14 **Abstract**

15 Reconstruction and observational studies imply a potential linkage of  
16 moisture/precipitation change in arid central Asia and monsoonal East Asia, in which  
17 the evolution of moisture/precipitation in central Asia is out-of-phase with that in  
18 northern China, but in-phase with that in southern China. In order to ascertain whether  
19 there is a robust linkage between the changes in climate in Asian arid regions and  
20 monsoon regions and to elucidate the underlying dynamic mechanisms, we analyzed  
21 the Last Millennium Reanalysis dataset and outputs from the Community Earth  
22 System Model-Last Millennium Ensemble (CESM-LME). The results indicate a  
23 significant decadal linkage between precipitation changes in central Asia's arid region  
24 and the Asian monsoon region during the last millennium, which is primarily driven  
25 by the Interdecadal Pacific Oscillation (IPO). In spring, the positive IPO could  
26 enhance westerlies over the Mediterranean Sea and to its east, which could transport  
27 more water vapor and cause increased precipitation over central Asia. In summer, the  
28 positive IPO is accompanied with weakened Asian monsoon and southward Asian  
29 subtropical westerly jet, which can lead to increased (decreased) summer precipitation  
30 over southern China (over northern China and South Asia). The IPO plays a dominant  
31 role in connecting the decadal variations in precipitation between arid central Asia and  
32 monsoonal Asia by modulating the precipitation of their respective major rainy  
33 seasons. Model results suggest that this decadal linkage stems entirely from the  
34 internal variability present in the CESM-LME control and all single-forcing  
35 simulations. Changes in external forcing factors do not alter this inherent linkage

36 caused by IPO. Moreover, based on analyses of the aridity index and soil moisture  
37 content, this relationship of precipitation variation also causes a similar decadal  
38 linkage of moisture changes in central Asia and monsoonal Asia. The differences in  
39 the multi-centennial-scale moisture/precipitation variations in the Asian arid region  
40 and the monsoon region between the Medieval Climate Anomaly and Little Ice Age  
41 are also likely caused by IPO-like sea surface temperature anomalies.

42

## 43 **1 Introduction**

44       The climate of the mid- to low-latitude Asian continent is characterized by an  
45 arid central Asian region and a moist monsoonal region. The climate in central Asia is  
46 mainly controlled by westerlies as a result of its geographical location and blocking  
47 by plateaus and mountains to the southeast (Chen et al., 2010). The main rainy  
48 seasons are spring and winter, especially in southern central Asia (Aizen et al., 2001;  
49 Chen et al., 2011; Xu et al., 2020; Wang et al., 2022). By contrast, the climate in  
50 monsoonal Asia is mainly controlled by the East Asian monsoon and the South Asian  
51 monsoon. The main rainy season is summer as a result of the warm, moist East Asian  
52 summer monsoon (Ding and Chan, 2005) and the South Asian summer monsoon  
53 (Turner and Annamalai, 2012).

54       The Asian arid and monsoonal climates should be independent of each other due  
55 to the dominance of different systems. However, the reconstruction records suggest a  
56 strong linkage between them on a centennial scale. Chen et al. (2015) reviewed  
57 numerous reconstruction studies and indicated that the climate was relatively wetter in  
58 central Asia and southern China, whereas it was relatively drier in northern China  
59 during the Little Ice Age (LIA; 1400–1900 AD) (Fig. 1). During the earlier Medieval  
60 Climate Anomaly (MCA; 1000–1300 AD), the wet and dry changes were the opposite,  
61 with drier conditions in central Asia and southern China and wetter conditions in  
62 northern China.

63

64 **Figure 1.** The reconstructed and simulated first leading precipitation mode. **(a)** The first leading  
 65 mode (EOF1) of the nine-year low-pass Lanczos filtered annual precipitation for the time period  
 66 850–2000 in the Last Millennium Reanalysis (LMR) dataset. The explained variance is given at  
 67 the top-right. **(b)** The average EOF1 of the nine-year low-pass Lanczos filtered annual  
 68 precipitation in CESM-LME 12 all-forcing simulations for the time period 850–2005; the shading  
 69 shows where at least two-thirds of the members agree on the sign of the average value. The  
 70 averaged explained variance is given at the top-right. The dots represent the reconstructed  
 71 precipitation/moisture records modified from Chen et al. (2015); the blue (red) dots denote wetter  
 72 (drier) conditions in the LIA than in the MCA.

73 Clues to the linkage between the climate of the Asian arid regions and the Asian  
 74 monsoon regions can also be found based on the limited length of observational data  
 75 from the modern era. Since the mid-20th century, the central Asia has become wetter  
 76 (Shi et al., 2007; Jiang et al., 2009; Chen et al., 2011; Huang et al., 2013). During the  
 77 same period, southern China experienced more precipitation, whereas northern China  
 78 received less precipitation and became drier (Ding et al., 2008; Zhao et al., 2010;  
 79 Wang et al., 2013). Focusing on two different climatic regions, the precipitation  
 80 observations during the period of 1960–2010 also show similar linkage (Huang et al.,  
 81 2015). On a decadal scale, central Asia experienced more (less) summer precipitation,  
 82 southern China received more (less) summer precipitation, whereas northern China

83 received less (more) summer precipitation.

84         However, the reconstruction records of the last millennium and the 50-year  
85 observational data only cover less than two periods on the multi-centennial or  
86 interdecadal scale, respectively. It is not sufficient to demonstrate a significant  
87 relationship between the climate of the Asian arid regions and the Asian monsoon  
88 regions. The specific mechanisms behind this possible linkage are still not clear. In  
89 addition, modeling results also indicate that only one out of nine coupled models  
90 within the Paleoclimate Modeling Intercomparison Project Phase 3 (PMIP3) is able to  
91 reproduce the similar climatic linkage between the Asian arid and monsoonal regions  
92 during the MCA and LIA (Shi et al., 2016). Due to the limitations of data length on  
93 the time scales of interest and the large uncertainty in existing model results, therefore,  
94 further research is still needed to confirm whether there is an inherent connection  
95 between the arid regions and monsoon regions in Asia in terms of their dry-wet  
96 variations.

97         In this study, we first focus on the decadal scale and intend to analyze whether  
98 there is a robust linkage between the changes in precipitation pattern in arid regions  
99 and monsoon regions in Asia using the newly released Last Millennium Reanalysis  
100 (LMR) dataset (Tardif et al., 2019; Anderson et al., 2019). Additionally, to further  
101 explore the possible mechanisms underlying the linkage and the potential impacts of  
102 different external forcing factors, the Community Earth System Model Last  
103 Millennium Ensemble (CESM-LME, Otto-Bliesner et al., 2016) is also utilized  
104 because of its good performance in simulating Asian precipitation and summer

105 monsoon (e.g., Hu et al., 2023; Mishra and Aadhar, 2021; Shi et al., 2018) and the  
106 availability of multiple samples forced by different forcing factors. Thus, the aim of  
107 this study is to investigate the linkage between precipitation/moisture changes in arid  
108 central Asia and monsoonal Asia during the last millennium and its driving factors.  
109 The data and methods used in this study are described in detail in Sect. 2. The linkage  
110 between the changes in precipitation/moisture pattern in arid regions and monsoon  
111 regions in Asia is examined and its driving factors are analyzed in Sect. 3. Finally, the  
112 discussion and conclusions are presented in Sect. 4 and Sect. 5, respectively.

## 113 **2 Data and methods**

### 114 **2.1 Reanalysis data and simulations**

115 In this study, we used the reconstructed annual precipitation anomalies (relative  
116 to the climatological mean of 1951–1980) at a spatial resolution of 2° for the time  
117 period 850–2000 from the LMR Version 2.1 dataset (Tardif et al., 2019; Anderson et  
118 al., 2019) to examine the possible linkage between the Asian arid and monsoonal  
119 regions. The proxy records assimilated in the LMR Version 2.1 dataset are from  
120 PAGES-2k (PAGES2k, 2017). The analyses based on LMR were started with the  
121 “grand mean”, which was an average of 20 LMR reconstructions contained in  
122 aforementioned array. In addition, the reconstructed sea surface temperature (SST)  
123 anomalies from the LMR Version 2.1 dataset are also used to verify the model results.

124 In order to investigate the underlying mechanisms, we analyzed the monthly  
125 outputs of CESM-LME project (Otto-Bliesner et al., 2016). The CESM-LME  
126 simulations are performed using the CESM 1.1 model, in which the atmospheric

127 component is the Community Atmosphere Model Version 5 (CAM5) (Hurrell et al.,  
128 2013). The atmosphere and land (ocean and sea ice) components in the CESM-LME  
129 simulations have the same  $\sim 2^\circ$  ( $\sim 1^\circ$ ) horizontal resolutions as the CESM1.1 model.  
130 We analyzed a total of 35 CESM-LME simulations: one control simulation, 12  
131 all-forcing simulations and 22 single-forcing simulations. The single-forcing  
132 simulations included a subset of five simulations forced by volcanic eruptions, a  
133 subset of four simulations forced by solar activity, a subset of four simulations forced  
134 by ozone and aerosols, three subsets of three simulations forced by greenhouse gases,  
135 land use and land cover, and the Earth's orbit, respectively. The subset of simulations  
136 forced by ozone and aerosols covered the time period 1850–2005, whereas the other  
137 simulations were available for the time period 850–2005. The analyses for the  
138 all-forcing simulations and the six subsets of single-forcing simulations were all based  
139 on the arithmetic mean of multiple members, which was the final step in the analyses.

140 In addition, we also referred to reconstructed moisture/precipitation changes  
141 (relative to the median of entire last millennium) in the LIA and MCA summarized by  
142 Chen et al. (2015). The reconstructions synthesized by Chen et al. (2015) include 71  
143 moisture/precipitation records derived from different types of proxy records (i.e., lake  
144 record, speleothem record, historical documents, tree-ring record, ice-core record,  
145 marine record, peat record, aeolian record, and river terrace). Based on these  
146 moisture/precipitation records, figure 3 in Chen et al. (2015) provided the wetness  
147 grades (i.e., the wetness was classified into dry, moderately dry, moderate, moderately  
148 wet, and wet) for the LIA and MCA at individual sites. The 55 moisture/precipitation

149 records with different wetness grades between the LIA and MCA were selected in this  
150 study to explore the moisture/precipitation changes between these two periods.

## 151 **2.2 Methods**

152 Following Henley et al. (2015), we defined the Interdecadal Pacific Oscillation  
153 (IPO) index as the difference between the SST anomalies averaged over the  
154 central-eastern equatorial Pacific (10 °S–10 °N, 170 °E–90 °W) and the average of the  
155 SST anomalies over the western-central subtropical North Pacific (25–45 °N, 140 °E–  
156 145 °W) and the western-central subtropical South Pacific (50–15 °S, 150 °E–160 °  
157 W). The base period for calculating the IPO index was 1850–1900. To obtain the  
158 filtered version of the index, a nine-year low-pass Lanczos filter was used, coinciding  
159 with the other analyses in this study.

160 We used the aridity index (AI) to quantify the moisture condition of the  
161 terrestrial climate (Middleton and Thomas, 1997):

$$162 \quad AI = \frac{P}{PET} \quad (1)$$

163 where  $P$  is the annual precipitation (units: mm day<sup>-1</sup>), representing the water supply to  
164 land and  $PET$  is the annual potential evapotranspiration (units: mm day<sup>-1</sup>), which  
165 measures the atmospheric demand of water. A larger aridity index indicates that  
166 relatively more moisture remains in the land, whereas a smaller aridity index  
167 represents drier condition. The outputs of the CESM-LME simulations for soil  
168 moisture (top 10 cm of soil; units: kg m<sup>-2</sup>) were also analyzed to examine the analyses  
169 based on the aridity index. Thus, the analyses related to moisture conditions in this  
170 study were based on both the aridity index and soil moisture content.

171 The Penman–Monteith algorithm (Penman, 1948; Monteith, 1965) is widely  
172 used to estimate the potential evapotranspiration and is recommended as a standard  
173 method by the Food and Agriculture Organization of the United Nations (Allen et al.,  
174 1998):

$$175 \quad PET = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{T_{\text{mean}} + 273} U(e_s - e_a)}{\Delta + \gamma(1 + 0.34U)} \quad (2)$$

176 where the  $R_n$  is the net surface radiation (units: MJ m<sup>-2</sup> day<sup>-1</sup>), the  $G$  is soil heat flux  
177 density (units: MJ m<sup>-2</sup> day<sup>-1</sup>); the difference between them represents the available  
178 energy.  $\gamma$  is the psychrometric constant (units: kPa °C<sup>-1</sup>),  $T_{\text{mean}}$  is the mean  
179 temperature (units: °C; i.e., the average of the 2-m daily maximum and daily  
180 minimum air temperatures);  $\Delta$  is the slope vapor pressure curve (units: kPa °C<sup>-1</sup>)  
181 derived from  $T_{\text{mean}}$ ,  $U$  is the 2-m wind speed (units: m s<sup>-1</sup>);  $e_s$  is the saturation vapor  
182 pressure (units: kPa), derived from the daily maximum and daily minimum air  
183 temperatures;  $e_a$  is the actual vapor pressure (units: kPa), calculated from  $e_s$  and the  
184 relative humidity.

185 Empirical orthogonal function (EOF) analysis was performed on the  
186 standardized annual precipitation to identify the first leading precipitation mode over  
187 the Asian continent. A nine-year low-pass Lanczos filter was applied to the  
188 standardized precipitation before EOF analysis to remove the variability on  
189 interannual and shorter timescales. The same analyses were also applied to the aridity  
190 index and the annual soil moisture content to obtain the first leading decadal moisture  
191 mode over the Asian continent. Linear regression and correlation analyses were  
192 applied to understand the root cause of the leading decadal precipitation/moisture

193 modes and their statistical significance was examined by a two-sided  $t$ -test. Because  
194 of the low-pass Lanczos filter before linear regression and correlation analyses, the  
195 effective degree of freedom  $N^*$  in the  $t$ -test was calculated following Bretherton et al.  
196 (1999):

$$197 \quad N^* = N \frac{1-r_a r_b}{1+r_a r_b} \quad (3)$$

198 where  $r_a$  ( $r_b$ ) is the autocorrelation at lag 1 for variables  $a$  ( $b$ ) and  $N$  is the original  
199 length of the time series. A two-sided  $t$ -test was also applied to examine the statistical  
200 significance of climate changes between the LIA and the MCA. Besides, the  
201 consistency of results derived from multiple members (i.e., analyses based on  
202 all-forcing simulations and the six subsets of single-forcing simulations) was  
203 examined by counting the percentage of members whose results' signs are the same as  
204 the arithmetic mean of multiple members. A power spectrum analysis was performed  
205 on the time series of the leading precipitation mode and the IPO index to obtain their  
206 dominant periodicity, the statistical significance of which was examined via the power  
207 spectrum of the mean red noise (Gilman et al., 1963).

208 In this study, winter, spring, summer, and autumn were defined as December–  
209 February, March–May, June–August, and September–November, respectively.

## 210 **3 Results**

### 211 **3.1 Reconstructed and simulated first leading precipitation mode**

212 Based on the LMR data, the first leading mode (EOF1) of the decadal changes in  
213 Asian precipitation in the last millennium showed the same changes in precipitation in  
214 arid central Asia and southern China, which were the opposite of those in the South

215 Asian monsoon region (including the southern Tibetan Plateau, the Indian Peninsula  
216 and the Indo-China Peninsula) and most of northern China (Fig. 1a). This mode  
217 accounted for 21.5% of the total variance of precipitation in Asia in the last  
218 millennium.

219 We also analyzed the outputs of the CESM-LME simulations. In the all-forcing  
220 simulations, most members reproduced similar first leading precipitation mode with  
221 the reconstruction for the time period 850–2005 (Fig. S1). Their ensemble pattern was  
222 also consistent with the reconstruction (Fig. 1b). The averaged explained variance was  
223 13.3% (ranging from 11.7 to 14.8%). These same patterns of changes in precipitation  
224 between the long-term simulations and the reconstruction suggest that, on the decadal  
225 scale, there is a robust linkage between the changes in precipitation pattern in arid  
226 regions and monsoon regions. This decadal linkage suggests that the evolution of  
227 precipitation in central Asia is out-of-phase with that in northern China and South  
228 Asian monsoon region, but in-phase with that in southern China. The linkage between  
229 the arid central Asian region and the East Asian monsoon region is consistent with the  
230 relationship of changes in precipitation based on observational data for the last 60  
231 years (Huang et al., 2015). Our analysis suggests that this observed relationship has  
232 persisted over the last millennium. Our results also indicated that the decadal changes  
233 in precipitation in the South Asian monsoon region are also closely related to the  
234 changes in the arid central Asian region and the East Asian monsoon region.

### 235 **3.2 Dominant role of the IPO**

236 Many studies have shown that the SST anomaly is an important factor in

237 modulating the decadal variability in precipitation over Asia (e.g., Chu et al., 2018;  
 238 Huang et al., 2019). We therefore calculated the linear regression of the SST onto the  
 239 time series of the leading precipitation mode. Figure 2a and 2c show that higher  
 240 (lower) SSTs appeared over the central-eastern equatorial Pacific (the western-central  
 241 parts of both the subtropical North Pacific and South Pacific) in the LMR and  
 242 all-forcing simulations. The Pacific basin-wide SST anomalies resembled the positive  
 243 pattern of the IPO (Power et al., 1999; Henley et al., 2015; Wang and Miao, 2018).  
 244 The precipitation anomalies during the positive phases of the IPO showed positive  
 245 anomalies in arid central Asia and southern China and negative anomalies in the  
 246 South Asian monsoon region and most of northern China (Fig. 2b and 2d), resembling  
 247 the leading decadal precipitation mode in the LMR and all-forcing simulations. It is  
 248 therefore likely that the IPO dominated the decadal linkage between the changes in  
 249 precipitation pattern in arid regions and monsoon regions in Asia.

250  
 251 **Figure 2.** The dominant role of the IPO. The reconstructed (a) annual SST anomalies (units: °C)  
 252 regressed onto the time series of the leading decadal precipitation mode and (b) annual

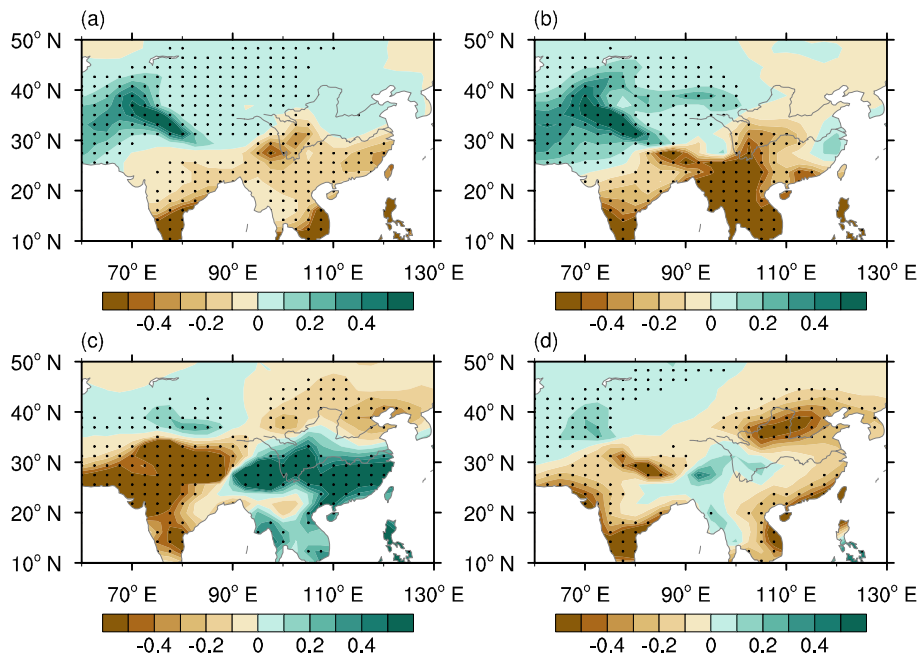

253 precipitation anomalies (units:  $\text{mm day}^{-1}$ ) regressed onto the time series of the IPO index in the  
254 LMR dataset. The dots in parts (a, b) show significant anomalies at the 95% confidence level. (c)  
255 Annual SST anomalies (units:  $^{\circ}\text{C}$ ) regressed onto time series of the leading decadal precipitation  
256 mode and (d) annual precipitation anomalies (units:  $\text{mm day}^{-1}$ ) regressed onto the time series of  
257 the IPO index simulated by multiple members of the CESM-LME all-forcing runs. Dots in parts (c,  
258 d) show that at least two-thirds of the members simulate significant changes (at the 95%  
259 significance level), and these significant changes agree on the sign of the average of multiple  
260 members.

261 We applied power spectrum analysis to explore the temporal characteristics of  
262 the first leading precipitation mode and the IPO. Both the leading precipitation mode  
263 and the IPO had a common frequency band of 10–20 years in the LMR and  
264 all-forcing simulations (Figs. S2–4), indicating that the IPO dominated the linkage  
265 between the changes in precipitation pattern in arid regions and monsoon regions in  
266 Asia at decadal to bi-decadal scales during the last millennium. The consistency  
267 between the reconstruction and the simulations indicates the reliability of the  
268 simulations, which is the foundation of the following analyses on the relevant  
269 mechanism based on simulations.

### 270 **3.3 Processes of the IPO modulating the leading precipitation pattern**

271 Because there is a seasonal cycle in precipitation and the atmospheric circulation  
272 over Asia, especially over monsoonal Asia, we analyzed the seasonal changes in  
273 precipitation associated with the IPO. During the positive phases of IPO, in the arid  
274 central Asia, the precipitation in the four seasons all increased and made a positive  
275 contribution to the increase in annual precipitation (Fig. 3). The precipitation  
276 anomalies were larger in spring and winter, especially in spring, in which season the

277 precipitation accounted for the most of the annual precipitation (Fig. S5). The largest  
 278 increase in spring precipitation was mainly in southern central Asia. In East Asia,  
 279 summer precipitation increased (decreased) over southern (northern) China and  
 280 autumn precipitation decreased over northern China, both contributing positively to  
 281 the annual changes in precipitation. By contrast, spring and winter precipitation both  
 282 decreased over southern China, partly offsetting the positive contribution of summer  
 283 precipitation to the increase in annual precipitation in this region. Precipitation in all  
 284 four seasons decreased in most of the South Asian monsoon regions, contributing  
 285 positively to the decrease in annual precipitation. Then, we analyzed the seasonal  
 286 atmospheric circulation anomalies associated with the IPO to determine the processes  
 287 by which the IPO modulated these seasonal changes in precipitation.

288  
 289 **Figure 3.** Simulated seasonal precipitation anomalies during the positive phases of the IPO.  
 290 Regressed maps of (a) winter, (b) spring, (c) summer, and (d) autumn precipitation anomalies  
 291 (units: mm day<sup>-1</sup>) onto the time series of the IPO index simulated by multiple members of the  
 292 CESM-LME all-forcing runs. Dots show that at least two-thirds of the members simulate

293 significant changes (at the 95% significance level), and these significant changes agree on the sign  
 294 of the average of multiple members.

295  
 296 **Figure 4.** Simulated seasonal temperature anomalies during the positive phases of the IPO.  
 297 Regressed maps of 850 hPa temperature anomalies (units: °C) in (a) winter, (c) spring, (e) summer,  
 298 and (g) autumn onto the time series of the IPO index simulated by multiple members of the  
 299 CESM-LME all-forcing runs. (b) Winter, (d) spring, (f) summer, and (h) autumn for 500 hPa  
 300 temperature anomalies (units: °C). Shading shows that at least two-thirds of the members simulate  
 301 significant changes (at the 95% significance level), and these significant changes agree on the sign  
 302 of the average of multiple members.

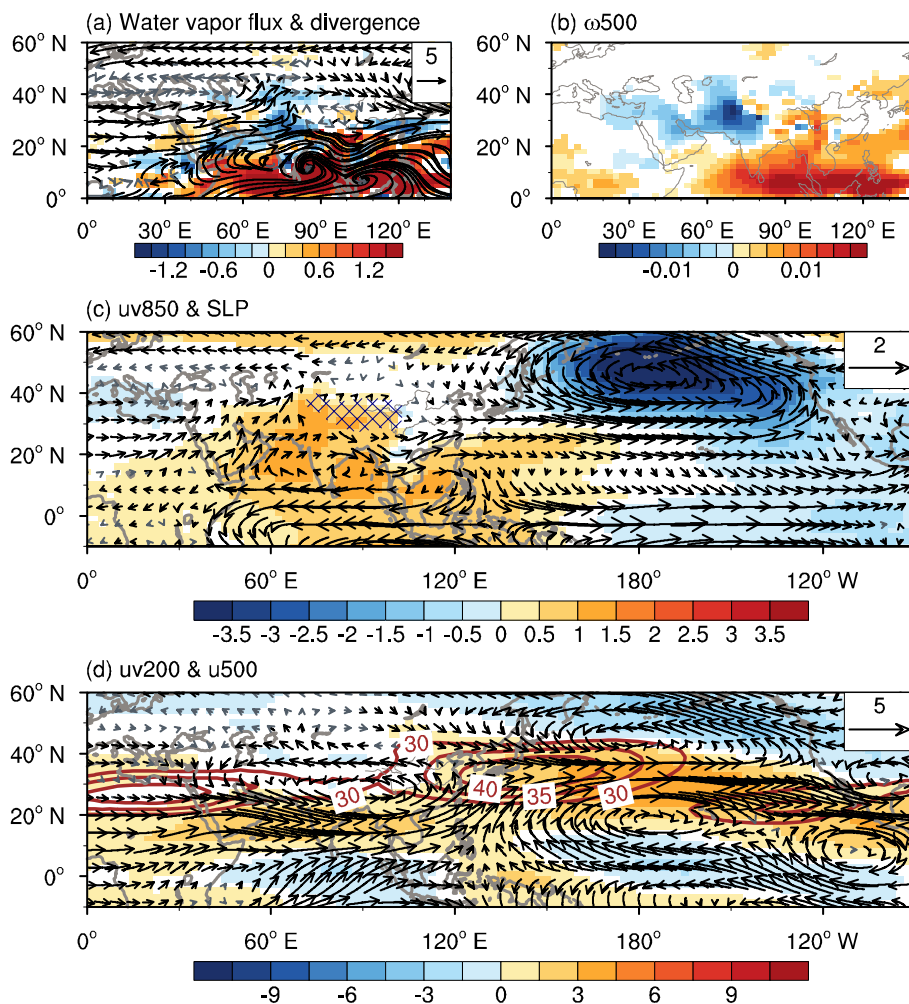

### 303 3.3.1 Arid central Asia

304 In spring, warming appeared over the northern low and high latitudes, whereas  
305 cooling appeared over the northern mid-latitudes, especially in the eastern hemisphere,  
306 corresponding to a positive phase of the IPO (Fig. 4c and 4d). The tropospheric  
307 temperature anomalies led to an enhanced (weakened) meridional temperature  
308 gradient over low (high) latitudes as the climatological temperature decreased from  
309 low to high latitudes. The anomalies in the temperature gradient contributed to  
310 enhanced westerlies over low latitudes and weakened westerlies over high latitudes  
311 via the thermal wind relation (Fig. 5c and 5d), indicating a southward shift of the  
312 mid-latitude westerlies. The enhanced westerlies over the Mediterranean Sea and to  
313 its east transported more water vapor from the Mediterranean Sea to southern central  
314 Asia (Fig. 5a).

315 Positive sea-level pressure (SLP) anomalies appeared over the Indo–western  
316 Pacific warm pool and negative SLP anomalies appeared over the eastern tropical  
317 Pacific (Fig. 5c), consistent with the SST anomalies during positive IPO phases. The  
318 distribution of the SLP anomalies indicated a weakened Walker circulation over the  
319 Pacific Ocean, which further led to suppressed convection over the maritime continent  
320 (Li et al., 2022). The decreased latent heating associated with the decreased  
321 precipitation over the maritime continent can produce westward-propagating  
322 baroclinic Rossby wave trains (Jiang et al., 2021). This resulted in anomalous  
323 low-level anticyclone and upper-level cyclone over the Indian subcontinent, both of  
324 which led to anomalous southerlies over central Asia (Fig. 5c and 5d). The anomalous  
325 southerlies induced warm advection and led to anomalous ascending motion in this

326 region (Fig. 5b). In addition, the anomalous southerlies at low troposphere also could  
 327 transport more water vapor from low latitudes to central Asia (Fig. 5a). The enhanced  
 328 transport of water vapor and the anomalous ascending motion both favored increased  
 329 precipitation in spring over central Asia. In summary, the IPO affected the  
 330 precipitation from westerly winds through modulating the mid-latitude westerlies and  
 331 the Walker circulation in the Pacific Ocean.

332  
 333 **Figure 5.** Simulated spring atmospheric circulation anomalies during the positive phases of the  
 334 IPO. Regressed maps of anomalous (a) vertically integrated water vapor flux from 1000 to 300  
 335 hPa (vectors; units:  $\text{kg m}^{-1} \text{s}^{-1}$ ) and its divergence (shading; units:  $10^{-5} \text{kg m}^{-2} \text{s}^{-1}$ ), (b) 500 hPa  
 336 vertical velocity ( $\omega_{500}$ ) (units:  $\text{Pa s}^{-1}$ ), (c) 850 hPa wind (uv850) (vectors; units:  $\text{m s}^{-1}$ ) and SLP  
 337 (shading; units: hPa), (d) 200 hPa wind (uv200) (vectors; units:  $\text{m s}^{-1}$ ) and 500 hPa zonal wind  
 338 (u500) (shading; units:  $\text{m s}^{-1}$ ) onto the time series of the IPO index simulated by the CESM-LME

339 all-forcing runs. The blue hatched patterns in part (c) indicate the region with an altitude >3000 m.  
340 The brown contours in part (d) are the climatological 200 hPa zonal wind (units:  $\text{m s}^{-1}$ ). The  
341 shading shows that at least two-thirds of the members simulate significant changes (at the 95%  
342 significance level), and these significant changes agree on the sign of the average of multiple  
343 members. The black vectors show that for the zonal or meridional component, at least two-thirds  
344 of the members simulate significant changes (at the 95% significance level), and these significant  
345 changes agree on the sign of the average.

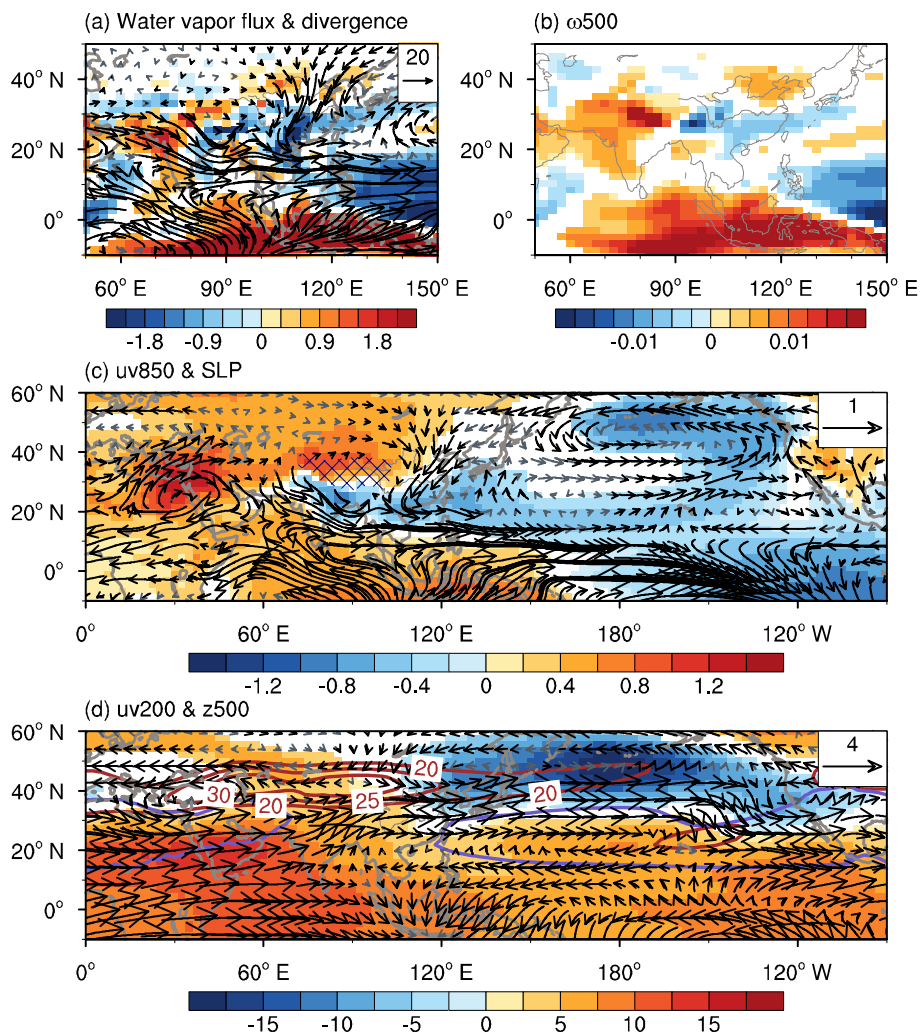

346 The circulation anomalies associated with the IPO in winter were similar to those  
347 in spring (Fig. S6), indicating that the processes by which the IPO modulated winter  
348 precipitation in central Asia were similar to those in spring.

### 349 **3.3.2 Asian monsoon regions**

350 In summer, higher (lower) SLPs appeared over the most of the Asian continent  
351 (northern Pacific) during the positive phases of the IPO (Fig. 6c). This was the reverse  
352 of the climatological state, in which the SLP over most of the Asian continent was  
353 lower than that over the neighboring oceans. A weakened land–sea thermal contrast  
354 was therefore induced. The weakened land–sea thermal contrast led to a weakened  
355 Asian summer monsoon (ASM), featured by northerly anomalies at 850 hPa over the  
356 whole of monsoonal Asia (Fig. 6c). The northerly anomalies further led to weakened  
357 water vapor transport in this region (Fig. 6a).

358 Anomalies also appeared in the tropospheric temperature (Fig. 4e and 4f) and  
359 caused westerly (easterly) anomalies over the south (north) of the climatological  
360 Asian subtropical westerly jet at 200 hPa (Fig. 6d). The wind anomalies indicated the  
361 southward shift in the Asian subtropical westerly jet and the associated secondary  
362 meridional–vertical circulation (Cressman, 1981; Ding, 2005; Zhang and Huang,

363 2011), which led to anomalous downward motion over northern China and anomalous  
 364 upward motion over southern China (Fig. 6b) (Wang et al., 2013; Zhu et al., 2015).  
 365 The western Pacific subtropical high shifted southeastward (Fig. 6d), which did not  
 366 favor the transport of water vapor to northern China (Fig. 6a). These circulation  
 367 anomalies all indicate a weakened ASM system (Webster and Yang, 1992; Wang,  
 368 2001). Precipitation over southern China therefore increased in summer, whereas  
 369 precipitation over northern China and most of the South Asian monsoon regions  
 370 decreased. In summary, the IPO affected the monsoon precipitation through  
 371 modulating the ASM system.

372  
 373 **Figure 6.** Simulated summer atmospheric circulation anomalies during the positive phases of the

374 IPO. Regressed maps of anomalous **(a)** vertically integrated water vapor flux from 1000 to 300  
375 hPa (vectors; units:  $\text{kg m}^{-1} \text{s}^{-1}$ ) and its divergence (shading; units:  $10^{-5} \text{kg m}^{-2} \text{s}^{-1}$ ), **(b)** 500 hPa  
376 vertical velocity ( $\omega_{500}$ ) (units:  $\text{Pa s}^{-1}$ ), **(c)** 850 hPa wind (uv850) (vectors; units:  $\text{m s}^{-1}$ ) and SLP  
377 (shading; units: hPa), and **(d)** 200 hPa wind (uv200) (vectors; units:  $\text{m s}^{-1}$ ) and 500 hPa  
378 geopotential height (z500) (shading; units: m) onto the time series of the IPO index simulated by  
379 the CESM-LME all-forcing runs. The blue hatched patterns in part **(c)** indicate the region with an  
380 altitude  $>3000$  m. The brown contours in part **(d)** are the climatological 200 hPa zonal wind (units:  
381  $\text{m s}^{-1}$ ). The purple line in part **(d)** is the isoline with a value of 5860 m in the climatology state.  
382 The shading shows that at least two-thirds of the members simulate significant changes (at the 95%  
383 significance level), and these significant changes agree on the sign of the average of multiple  
384 members. The black vectors show that for the zonal or meridional component, at least two-thirds  
385 of the members simulate significant changes (at the 95% significance level), and these significant  
386 changes agree on the sign of the average.

387 In autumn, negative anomalies in the 500 hPa geopotential height appeared over  
388 the Korean Peninsula (Fig. S7d), indicating a strengthened East Asian trough (EAT)  
389 during the positive phases of the IPO (Qin et al., 2018, 2020; Li et al., 2020). The  
390 strengthened EAT contributed to northerly anomalies over East Asia (Fig. S7c), which  
391 led to weakened water vapor transport in this region (Fig. S7a). The anomalous  
392 northerlies to the west of the strengthened EAT induced cold advection (Fig. S7c and  
393 S7d) and led to anomalous descending motion over northern China (Fig. S7b).  
394 Precipitation therefore decreased over northern China in autumn.

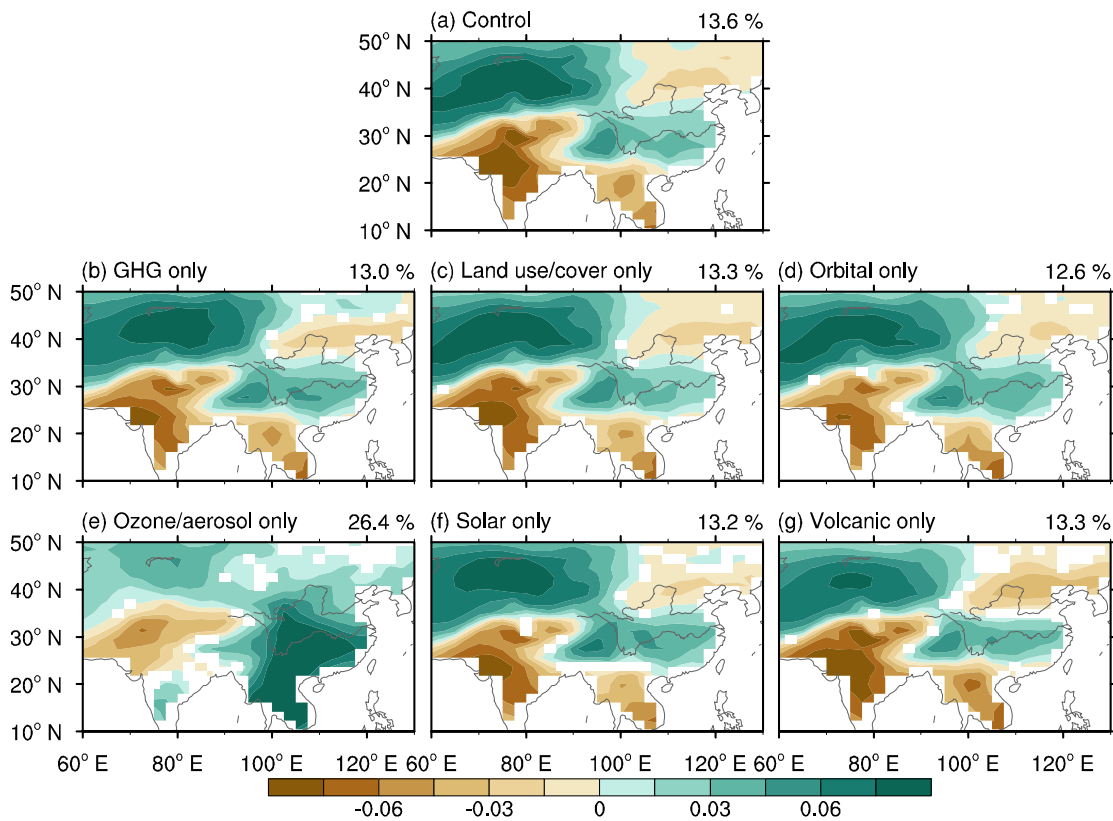

395 Consistent with the SST anomalies during the positive phases of the IPO,  
396 positive (negative) SLP anomalies appeared over the Indo–western Pacific warm pool  
397 (eastern tropical Pacific) in all four seasons (Figs. 5c, 6c, S6c and S7c), indicating a  
398 weakened Walker circulation in the Pacific Ocean, which is in agreement with the

399 results in Dong and Lu (2013) and Zhao et al. (2021). This weakened Walker  
400 circulation contributed to decreased precipitation over most of the South Asian  
401 monsoon regions (Krishnamurthy and Krishnamurthy, 2014; Li et al., 2021).

### 402 **3.4 Decisive role of internal variability**

403 Many studies have suggested that both external forcings and internal variability  
404 could affect the decadal variability of precipitation over Asia (e.g., Wang et al., 2013;  
405 Jin et al., 2019; Zhu et al., 2022). To identify the roles of internal variability and  
406 external forcing, Fig. 7 shows the first leading decadal precipitation modes of the  
407 control and single-forcing simulations. The decadal linkage between the changes in  
408 precipitation pattern in central Asia and monsoonal Asia in the all-forcing simulations  
409 also appeared in the control simulation (Fig. 7a), implying this decadal linkage was  
410 mainly caused by the internal variability. Nearly all the single-forcing simulations  
411 presented similar decadal linkage with all-forcing simulations, apart from the  
412 simulations forced by ozone and aerosols (Fig. 7b–g). This indicated that, during the  
413 last millennium, volcanic eruptions, solar activity, greenhouse gases, land use and  
414 land cover, and the Earth’s orbit were unable to change the decadal linkage between  
415 the changes in precipitation pattern in arid regions and monsoon regions in Asia,  
416 which was dominated by the internal variability. Only in the ozone and aerosols  
417 forcing simulations, which covered the period of 1850–2005, the decadal linkage of  
418 precipitation changes disappeared. We further examined the results of other forcing  
419 simulations for the period of 1850–2005 (Fig. S8), and all the first decadal  
420 precipitation modes simulated by other forcing experiments still indicated similar

421 decadal linkage with all-forcing last-millennium simulations. This meant that since  
 422 the industrial revolution, only the ozone and aerosol forcing factors can change the  
 423 dominant mode of the reverse variation of precipitation in East Asia from north to  
 424 south and present stronger local climate effects. As noted by Wang et al. (2013), it  
 425 may be that anthropogenic aerosols play a more important role in regulating  
 426 precipitation in East Asia, which needs further analysis.

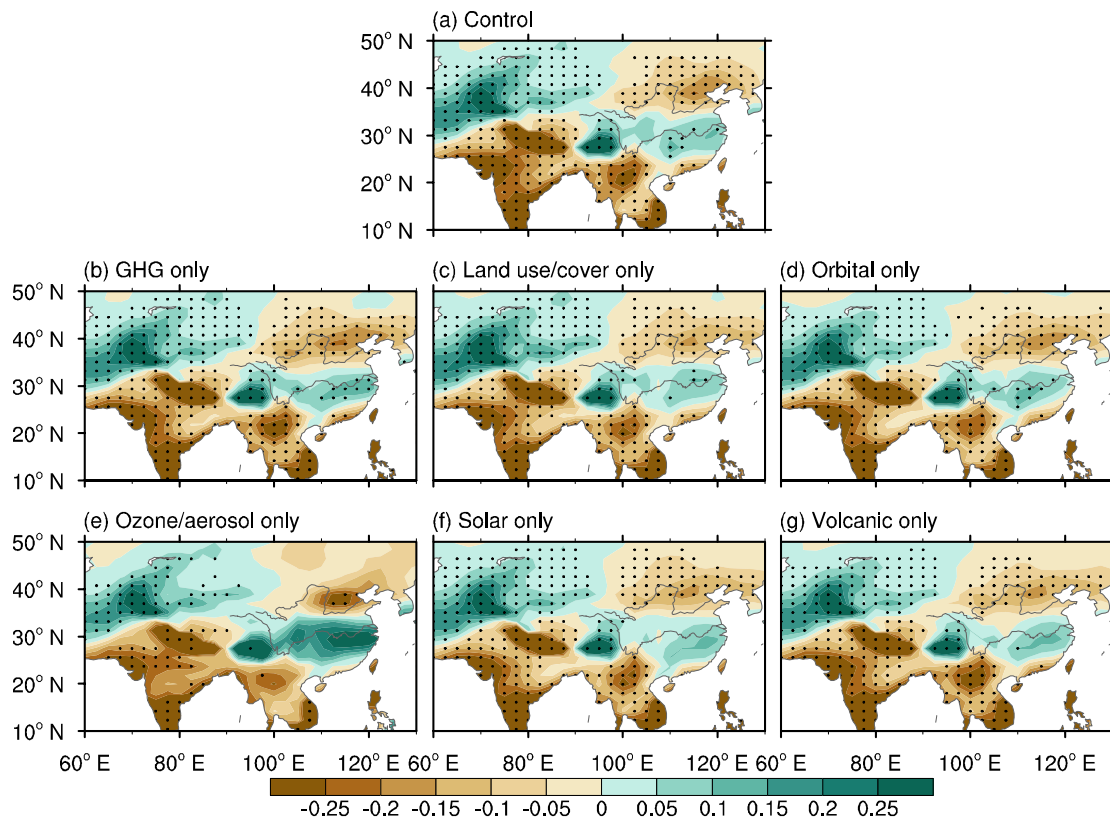

427  
 428 **Figure 7.** The leading decadal precipitation mode for the time period 850–2005 in the control and  
 429 single-forcing simulations, with the exception of leading mode for the time period 1850–2005 in  
 430 experiment forced by ozone and aerosols. **(a)** EOF1 of the nine-year low-pass Lanczos filtered  
 431 annual precipitation in the control simulation. The explained variance is given at the top-right. **(b–**  
 432 **g)** The average EOF1 of the nine-year low-pass Lanczos filtered annual precipitation in six subsets  
 433 of the single-forcing simulations: a subset of three simulations forced by greenhouse gas  
 434 emissions (GHG); a subset of three simulations forced by land use and land cover; a subset of  
 435 three simulations forced by the Earth’s orbit; a subset of four simulations forced by ozone and

436 aerosols; a subset of four simulations forced by solar activity; and a subset of five simulations  
437 forced by volcanic eruptions. The averaged explained variance is given at the top-right. The  
438 shading in parts **(b–g)** shows where at least two-thirds of the members agree on the sign of the  
439 average of multiple members.

440       Apart from the simulations forced by ozone and aerosols, the SST anomalies  
441 associated with the leading precipitation mode in the control and single-forcing  
442 simulations all showed a positive IPO pattern (Fig. S9), consistent with the all-forcing  
443 simulations. At the same time, the precipitation anomalies associated with the positive  
444 IPO in the control and single-forcing simulations all showed positive anomalies in  
445 arid central Asia and southern China and negative anomalies in the South Asian  
446 monsoon region and most of northern China (Fig. 8), also consistent with the  
447 all-forcing simulations. This suggested that these external forcing factors cannot  
448 change the dominant influence of IPO on Asian decadal precipitation and lead to the  
449 decadal linkage between the changes in precipitation pattern in arid regions and  
450 monsoon regions in Asia during the last millennium. It is therefore clear that the  
451 internal variability associated with the IPO had a decisive role in shaping the decadal  
452 linkage of precipitation changes.

453

454 **Figure 8.** Simulated precipitation anomalies during the positive phases of the IPO in the control  
 455 and single-forcing simulations. **(a)** Precipitation anomalies (units:  $\text{mm day}^{-1}$ ) regressed onto the  
 456 time series of the IPO index in the control run. **(b–g)** Precipitation anomalies (units:  $\text{mm day}^{-1}$ )  
 457 regressed onto the time series of the IPO index in six subsets of the single-forcing simulations.  
 458 The dots in part (a) show significant anomalies at the 95% confidence level and the dots in parts  
 459 (b–g) denote that at least two-thirds of the members simulate significant changes (at the 95%  
 460 significance level), and these significant changes agree on the sign of the average of multiple  
 461 members.

462 In the ozone and aerosols forcing simulations, we can find positive precipitation  
 463 anomalies in arid central Asia and southern China and negative precipitation  
 464 anomalies in the South Asian monsoon region and most of northern China during the  
 465 positive phases of the IPO (Fig. 8e). However, the changes in East Asian precipitation  
 466 were no longer significant, which meant that the impacts of IPO on East Asian  
 467 precipitation in this experiment were weakened.

### 468 **3.5 Simulated first leading moisture mode**

469 Terrestrial moisture conditions are closely related to precipitation changes and  
470 could strongly affect terrestrial ecosystems. The terrestrial moisture condition is  
471 quantified by both aridity index and soil moisture content here. Based on our analyses  
472 of the aridity index (Fig. 9a) and the soil moisture content (Fig. S10a), we found that  
473 the EOF1 of the decadal changes in Asian moisture during the last millennium also  
474 showed the same changes in moisture in arid central Asia and southern China, which  
475 were the opposite of those in the South Asian monsoon region and most of northern  
476 China. This is consistent with the first leading precipitation mode, suggesting the  
477 important contribution of precipitation to the decadal linkage between the changes in  
478 moisture pattern in arid regions and monsoon regions in Asia. Similar first leading  
479 moisture mode was seen in all the experiments apart from those with only ozone and  
480 aerosol forcing (Figs. 9 and S10), indicating the decisive role of internal variability on  
481 the decadal linkage of moisture changes.

482

483 **Figure 9.** The simulated leading decadal aridity index mode for the time period 850–2005 in all  
 484 the experiments, with the exception of leading mode for the time period 1850–2005 in experiment  
 485 forced by ozone and aerosols. **(a)** The average EOF1 of the nine-year low-pass Lanczos filtered  
 486 aridity index in the all-forcing simulations. The averaged explained variance is given at the  
 487 top-right. **(b)** EOF1 of the nine-year low-pass Lanczos filtered aridity index in the control  
 488 simulation. The explained variance is given at the top-right. **(c–h)** The average EOF1 of the  
 489 nine-year low-pass Lanczos filtered aridity index in six subsets of the single-forcing simulations.  
 490 The averaged explained variance is given at the top-right. The shading in parts **(a, c–h)** shows  
 491 where at least two-thirds of the members agree on the sign of the average of multiple members.

492 The SST anomalies associated with the leading moisture mode in all experiments,  
 493 apart from those with only ozone and aerosol forcing, showed a positive IPO pattern  
 494 (Figs. S11 and S12), indicating the dominant role of the IPO on the decadal linkage of  
 495 moisture changes. The moisture anomalies associated with the positive IPO showed  
 496 positive anomalies in arid central Asia and southern China and negative anomalies in

497 the South Asian monsoon region and most of northern China in all the experiments  
 498 (Figs. 10 and S13), consistent with the leading moisture mode. This further confirmed  
 499 the aforementioned dominant role of the IPO. Therefore, the internal variability  
 500 associated with the IPO also had a decisive role in shaping the decadal linkage  
 501 between the changes in moisture pattern in arid regions and monsoon regions in Asia  
 502 through regulating precipitation during the last millennium.

503  
 504 **Figure 10.** Simulated aridity index anomalies during the positive phases of the IPO. The aridity  
 505 index anomalies regressed onto the time series of the IPO index in the (a) all-forcing simulations,  
 506 (b) control simulation, and (c–h) six subsets of the single-forcing simulations. The dots in part (b)  
 507 show significant anomalies at the 95% confidence level and the dots in parts (a, c–h) denote that  
 508 at least two-thirds of the members simulate significant changes (at the 95% significance level),  
 509 and these significant changes agree on the sign of the average of multiple members.

#### 510 4 Discussion

#### 511 **4.1 Limited impacts of external forcings on decadal precipitation linkage**

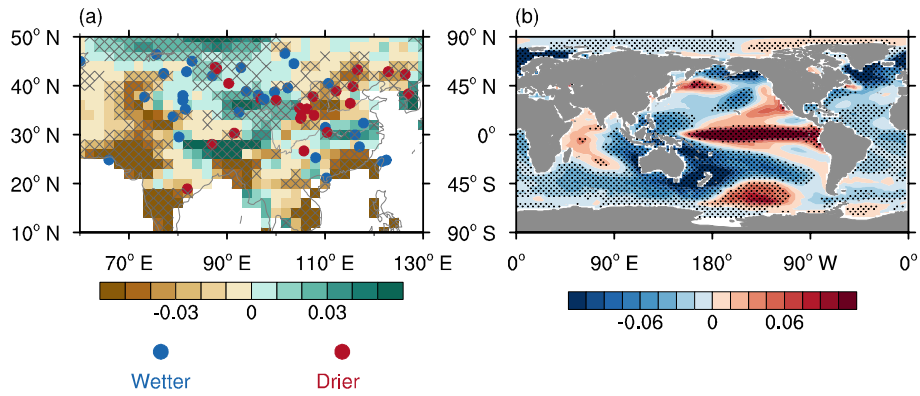

512 As stated in section 3.4, the spatial pattern of leading decadal precipitation mode  
513 in all-forcing simulations also appears in control and all single-forcing simulations,  
514 apart from the simulations forced by ozone and aerosols. This indicates the dominant  
515 role of internal variability in shaping the spatial pattern of leading decadal  
516 precipitation mode during the last millennium. Moreover, this process can be partially  
517 influenced by the impacts of ozone and aerosol forcing since the industrial revolution.  
518 During this period, ozone and aerosols have played crucial roles in regulating the  
519 climate at mid-latitudes in the Northern Hemisphere (Miao et al., 2022). However, the  
520 relative impact of internal variability and external forcings on the time variations of  
521 the leading decadal precipitation mode during the last millennium remains unclear.  
522 Thus, we calculated the correlations across the time series of the leading decadal  
523 precipitation mode (i.e., the principal components) simulated by CESM-LME 12  
524 all-forcing simulations (Table S1). Except for autocorrelations for each principal  
525 component, the other correlations range from -0.06 to 0.35, and only 13.6%  
526 correlations are significant at the 95% confidence level. These relatively small  
527 correlations indicate the impacts of external forcings on the time variations of the  
528 leading decadal precipitation mode are very weak. The several significant correlations  
529 suggest that, to a limited extent, the time variations of the leading decadal  
530 precipitation mode could be affected by external forcings (e.g., volcanic eruptions and  
531 solar radiation) (Ning et al., 2020; Xue et al., 2023). Therefore, internal variability  
532 played a dominant role in shaping the time variations of the leading decadal

533 precipitation mode.

534 In summary, the impacts of external forcings on both spatial pattern and time  
535 variations of the leading decadal precipitation mode are relatively weak, which  
536 indicates limited impacts of external forcings on decadal linkage between  
537 precipitation changes in arid central Asia and humid monsoonal Asia during the last  
538 millennium. This is quite different from the dominating role of external forcings in  
539 regulating the variations of Asian precipitation at suborbital and longer timescales (Xu  
540 et al., 2023).

#### 541 **4.2 Centennial precipitation/moisture linkage**

542 The features of decadal linkage between moisture/precipitation changes in arid  
543 central Asia and humid monsoonal Asia during the last millennium have been  
544 investigated and the dynamic mechanisms associated with the decadal linkage have  
545 been explored above. Next, the potential linkage on multi-centennial scale implied by  
546 reconstruction is discussed here. Between the LIA and MCA, on multi-centennial  
547 scale, wetter (drier) conditions over arid central Asia and southern China (most of  
548 northern China) were reconstructed in Chen et al. (2015) (Fig. 11a). Besides, the  
549 changes in precipitation between the LIA and the MCA based on the LMR showed  
550 more (less) precipitation over eastern central Asia and southern China (the South  
551 Asian monsoon region and most of northern China) (Fig. 11a), consistent with the  
552 reconstructed changes in precipitation/moisture in Chen et al. (2015). These results  
553 suggest a robust centennial linkage of the changes in precipitation/moisture in central  
554 Asia and monsoonal Asia, similar to the decadal precipitation/moisture linkage.

555

556 **Figure 11.** Reconstructed changes in **(a)** precipitation (units:  $\text{mm day}^{-1}$ ) and **(b)** SST (units:  $^{\circ}\text{C}$ )  
 557 between the LIA and MCA in the LMR. The gray hatched patterns in part **(a)** and black dots in  
 558 part **(b)** indicate significant anomalies at the 95% confidence level. The dots in part **(a)** represent  
 559 the reconstructed precipitation/moisture records modified from Chen et al. (2015); the blue (red)  
 560 dots denote wetter (drier) conditions in the LIA than in the MCA.

561 The reconstructed changes in the SST between the LIA and MCA showed higher  
 562 (lower) SSTs over the central-eastern equatorial Pacific (the western-central parts of  
 563 both the subtropical North Pacific and South Pacific) (Fig. 11b). According to the  
 564 present study, the IPO-like condition may be the primary cause of the centennial  
 565 linkage of changes in precipitation/moisture in central Asia and monsoonal Asia.  
 566 However, most current models still cannot reproduce the evolution of the Pacific  
 567 Decadal Oscillation (Wang and Miao, 2018). The CESM-LME simulations were also  
 568 unable to produce the reconstructed centennial changes in SST between the LIA and  
 569 MCA. Therefore, in the present study, we cannot directly obtain the evidence of the  
 570 aforementioned centennial linkage from the CESM-LME results. The failure of  
 571 CESM-LME simulations in reproducing the centennial linkage further limits our  
 572 understanding of the relative roles of the external forcings and internal variability in  
 573 shaping the centennial linkage. Thus, further investigation remains needed.

574 **5 Conclusions**

575       Based on the LMR dataset and CESM-LME all-forcing simulations, the first  
576 leading precipitation mode in Asia on decadal scale during the last millennium  
577 showed the same changes in precipitation in arid central Asia and southern China,  
578 which were the opposite of those in the South Asian monsoon region and most of  
579 northern China. This mode indicated a robust linkage between the changes in  
580 precipitation pattern in arid regions and monsoon regions in Asia on decadal scale, in  
581 which the evolution of precipitation in central Asia was out-of-phase with that of  
582 northern China and the South Asian monsoon regions and in-phase with that of  
583 southern China.

584       Further analysis based on CESM-LME all-forcing, control and all single-forcing  
585 simulations showed that the internal variability associated with the IPO plays a  
586 dominant role in connecting the decadal variations in precipitation between arid  
587 central Asia and monsoonal Asia by modulating the precipitation of their respective  
588 major rainy seasons during the last millennium. In spring, the positive IPO could  
589 enhance westerlies over the Mediterranean Sea and to its east, which could transport  
590 more water vapor and cause increased precipitation over central Asia. In summer, the  
591 positive IPO is accompanied with weakened Asian summer monsoon and southward  
592 Asian subtropical westerly jet, which further lead to increased (decreased) summer  
593 precipitation over southern China (over northern China and South Asian monsoon  
594 region). Besides, the positive IPO can weaken Pacific Walker circulation, which  
595 contributes to precipitation decrease over South Asian monsoon regions in all four

596 seasons.

597 In addition, this decadal linkage of precipitation variation also causes a similar  
598 decadal linkage of moisture changes in central Asia and monsoonal Asia during the  
599 last millennium.
