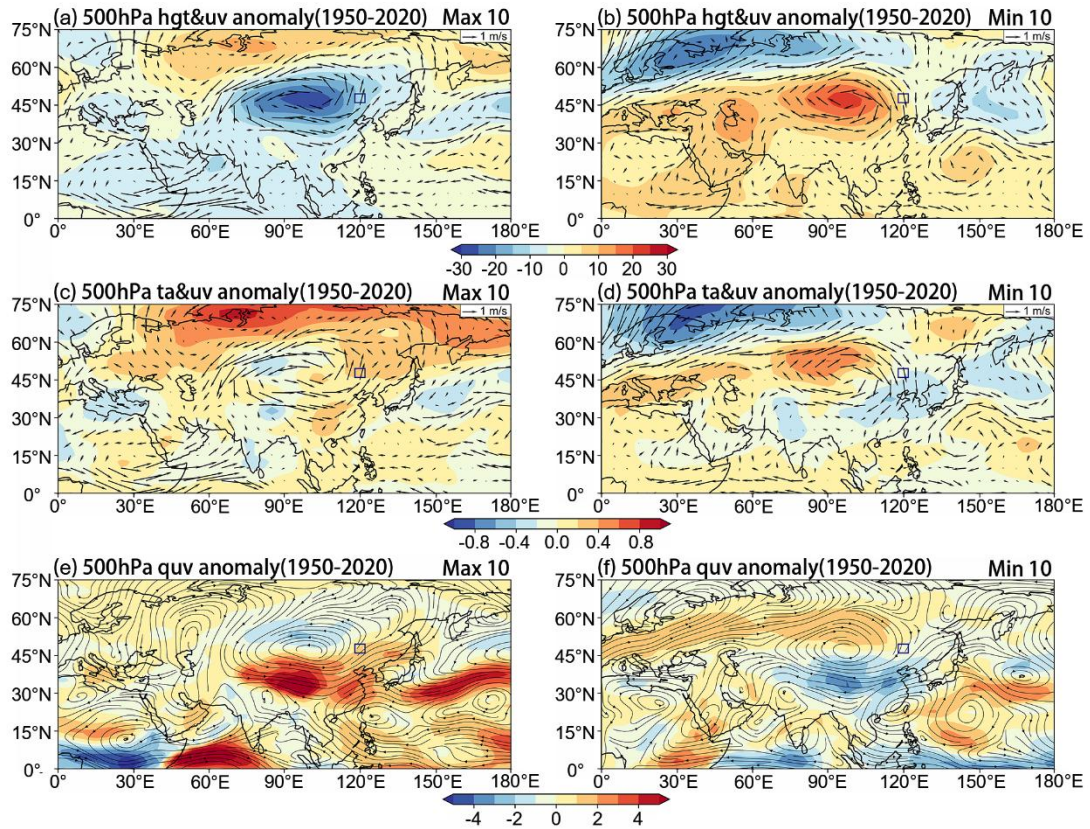

624 **Figure 6.** Spatial correlation maps of the reconstructed scPDSI with the CRU gridded
 625 mean May–July scPDSI (a), the CRU gridded total May–July precipitation (c) since
 626 1901 CE. The rectangle indicates the location of the range of the grid, shaded areas
 627 represent the 99% significance level, dark curves represent 10-year low-pass filtered
 628 curves and the same below. The graphs on the right show a comparison of the
 629 reconstructed scPDSI with the regional mean scPDSI (b) and precipitation (d) curves
 630 from the CRU, dark curves represent ten years of low-pass filtering. (e) Reconstructed
 631 scPDSI with G-RUN gridded May–July mean runoff spatial correlation maps for the
 632 period of 1902–2019. (f) Comparison of reconstructed scPDSI, hydrological station
 633 runoff data, and the G-RUN regional mean runoff data for the period of 1902–1985.
 634

Figure 9. (a) Anomaly composites of the mean precipitation rate ($\text{kg/s}\cdot\text{m}^2$) and the whole layer moisture flux ($\text{kg}\cdot\text{m/s}$) for May–July of the driest decade in the study area ($115\text{--}125^\circ\text{E}$, $42.5\text{--}52.5^\circ\text{N}$) relative to that of May–July for the period of 1950–2020 (arrows represent the the whole layer moisture flux, filled colors represent the precipitation rate). (b) Schematic diagram of the land-atmosphere water balance in the study area during the climatic period (1950–2020) and dry years. The variables in this plot (i.e., F_{in} , F_{out-a} , F_{out-e} , F_{out} , P_a , P_e , P , E) are explained in Section 2.4. The blue labels (in kg/s) indicate climatic averages, while the red labels indicate averages during drought.
