18 **Abstract:** The economic and environmental impacts of persistent droughts in East  
19 Asia are of growing concern, and therefore it is important to study the cyclicity and  
20 causes of these regional droughts. The self-calibrating Palmer Drought Severity Index  
21 (scPDSI) has been extensively employed to describe the severity of regional drought,  
22 and several PDSI reconstructions based on tree rings have been produced. We compiled  
23 a tree-ring chronology for Hailar pine (*Pinus sylvestris* var. *Mongolica*) from two sites  
24 in the Hailar region in the Upper Heilongjiang (Amur) River Basin. Analysis of the  
25 climate response revealed that scPDSI was the primary factor limiting tree ring growth

26 from May to July. The mean May to July scPDSI in the Hailar region since 1796 was  
27 reconstructed from the tree-ring width chronology. The results of spatial correlation  
28 analysis revealed that the reconstructed scPDSI in this region responded significantly  
29 to climate change. Analysis of the synoptic climatology indicated that the drought in  
30 the Upper Heilongjiang (Amur) River Basin is closely related to ENSO and the Silk  
31 Road teleconnection. The results of atmospheric water cycle analysis show that water  
32 vapor transport processes are the dominant factor in the development of drought in this  
33 region.

## 36 **1. Introduction**

37 Drought—accompanied by persistent high temperatures and below-average  
38 precipitation over intervals of months to years—is of growing concern. As a natural  
39 disaster, the frequency and duration of drought have increased as global warming has  
40 intensified. The impact of drought on human well-being and economic productivity is  
41 also increasing, given that drought severely threatens food and water security (Lesk et  
42 al. 2016; Trenberth et al. 2014; Wang et al. 2016; Chen et al. 2022). Due to regional  
43 water shortages, droughts frequently wreak havoc on agriculture and the quality of life  
44 in northeast Asia. Hence, understanding the variability of drought in this region and its  
45 causal mechanisms is essential for both drought prediction and the formulation of  
46 disaster response strategies (Li et al. 2019; Yuan and Wood 2013).

47 However, only short-duration instrumental records of drought variability are

48 available for northeast Asia, most of them from the 1950s onwards. However, this  
49 deficiency can be addressed via proxy paleoclimate records, such as tree-ring widths  
50 (Fritts, 1991). With their high annual precision and extensive coverage, tree rings have  
51 been used as a reliable proxy for reconstructing historical climatic and hydrological  
52 changes (Cook et al. 2016; Chen et al. 2021; Pearson et al. 2020). Hailar is located in  
53 the Upper Heilongjiang (Amur) River Basin, in the woodland-steppe interface of  
54 northeast Asia, part of the eastern edge of the Hulunbuir grasslands, a region highly  
55 susceptible to climatic and environmental changes and that has experienced drought  
56 over the past few decades (Zhang et al. 1997; Wang et al. 2010; Bao et al. 2015; Chen  
57 et al. 2012). Drought reconstructions based on tree-ring widths can potentially make a  
58 valuable contribution to regional planning and ecological conservation in this region.  
59 Over the past two decades, several studies based on tree-ring width have been  
60 conducted in Northeast Asia (Cook et al. 2010; Bao et al. 2015; Chen et al. 2012; Liu  
61 et al. 2016; Chen et al. 2022, Zhao et al. 2023). However, there is a requirement to focus  
62 research efforts on the agro-pastoral zone located in the western region of the northeast  
63 Asia. This area is characterized by a delicate ecological balance and high climate  
64 susceptibility, making it imperative to enhance our comprehension of drought patterns  
65 and underlying mechanisms.

66 Severe drought events are a serious problem in northern China, especially since the  
67 late 1970s, when the weakening of the East Asian Summer Monsoon (EASM)  
68 contributed to the 'southern flooding and northern drought' climatic pattern, with  
69 frequent intense drought events in the north (Wang, 2002; Yu et al. 2004; Ding et al.

70 2009). Regarding the climatic mechanisms responsible for the northeast Asia drought,  
71 it has been suggested that variations in the Pacific Ocean interdecadal oscillation (PDO)  
72 and in Arctic Ocean sea-ice cover have contributed to an interdecadal decrease in  
73 precipitation in northeast Asia, leading to drought (Han et al. 2015). It has also been  
74 suggested that the global distribution of sea surface temperature and ENSO events are  
75 closely linked to summer precipitation in northeast Asia, thus explaining the summer  
76 drought mechanism in the northeast Asia from an interannual perspective (Han et al.  
77 2017). Winter NAO has also been shown to impact the interannual variability of  
78 summer drought events in northeast Asia (Fu and Zeng, 2005). Anticyclonic circulation  
79 anomalies can often trigger extreme and prolonged drought events. Such anomalies  
80 always occur as a major product of specific remote teleconnection patterns, called  
81 stationary wave patterns (Schubert et al. 2014). Several steady wave models have been  
82 shown to generate extreme drought events, with the 2014 summer drought in northern  
83 China attributed to the European Union pattern. It has also been confirmed that the Silk  
84 Road, Pacific-Japanese, and European Union models caused the July–August 2014  
85 drought in north and northeastern China (Wang and He, 2015; Wang et al. 2017; Xu et  
86 al. 2017). While many of the above studies describe water vapor flux anomalies during  
87 periods of extreme drought, our understanding of the role of water vapor derived from  
88 local evaporation and advective transport is limited. Quantifying the contribution of  
89 advected water vapor transport and precipitation circulation processes to precipitation  
90 is essential for understanding the water vapor cycle and anticipating the intensity of  
91 severe drought episodes (Findell and Eltahir, 2003; Guan et al. 2022).

92 The objectives of the present study are: (1) to reconstruct the scPDSI of the Hailar  
93 region and to analyze changes in the temporal variations of regional drought; (2) to  
94 determine the atmospheric circulation mechanisms generating extreme drought events;  
95 and (3) to analyze the contribution of advective water vapor transport and local  
96 evaporation to precipitation during droughts, and to determine their leading causes.

## 97 **2. Materials and Methods**

### 98 **2.1 Study area**

99 Tree-ring sampling sites NEGC (119°36' E, 47°58' N, 600-700m a.s.l.) and MGET  
100 (119°24' E, 47°59' N, 1100-1200 m a.s.l.) are located in the Upper Heilongjiang (Amur)  
101 River Basin (Fig. 1). The region lies within the arid and semi-arid region of Northeast  
102 China (NEC), on the eastern edge of the Hulunbeier steppe and close to the western  
103 slopes of the Greater Khingan Range. This region has a continental and monsoonal  
104 climate (Bao et al. 2012). Due to the incursion of high-latitude cold and dry air masses  
105 in winter and of warm and moist air masses from low-latitude areas in summer, the  
106 climate tends to alternate between cold and dry in winter and warm and humid in  
107 summer. The average annual temperature is around -0.9 °C and the average yearly  
108 precipitation is ~382.8 mm (Fig. 2a). December–January is the coldest period, with  
109 sparse rainfall, while June–August is the hottest period when precipitation is abundant  
110 (Fig. 2b). Thus, the climate is generally cold and dry. The grassland in this region is  
111 undergoing severe desertification and degradation in response to global and regional  
112 climate change (Zhang et al. 2011).

### 113 **2.2 Tree-ring data**

114 The dominant tree species in the Hailar region is Hailar pine (*Pinus sylvestris* var.  
115 *Mongolica*), which was sampled for tree-ring analysis. Both sites were located at the  
116 upper tree line, on steep slopes with thin soils. Information about the sampling sites is  
117 given in Table 1. Samples were taken from breast height using a 10-mm diameter  
118 incremental borer. Forty cores were collected from 20 trees at sampling site NEGC, and  
119 63 cores were collected from 33 trees at sampling site MGET. In the laboratory, the  
120 core samples were dried, mounted and successively sanded with 320- and 600-grit  
121 sandpaper until the tree-ring widths were visible, and were then imaged using a high-  
122 precision scanner. Tree-ring width data were measured using CooRecorder 9.4 software,  
123 and the data quality was checked by cross-matching using the quality control program  
124 COFFCHA (Holmes, 1983). The ARSTAN procedure was then used to remove non-  
125 climatic influences on the tree-ring width data, due to age and growth, using  
126 exponential detrending. This procedure resulted in a standardized chronology of tree-  
127 ring widths (STD), a chronology of differences (RES), and an autoregressive  
128 chronology (ARS). The individual detrended chronologies from the two sites were  
129 combined to produce a new RC chronology using a robust averaging method (Cook,  
130 1985). The STD chronology was selected to retain high and low-frequency variations  
131 based on the considerations of subsequent analyses. The data series were truncated  
132 according to thresholds of at least  $EPS > 0.85$  and 6 (3 trees) for the expressed  
133 population signal and sample size, respectively, resulting in a reliable reconstruction  
134 for the period of 1796–2020.

### 135 **2.3 Climate data and statistical methods**

136 Monthly instrumental climate data from Hailar meteorological station (49°15' E,  
137 119°42' N, 650 m a.s.l.), affiliated to the National Meteorological Administration of  
138 China, including monthly mean temperature and monthly total precipitation, were  
139 obtained for the period of 1951–2020. Monthly mean runoff data from Khabarovsk  
140 Hydrological Station on the lower Heilongjiang River were used to analyze the  
141 response of the reconstructed scPDSI to runoff variations. The locations of the  
142 meteorological and hydrological stations are shown in Fig. 2a. scPDSI gridded climate  
143 data of CRU TS 4.06 from the Climate Research Unit (CRU) of the University of East  
144 Anglia were also used in this study (Harris et al. 2014). SPSS 22.0 was used to assess  
145 the correlation coefficient of the climate signals contained in the three chronologies for  
146 the individual months from July of the previous year to September of the current year.  
147 Based on the results of this correlation coefficient analysis, several seasonal climate  
148 combinations from July of the last year to September of the current year were filtered,  
149 and the seasonal climate combinations with the highest correlation were selected for  
150 climate reconstruction, using one-dimensional linear regression. A split calibration-  
151 verification test was used to test the reliability of the reconstructed models, dividing the  
152 period of 1951–2020 into independent calibration and validation periods. The main  
153 parameters assessed were the correlation coefficient (R), explained variance (R<sup>2</sup>),  
154 efficiency coefficient (CE), error reduction value (RE), sign test (ST1), and the first-  
155 order difference sign test (ST2) (Cook and Kairiukstis, 2013). In this study, after 15-  
156 year low-pass filtering, intervals of more than 10 years below/above the mean of the  
157 reconstructed series were defined as dry/wet periods, and the years below or above 1.5

158 times the standard deviation of the series mean were defined as extreme dry/wet years.  
 159 The quasi-periodic characteristics of the reconstructed scPDSI were analyzed using  
 160 Multitaper spectral analysis (MTM) (Mann and Lees, 1996). Spatial correlation maps  
 161 were generated between the reconstructed scPDSI series and the grid data, including  
 162 precipitation and scPDSI data from CRU TS 4.06, and runoff grid point data from G-  
 163 RUN (Harris et al. 2014; Ghiggi et al. 2021).

## 164 **2.4 Land-atmosphere water balance**

165 The Brubaker binary model has been used to quantify the contribution of external  
 166 water vapor transport and local evaporative water vapor to precipitation, based on the  
 167 atmospheric water vapor balance (Brubaker et al. 1993). The water vapor equation for  
 168 the vertical integration per unit area can be expressed as follows (Brubaker et al. 1993;  
 169 Guo et al. 2018):

$$170 \quad \frac{\partial Q}{\partial t} = -\left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y}\right) + E - P, \quad (1)$$

171 Where  $Q$  is the vertically integrated water vapor concentration;  $F_u$  and  $F_v$  are the  
 172 vertically integrated latitudinal and meridional water vapor fluxes, respectively; and  $E$   
 173 and  $P$  are the vertically integrated land evaporation and rainfall, respectively.

174 Compared to the magnitude of the water vapor flux, the vertically integrated water  
 175 vapor content varies very little over time and is insignificant on longer timescales  
 176 (Burde and Zangvil, 2001). Thus, the left side of equation (1) is 0. In addition, the water  
 177 vapor balance equation for the external water vapor transport term is as follows (Guo  
 178 et al. 2018; Zhao and Zhou, 2021; Li et al. 2020):

$$179 \quad -\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) = P_a \quad (2)$$

180 Where  $F_u^a$  and  $F_v^a$  represent the vertically integrated latitudinal and longitudinal  
 181 water vapor transport from external inputs, respectively. Assuming P, E and  $P_a$  are  
 182 constant within the study area during the interval of concern (Burde and Zangvil,  
 183 2001). Assuming that externally imported water vapor and locally evaporated water  
 184 vapor are well mixed over the study area, and that the proportions of evaporated and  
 185 advected water vapor contribute equally to the development of precipitation and  
 186 moisture fluxes. Using the above assumptions and the Gaussian scattering  
 187 assumptions, equations (1) and (2) can be applied to a region of area A (in m), as  
 188 follows:

$$189 \quad -\left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y}\right) |A = F_{in} - F_{out} = (P - E)A \quad (3)$$

$$190 \quad -\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) |A = F_{in} - F_{out-a} = P_a A \quad (4)$$

191 Here,  $-\left(\frac{\partial F_u}{\partial x} + \frac{\partial F_v}{\partial y}\right) |A$  and  $-\left(\frac{\partial F_u^a}{\partial x} + \frac{\partial F_v^a}{\partial y}\right) |A$  represent the total water vapour  
 192 irradiation dispersion in the targeted region and the irradiation dispersion of externally  
 193 transported water vapor, respectively;  $F_{out}$  and  $F_{out-a}$  represent the total water  
 194 vapour leaving the calculated area and the part of the external input water vapour  
 195 flowing away from the calculated area again, respectively; and  $F_{in}$  represents the  
 196 total water vapor transported to the targeted area from outside. This enables an  
 197 estimate to be made of the contribution of external moisture transport and local land  
 198 surface evaporation to precipitation, as follows (Guo et al. 2018; Li et al. 2020):

$$199 \quad r = \frac{P_a}{P} = \frac{2F_{in}}{2F_{in} + EA} \quad (5)$$

$$200 \quad \rho = 1 - \frac{P_a}{P} = \frac{EA}{2F_{in} + EA} \quad (6)$$

201 Where  $r$  and  $\rho$  are the contributions to precipitation from external water vapor

202 transport and local land surface evaporation, respectively, and  $\rho$  is the precipitation  
203 recirculation rate.

204 The Brubaker binary model water vapor transport process is based mainly on  
205 advection terms, which can be applied to calculate the precipitation recirculation rates  
206 in the study area. Given that the calculation of these precipitation recirculation rates  
207 depends on the size of the selected area, the study area was enlarged (42.5–52.5° N, 115–  
208 125° E) for the purpose of calculation.

### 209 **3. Results**

#### 210 **3.1 scPDSI reconstruction**

211 All the tree ring chronologies show a high mean sensitivity and standard deviation,  
212 typical of trees growing in arid and semi-arid regions, due to the location of the Hailar  
213 region. The high inter-series correlation coefficient suggests that our tree-ring width  
214 chronology reliably captures several standard climate signals. The EPS of the RC  
215 chronology passed the test for signal strength ( $\text{EPS} > 0.85$ ) after 1796 (Table 2 and Fig.  
216 3). The tree-ring width series has a significant negative correlation with temperature, a  
217 significant positive correlation with precipitation, and a significant positive correlation  
218 with scPDSI, according to the climate response results ( $p < 0.05$ ) (Fig. 4a, b). Screening  
219 for seasonal combinations of temperature, precipitation, and scPDSI revealed the  
220 strongest correlation coefficient between the RC tree ring width chronology and mean  
221 scPDSI from May to July ( $r = 0.645$ ,  $p < 0.01$ ). Accordingly, we reconstructed the May  
222 to July scPDSI for the Hailar region since 1796 CE, using the following equation (Fig.  
223 4d):

224 
$$Y = 3.681X - 4.146 \quad (7)$$

225 
$$(n = 70, r = 0.645, R^2 = 41.6\%, R_{adj}^2 = 40.7\%, F = 48.385, p < 0.01)$$

226 Where  $Y$  is the mean reconstructed scPDSI for May to July, and  $X$  is the tree ring  
227 width index from the composite chronology.

228 In equation (7), the correlation between the mean May–July scPDSI and the tree-  
229 ring width index over the period of 1951–2020 is 0.645, with the tree-ring width index  
230 explaining 41.6% (40.7% after adjustment for the degrees of freedom) of the mean  
231 scPDSI variance,  $F = 48.385$  and  $p < 0.01$ . Except for several anomalously high values,  
232 the reconstructed mean scPDSI values agree well with the instrumental data (Fig. 4c).  
233 The first-order differencing correlation coefficient is 0.571. The split calibration-  
234 verification test results show that the reconstruction model has good reliability and  
235 stability, with values of RE and CE  $> 0.20$ . The sign and first-order difference sign tests  
236 are significant at the 0.05 level (Table 3). These results suggest that our scPDSI  
237 reconstruction has reliably recorded climate signals.

### 238 **3.2 Characteristics of the scPDSI reconstruction**

239 Our scPDSI reconstructions reveal oscillations between drier and wetter conditions  
240 in the Hailar region during 1796–2020 CE (Fig. 4e). Dry/wet periods after 15-year low-  
241 pass filtering were continuously below/above the long-term mean for more than 10  
242 years. Four dry periods (1809–1819, 1829–1878, 1937–1950, 1990–2012), and five wet  
243 periods (1796–1808, 1879–1900, 1910–1936, 1951–1963, 1970–1989) are evident in the  
244 record. A data value  $< 1.5$  times the standard deviation of the long-term mean is defined  
245 as an extreme drought year, and such years occurred in 1779, 1826, 1837, 1840, 1842,

246 1857, 1864, 1866, 1951, 1996 and 2007. The curves also show an increase following  
247 lower values in the 1870s, and a clear decreasing trend in the last 10 years, which is  
248 consistent with the instrumental observations (Fig. 4e). The results of the MTM analysis  
249 revealed periodicities of 2–8.1 years (Fig. 5). The results of spatial correlation analysis  
250 revealed a strong positive correlation between the reconstructed scPDSI series on the  
251 scale of the upper basin of the Heilongjiang (Amur) River and the gridded scPDSI, total  
252 rainfall, and runoff, from May to July (Fig. 6a, b). After obtaining the mean series of  
253 the gridded data, good correlation coefficients were obtained between the reconstructed  
254 scPDSI and the regional mean of the gridded data, with  $r = 0.57$  ( $p < 0.01$ ), and  $r = 0.35$   
255 ( $p < 0.01$ ), with CRU scPDSI and CRU precipitation, respectively (Fig. 6a, b, c). The  
256 correlation coefficients between reconstructed scPDSI and G-RUN runoff and runoff  
257 from the Khabarovsk Hydrological Station runoff were  $r = 0.34$  ( $p < 0.01$ ) and  $r = 0.36$   
258 ( $p < 0.01$ ), respectively (Fig. 6d). These results indicate that our scPDSI reconstructions  
259 reliably reflect the regional drought characteristics and changes in runoff in the Upper  
260 Heilongjiang (Amur) River Basin.

## 261 **4. Discussion**

### 262 **4.1 Climate–tree ring growth relationships and temporal variations** 263 **in regional drought**

264 The positive correlation between tree-ring width and rainfall and the negative  
265 correlation with temperature indicate that the increase in the circumference of *P.*  
266 *sylvestris var. Mongolica* in the Hailar area is described by a humidity-sensitive growth  
267 model. Temperature is much a greater stressor for tree growth in arid and semi-arid

268 regions than precipitation (Bao et al. 2015; Fang et al. 2010; Sun et al. 2012). The higher  
269 correlation coefficients between temperature and the tree-ring indices in our dataset  
270 indicate that the radial expansion of *P. sylvestris* var. *Mongolica* in the Hailar region is  
271 mainly influenced by soil moisture conditions modulated by temperature variations (Fig.  
272 4a). Compared with precipitation alone, PDSI better reflects changes in soil moisture  
273 caused by precipitation and temperature stress on the radial growth of trees. The PDSI  
274 during the growing season from May to July also shows the highest correlation with  
275 scPDSI ( $r = 0.645$ ,  $p < 0.01$ ) (Fig. 4c). The radial growth of *P. sylvestris* var. *Mongolica*  
276 is mainly determined by the control of soil moisture by precipitation (Song et al. 2015).  
277 However, in semiarid areas, the increasing temperature during the growing season  
278 accelerates the evaporation of soil moisture and enhances plant transpiration, and thus  
279 the soil moisture supply is insufficient for tree growth (Shang et al. 2012). In contrast,  
280 temperatures above a certain threshold during the growth season can adversely affect  
281 tree growth because the decrease in the net photosynthetic rate and excessive  
282 temperatures will lead to more severe drought stress (D'arrigo et al. 2004).

283 The reconstructed scPDSI reveals ten extreme drought years during 1796–2000,  
284 seven of which can be identified in historical documents (Zhang, 2004; Liu and Wen,  
285 2008). (Table 4). The historical literature includes detailed descriptions of drought  
286 events; for example, 1951 was a drought year throughout Inner Mongolia—one of a  
287 series of relatively severe droughts—when the lack of rainfall in summer and autumn  
288 was more severe than in spring. Numerous seedlings of crop plants in Hulunbuir were  
289 killed by the drought and the grain yield of the entire region was significantly reduced

290 (Liu and Wen, 2008). In 1996, a severe drought affected the north-central part of Inner  
291 Mongolia in early summer (Liu and Wen, 2008). Our reconstruction captures several  
292 extreme drought events in the past decade. The intense heat in NEC during July–August  
293 2016 resulted in severe crop yield reductions and economic losses amounting to \$15,61  
294 billion (Li et al. 2018). In 2017, the Northeast China (NEC) region encountered an  
295 exceptionally severe spring and summer drought event (Zeng et al. 2019). This event  
296 had a significant impact on the cultivated area in eastern Inner Mongolia. Notably, the  
297 crop failure extent and ensuing economic losses ranked as the second highest since  
298 2012. The drought affected an area of  $74.3 \times 10^4$  km<sup>2</sup> across the region, with the  
299 western Hulunbuir area experiencing primarily moderately intense drought (Zhang et  
300 al. 2017).

#### 301 **4.2 Synoptic meteorological analysis of severe drought**

302 To explore the climatic drivers of the extreme drought events, we screened the  
303 wettest and driest decades from 1891 to 2020. SST changes in the previous winter are  
304 critical for precipitation in East Asia in the following year (Juneng and Tangang, 2005),  
305 and thus we selected the winter SST from December of the previous year to January of  
306 the current year to analyze the respective decadal SST anomalies. The results indicate  
307 that during wet years, SST has the negative ENSO phase pattern, while in dry years, it  
308 has the positive ENSO phase pattern (Fig. 7a, b). The reconstructed scPDSI also has  
309 the same 2–5 year cycle as ENSO (Fig. 5), suggesting that ENSO may have contributed  
310 to drought in the Upper Heilongjiang (Amur) River Basin. The wettest decade and the  
311 driest decade from 1950 to 2020 were also selected for climatological analysis, which

312 revealed the following relationships. During the wet years, the SST in the preceding  
313 winter had the negative ENSO phase pattern, the SST in the eastern equatorial Pacific  
314 decreased, and the western Pacific warm pool and the Walker circulation intensified. At  
315 the same time, the western Pacific subtropical high pressure weakened and shifted  
316 northward, the Mongolian high pressure weakened significantly (Fig. 8a), the  
317 anomalous cyclone in the wet years corresponded to a cold anomaly (Fig. 8c), and the  
318 major rainfall band in May–July (MJJ) shifted northward. This scenario caused an  
319 anomalous increase in precipitation in the Upper Heilongjiang (Amur) River Basin  
320 during the selected wet years. In dry years, the SST in the preceding winter had an  
321 ENSO positive phase pattern, the SST difference between the western and eastern  
322 equatorial Pacific decreased, the latitudinal Walker circulation weakened, the western  
323 Pacific subtropical high pressure strengthens and shifted southward compared to  
324 normal. These events result in weak East Asian summer winds and a significantly more  
325 intense Mongolian high (Fig. 8b). The anomalous cyclone in dry years corresponds to  
326 a warm anomaly (Fig. 8d), and the anticyclone corresponds to a warm anomaly (Fig.  
327 8d), which is controlled by an eccentric northerly component that favors cold air  
328 transport from high latitudes to the northeast during dry years. This results in anomalous  
329 descending motion and a southward shift of the main rain and wind belts, leading to  
330 drought (Fig. 8f).

331 Several additional studies have found that Nino3 SST has a significant negative  
332 correlation with precipitation in North China (Wang 2002, Yu et al. 2004), and the  
333 negative correlation between rainfall and ENSO in northern China is associated with

334 anomalous cyclones over East Asia (Wu, Hu et al. 2003). These findings exhibit  
335 congruence with the outcomes derived from our analytical examinations. In summary,  
336 the large-scale ocean-atmosphere-land circulation system is a critical driver of drought  
337 development in the Upper Heilongjiang (Amur) River Basin.

### 338 **4.3 Atmospheric water cycle during drought years**

339 Based on NCEP-NCAR reanalysis 1 data (Kalnay et al. 1996), we quantified the  
340 meteorological conditions and atmospheric hydrological cycle anomalies in the Hailar  
341 region during May–July of the driest decade of 1950–2020, based on the reconstructed  
342 scPDSI. The total climatic precipitation for May–July of 1950–2020 was  $27.0 \times 10^6$   
343 kg/s, while the total precipitation for May–July in a drought year was  $23.0 \times 10^6$  kg/s,  
344 a decrease of 14.8%. The external advective input ( $F_{in}$ ) under climatic conditions was  
345  $230.9 \times 10^6$  kg/s, compared to  $211.4 \times 10^6$  kg/s during the dry year, with an 8.4%  
346 reduction in external advective input during the drought. Evaporation ( $E$ ) was  $30.7 \times$   
347  $10^6$  kg/s under these climatic conditions, and  $29.5 \times 10^6$  kg/s during dry years, with a  
348 3.9% reduction in evaporation during the drought. Precipitation formed by external  
349 advective input ( $P_a$ ) under these climatic conditions was  $25.3 \times 10^6$  kg/s, contributing  
350 93.8% to precipitation, and precipitation formed by evaporation ( $P_e$ ) was  $1.7 \times 10^6$  kg/s,  
351 with a precipitation recirculation rate of 6.2%. Precipitation formed by external  
352 advection input ( $P_a$ ) during the dry year was  $21.4 \times 10^6$  kg/s, contributing 93.5% to  
353 precipitation, and precipitation formed by evaporation ( $P_e$ ) was  $1.5 \times 10^6$  kg/s, with the  
354 precipitation recirculation rate of 6.5% (Fig. 9b). During the dry year, total precipitation  
355 decreased by 14.8% compared to the climatic mean, and the external advective input of

356 water vapor decreased significantly (8.4%), resulting in a 15.4% decrease in  
357 precipitation formed from the external advective input of water vapor, with little change  
358 in evaporation and precipitation formed by evaporation. These results suggest that the  
359 drought in the Upper Heilongjiang (Amur) Basin is mainly caused by a reduction in the  
360 external advective water vapor input rather than by anomalies in the precipitation cycle.  
361 Synthetic anomalies in the whole layer water vapor fluxes and precipitation rates also  
362 indicate a decrease in advective water vapor transport and precipitation during the  
363 drought (Fig. 9a). These results indicate that variations in the process of moisture  
364 transport play a pivotal role in the formation of drought in the Upper Heilongjiang  
365 (Amur) River Basin.

## 366 **5. Conclusion**

367 We built a composite tree-ring chronology for two sampling sites in the Hailar region.  
368 Based on this chronology, we reconstructed the monthly mean scPDSI for May–July in  
369 the Upper Heilongjiang (Amur) Basin since 1796. the reconstructed sequence  
370 comprises more than 220 years of wet and dry variations in the Upper Heilongjiang  
371 (Amur) River Basin, which experienced four consecutive dry periods and five  
372 consecutive wet periods, since 1796 CE, with a significant 2-8-year cyclicality. The  
373 drought reconstruction accurately captured the recent trends in dry/wet variability and  
374 it reflects drought variability across a large area.

375 Our synoptic climatological analysis of extreme drought years suggests that the  
376 dry/wet variability in the Upper Heilongjiang (Amur) River Basin is related to several  
377 large-scale climate stresses and atmospheric circulation patterns (the ENSO and Silk

378 Road models), and that one of the critical drivers of drought development in the Upper  
379 Heilongjiang (Amur) River Basin is the large-scale ocean-atmosphere-land circulation  
380 system. Our atmospheric water circulation analysis suggests that the cause of drought  
381 is primarily a reduction in advective water vapor transport, rather than precipitation  
382 circulation processes, which further implies that atmospheric circulation systems  
383 control wet/dry variability in the Upper Heilongjiang (Amur) River Basin.

384 Our drought reconstruction has several shortcomings since it is based on only two  
385 sample sites, and it spans a relatively short interval (230 years), and represents only a  
386 very small region. Therefore, it is essential to systematically compile additional tree  
387 ring-based climate records from this region to provide drought reconstructions on a  
388 large spatial scale, which may help characterize the spatio-temporal variability and  
389 impact mechanisms of drought within NEC.

## 390 **6. Code and data availability**

391 ScPDSI reconstruction in the Upper Heilongjiang (Amur) River Basin will be  
392 available in the Supplement. The data that support the findings of this study are  
393 available from the corresponding author upon reasonable request.

## 394 **7. Author contribution**

395 Feng Chen conceived the study, Yang Xu conducted the analyses and wrote the  
396 manuscript, other authors were involved in the sample collection. All authors  
397 interpreted and discussed the results.

570 **Tables**

571 **Table 1.** Information about the tree-ring sampling sites in the Upper Amur  
572 (Heilongjiang) River Basin.

Site code	Lat. (N)	long. (E)	Elevation (m)	Sample	Slope inclination	Exposure	Species
MGET	121°49'	46°42'	1120	63/33	5°-20°	0.2	<i>P sylvestris var.</i> <i>Mongolica</i>
NEGC	118°44'	49°12'	1540	40/20	10°-20°	0.3	<i>P sylvestris var.</i> <i>Mongolica</i>
RC				103/53			<i>P sylvestris var.</i> <i>Mongolica</i>

573 **Table 2.** Statistical properties of the tree-ring width chronologies from the Upper Amur  
574 (Heilongjiang) River Bas

Statistic	MGET	NEGC	RC
Mean sensitivity	0.285	0.367	0.307
Standard deviation	0.198	0.21	0.19
Mean correlation between the trees	0.658	0.723	0.653
Signal to noise ratio (SNR)	86.651	60.15	26.063
Variance of the first eigenvector (%)	58.6	66.4	38.6

575 **Table 3.** Results of verification and calibration tests for the scPDSI reconstruction.

Statistical procedure	Calibration (1951-1985)	Verification (1986-2020)	Calibration (1986-2020)	Verification (1951-1985)	Full calibration (1951-2020)
R	0.727	0.611	0.661	0.611	0.645
r2	0.529	0.374	0.436	0.374	0.416
RE		0.357		0.491	
CE		0.378		0.566	
Sign test		24+/11-		23+/12-	
First-order sign test		22+/12-		22+/12-	

576

577

578 **Table 4.** Comparisons between the reconstructed scPDSI and documented climatic  
 579 events.

<b>Year</b>	<b>PDSI<sub>5-7</sub></b>	<b>Local historical documents</b>
1779	-2.93	Famine in Taiyuan and Baotou
1837	-2.31	Drought in Qiqihaer
1842	-2.62	Drought in Baotou
1857	-2.28	Drought in Baotou and the Qingshuihe river
1866	-2.79	Drought in Hulunbuir
1951	-3.01	Inner Mongolia region drought, decrease I in Hulunbuir grain production
1996	-2.23	Drought in North Central Inner Mongolia in early summer

**Figure 3.** Chronologies of the two tree-rings records (MGET and NEGC) and the RC from the Upper Amur (Heilongjiang) River Basin. The thick black curve illustrates the 15-year low-pass filtered curve of the tree-ring width index. The inter-series correlation (Rbar) and the EPS are shown in the lowermost panel.

**Figure 4.** (a) Correlation coefficients between the tree-ring chronologies and monthly total precipitation and mean temperature. (b) Correlation coefficients between the RC tree-ring chronologies and monthly mean scPDSI of the CRU. Correlations are calculated from the previous June to the current September over the time period of 1951–2020 (\* represent the 95% significance level, and \*\* represents the 99% significance level). (c) Comparison between the instrumental and reconstructed mean May–July scPDSI for the Hailar region during 1951–2020. (d) One-dimensional linear regression fits for the May to July scPDSI for 1796–2020. (e) Reconstructed mean May–July scPDSI and its 15-year low-pass filtered version since 1796 CE. The horizontal central line represents the average reconstructed scPDSI. The horizontal dotted lines represent  $\pm 1$  SD and  $\pm 1.5$  SD on a mean value basis.
