**Abstract.** We investigated the geochemical and rock magnetic properties of the magnetostratigraphically-calibrated Pignola-  
15 Abriola section (Italy) in order to understand the climatic perturbations that characterize the late Norian–early Rhaetian interval (Late Triassic). We performed experiments on anhysteretic and isothermal remanence (ARM, IRM), and on magnetic susceptibility ( $\chi$ ), to obtain the rock magnetic parameters necessary for our paleoclimatic investigation. An episode of increase in relative quantity of hematite, suggesting enhanced subaerial oxidation of iron minerals, was identified in the  
20 Norian from ~217 Ma in the Alaunian up to ~211 Ma in the early Sevatian, followed by a decline up to 207–206 Ma at the end of the Norian (late Sevatian). The results of geochemical and multivariate statistical analyses support a long-term increase and reduction in rock weathering, confirming and extending previous <sup>87</sup>Sr/<sup>86</sup>Sr data from the Pizzo Mondello section (Italy). Possible causes of these long-term weathering trends are the multiphase uplifting of the Cimmerian orogen, occurring at mid northern latitudes along the southern margin of Asia in the Late Triassic, and/or the northward motion of Pangea  
25 Norian/Rhaetian boundary, the origin of which has still to be determined.

## 1 Introduction

The late Norian–early Rhaetian interval (Late Triassic) is characterized by climatic perturbations associated with a biotic crisis (Rampino and Stothers, 1988; Wignall, 2001; Jones and Jenkyns, 2001; Pálfy et al., 2001; Ward et al., 2004; Richoz et al., 2007; van de Schootbrugge et al., 2008; Jenkyns, 2010; Lucas, 2010; Tanner, 2010; Trotter et al., 2015; Clapham and  
30 Renne, 2018; Zaffani et al., 2017; Rigo et al., 2020). Sedimentary rocks can record the effects of climate change through variations in water chemistry and sedimentary input. Geochemistry is therefore widely applied, but also rock magnetism can

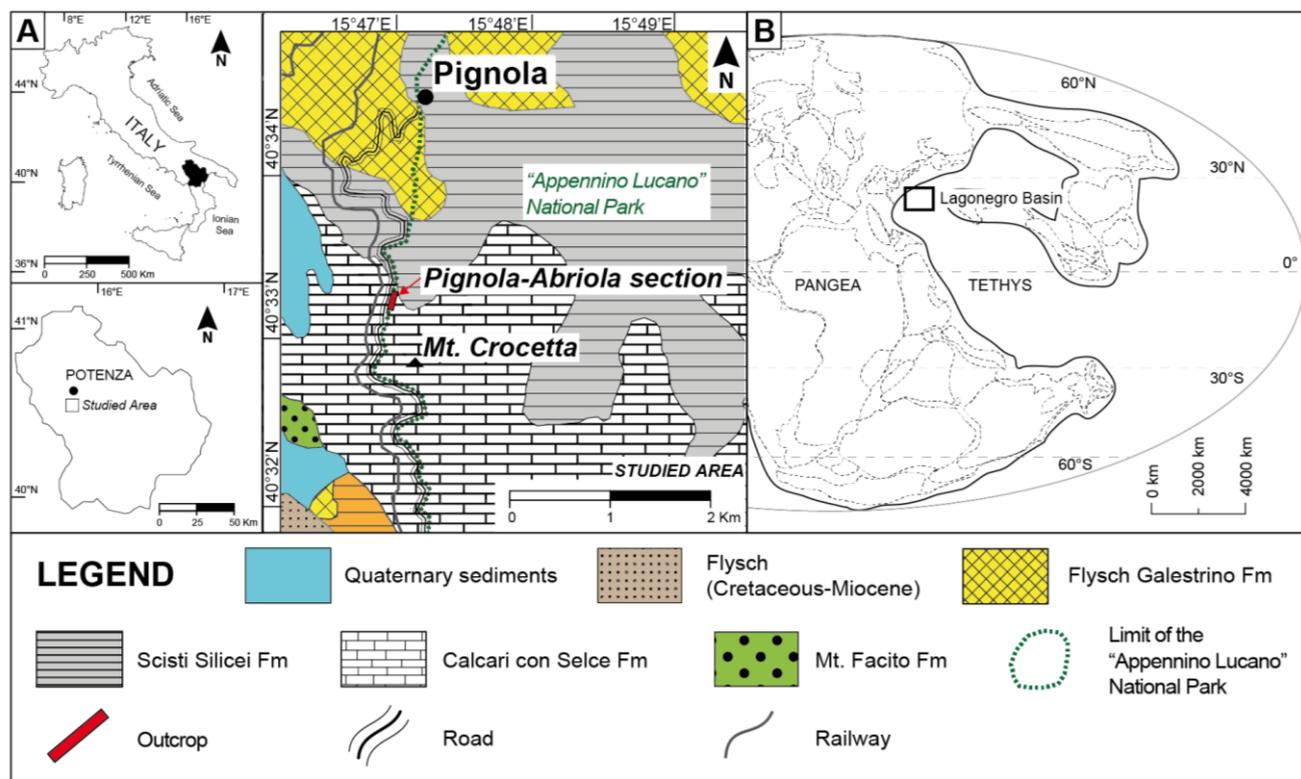

effectively contribute to unveil paleoclimate variability (e.g., Bloemendal and DeMenocal, 1989; Thouveny et al., 1994; Vlag et al., 1997; Van der Post et al., 1997; Snowball et al., 1999; Vigliotti et al., 1999; Ortega et al., 2002; Wang X. et al., 2008; Lascu et al., 2012; Abrajevitch et al., 2013; Just et al., 2016; Chang et al., 2018; Wang et al., 2018; Rodelli et al., 2019). In order to obtain paleoclimatic information for the late Norian-early Rhaetian, we provide new geochemical and rock magnetic data from the Pignola-Abriola section (southern Apennines, Italy), which is a Global Stratigraphic Section and Point candidate of the Rhaetian Stage (Rigo et al., 2016), already provided with biostratigraphy (Bazzucchi et al., 2005; Rigo et al., 2005, 2016; Bertinelli et al., 2016), carbon isotope data (Zaffani et al., 2017), and magnetostratigraphy (Maron et al., 2015). We also examined stratigraphic variations in major elements to trace changes in the degree of chemical weathering in hinterland regions, and applied principal component analysis (PCA) to major element contents. The PCA results allowed to separate signals from multiple source materials, and to constrain the degree of hinterland weathering (Soda and Onoue, 2019; Onoue et al., 2021, 2022).

## 2 Geological Setting

The Pignola-Abriola section (40°33'23.5" N, 15°47'1.7" E) is located on the western side of Mt. Crocetta, along road SP5 between the towns of Pignola and Abriola (Fig. 1). The section comprises 63 m of a basinal sequence belonging to the Calcarei con Selce Formation deposited in the Lagonegro Basin, a branch of the western Tethys Ocean active since the Permian (Scandone, 1967; Finetti, 1985; Amodeo et al., 1993; Amodeo, 1999; Ciarapica and Passeri, 2002, 2005; Argnani, 2005; Bazzucchi et al., 2005; Rigo et al., 2005, 2012, 2016; Giordano et al., 2010; Maron et al., 2015, 2017; Bertinelli et al., 2016; Zaffani et al., 2017). The studied interval covers the middle-upper Norian (Alaunian and Sevatian) and the lower Rhaetian portion of the Calcarei con Selce Fm. The dominant lithology is represented by bedded cherty limestones, partially dolomitized in the lower part of the section, with sporadic centimeter-thick calcarenites due to turbiditic events or gravity flows (e.g., Amodeo, 1999; Giordano et al., 2011; Bertinelli et al., 2016). Shales, radiolarites and marls become more abundant in the uppermost part of the Calcarei con Selce, at the transition with the overlying Scisti Silicei Formation, where the siliciclastic fraction and the biosiliceous sedimentation are dominant. Conodonts and radiolarians are the most common fossils in the Pignola-Abriola section (Amodeo, 1999; Bazzucchi et al., 2005; Rigo et al., 2005, 2012, 2016; Giordano et al., 2010). The first appearance datum of conodont *Misikella posthernsteini* s.s. marks the Norian/Rhaetian boundary (hereafter NRB) at meter 44.9 (Giordano et al., 2010; Maron et al., 2015; Rigo et al., 2016), and falls within the base of the *Proparvicingula moniliformis* radiolarian Zone, which defines the Rhaetian Stage. The NRB is also marked by a  $\delta^{13}\text{C}_{\text{org}}$  negative excursion recorded in marine (e.g., Pignola-Abriola, Mt. Volturino and Madonna del Sirino in Italy, Wombat Basin in Australia, Kiritehere in New Zealand, Kennecott Point in Canada, New York Canyon in USA, Kastelli in Greece; Maron et al., 2015, 2019; Rigo et al., 2016, 2020; Bertinelli et al., 2016; Zaffani et al., 2017) and terrestrial sections (e.g., Xujiache in China; Jin et al., 2022). The magnetostratigraphy of Pignola-Abriola is represented by ten magnetozones, five of normal polarity and five of reverse polarity, and is coherent with the magnetostratigraphy of the main stratigraphic sections of late

Norian-early Rhaetian age (Maron et al., 2015, 2019). The magnetostratigraphic correlation to the Newark  
 65 Astrochronological Polarity Time Scale (Newark-APTS) assigned an age of 205.7 Ma to the Norian/Rhaetian boundary at  
 Pignola-Abriola (Maron et al., 2015, 2019).

**Figure 1.** A. location of the Pignola-Abriola section (40°33'23.5" N, 15°47'1.7" E) in the Lagonegro Basin (southern Apennines, Italy), and paleogeographic reconstruction of the area in the Late Triassic (modified from Maron et al., 2015); B. Paleogeographic reconstruction of the Lagonegro Basin, located in the western Tethys during the Late Triassic.

## 70 3 Methods

### 3.1 Rock Magnetism

Rock magnetism experiments have been performed on 136 non-oriented samples from the Pignola-Abriola section. Analyses of mass susceptibility ( $\chi$ ) has been performed with an AGICO MFK2-A on all samples, while temperature dependent mass susceptibility ( $\chi$  vs. T) was measured on 59 samples representative of the main lithologies and equally distributed along the  
 75 section, using an AGICO CS4 furnace apparatus. An ASC Scientific D-2000 AF demagnetizer has been used to apply an anhysteretic remanence (ARM) to the samples, using a bias DC field of 0.1 mT and an AC field of 100 mT. The acquisition of isothermal remanent magnetization (IRM) curves (maximum field = 1 T) was performed with a Bussi pulse magnetizer.

The unmixing of IRM acquisition curves has been performed with the MAX UnMix software (Maxbauer et al., 2016a). ARM and IRM were measured using an AGICO JR6 spinner magnetometer (sensitivity:  $2.4 \times 10^{-6}$  A/m). S-Ratio (Eq. 1):

$$80 \quad S_{-0.3T} = 0.5 \times \frac{IRM_{1T} - IRM_{-0.3T}}{IRM_{1T}}, \quad (1)$$

and HIRM (Eq. 2):

$$H = \frac{IRM_{-0.3T} + IRM_{1T}}{2}, \quad (2)$$

were calculated from IRM backfield data. To calculate the S-Ratio, we used the formula of Bloemendal et al. (1992), which discriminates better the contribution of high-coercivity antiferromagnetic minerals (Maxbauer et al., 2016b). Hysteresis curves on 43 samples have been acquired with the Microsense EZ7 vibrating sample magnetometer. All the analyses have been performed at the paleomagnetic laboratories CIMaN-ALP (Peveragno) and LASA (Segrate), Italy. The stratigraphic curves of the rock magnetic parameters have been smoothed using local regression (LOESS) using PAST software (Hammer et al., 2001).

## 3.2 Geochemistry

### 90 3.2.1 Major elements analysis

Samples for whole-rock geochemical analysis were collected from 56 beds in the Pignola-Abriola section. The shale-dominated samples were crushed in an agate mortar and washed with ultrapure water. After drying, the fragments were carefully hand-picked to avoid contamination by altered and weathered material. The hand-picked fragments were then pulverized in an agate mortar.

95 Major element concentrations of 47 samples were determined by X-ray fluorescence spectrometry (PANalytical Epsilon 3XLE with a Mo X-ray tube) using pressed powder pellets. Samples were calibrated using 19 standard rock samples issued by the Geological Survey of Japan. Reproducibility, based on the replicate analysis of four standards (JSd-1, JSd-2, JLs-1, JDo-1), was better than  $\pm 0.5\%$  for MgO, Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub>, K<sub>2</sub>O, CaO, TiO<sub>2</sub>, and Fe<sub>2</sub>O<sub>3</sub>; better than  $\pm 1\%$  for Na<sub>2</sub>O and MnO; and better than  $\pm 10\%$  for P<sub>2</sub>O<sub>5</sub> (Supplementary Table S1 in online dataset, Maron et al., 2023).

100 The bulk chemical composition of 9 samples was also determined by X-ray fluorescence spectroscopy (XRF) using a WDS sequential Philips PW2400 spectrometer equipped with a 3 kW Rh X-ray tube. The analyses, performed under vacuum conditions, and using the SuperQ software from Panalytical, were based on calibrations calculated on geological reference standards (Govindaraju, 1994). The sample powders were first used to determine the loss on ignition (LOI) heating them in a furnace at 860°C for 20 minutes, and then at 980°C for 2 hours. The calcined powders were then diluted with flux di-lithium tetraborate Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub> (1:10 ratio) and melted with a fluxer Claisse Fluxy (reaching a temperature of about 1150°C) to obtain  
105 glass beads for XRF analyses. Instrumental precision (defined by several measurements performed on the same sample) is within 0.6% relative for major elements. The XRF accuracy was checked by reference standards (Govindaraju, 1994) and was within 0.5 wt% for Si, lower than 3% for other major elements. The lowest detection limits of XRF were within 0.02

wt% for Al<sub>2</sub>O<sub>3</sub>, MgO and Na<sub>2</sub>O, within 0.4 wt% for SiO<sub>2</sub> and within 0.005 wt% for TiO<sub>2</sub>, Fe<sub>2</sub>O<sub>3</sub>, MnO, CaO, K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub>.  
110 The stratigraphic curves of the geochemical parameters have been smoothed using local regression (LOESS) using PAST software (Hammer et al., 2001).

### 3.2.2 Principal component analysis

To extract paleoenvironmental changes from compositional data, principal component analysis (PCA) was applied to data of ten major oxides (SiO<sub>2</sub>, TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, MnO, MgO, CaO, Na<sub>2</sub>O, K<sub>2</sub>O, and P<sub>2</sub>O<sub>5</sub>). The data were normalized to the Ti  
115 contents and compared with those of upper continental crust (UCC; McLennan, 2001) in order to obtain enrichment factors as in the following Eq. (3):

$$X_{EF} = \frac{\left(\frac{X_{sample}}{Ti_{sample}}\right)}{\left(\frac{X_{UCC}}{Ti_{UCC}}\right)}, \quad (3)$$

where X and Ti are the weight concentrations of element X and Ti, respectively.

PCA is an operation that synthesizes numerous observational variables into several orthogonalized components, increasing  
120 the respective variances. Before applying Q-mode PCA on correlation coefficient matrix using singular value decomposition (Golub and Van Loan, 1989; Van Huffel and Vanderwalle, 1991; Albarède, 1995), the enrichment factors were converted into additive log ratios (alr) to map the simplex sample space onto the Euclidean real sample space for constant sum constraint of compositional data (Aitchison, 1986). This transformation has the advantage that most of the transformed compositional data follow multivariate normal distributions (Aitchison and Shen, 1980), which is a prerequisite for PCA  
125 (Atkinson et al., 2004). The detailed procedure of PCA for geochemical dataset is described in Soda and Onoue (2019) and Onoue et al. (2021).

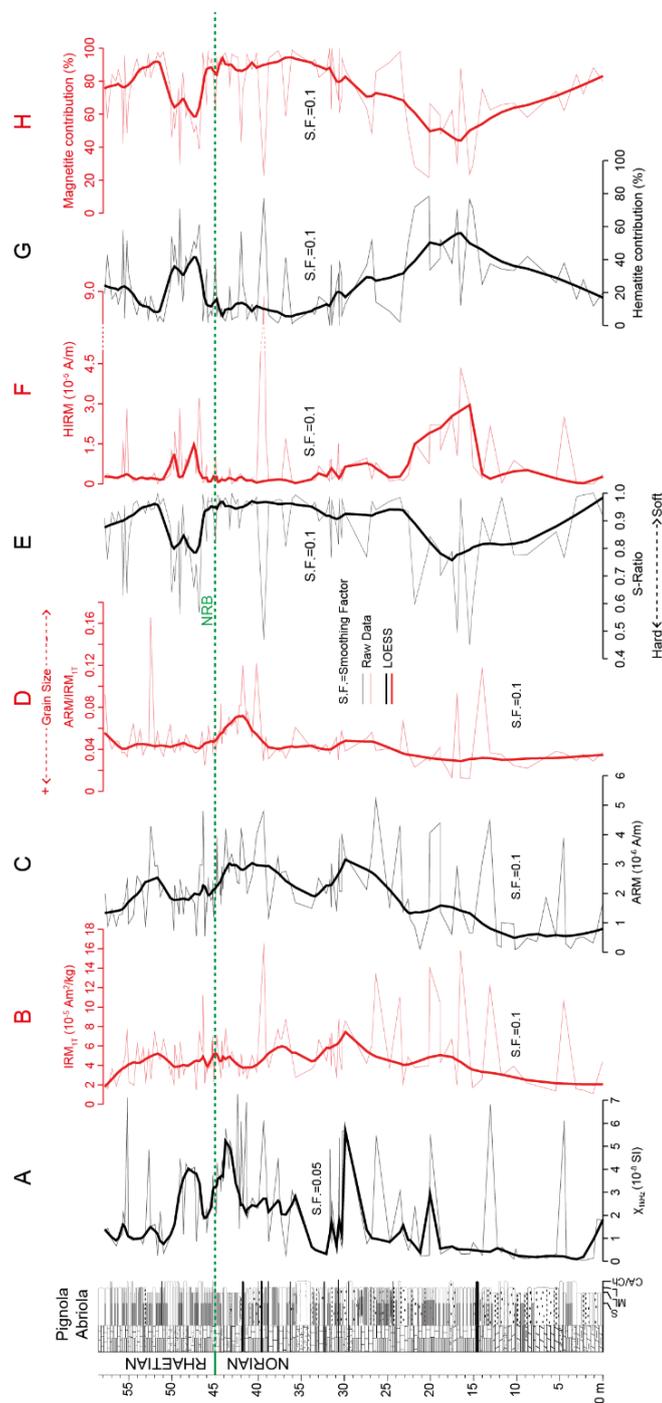

Elements concentration and PCA, plotted against stratigraphy, are reported in Fig. A1.

## 4 Results

### 4.1 Rock Magnetism

#### 130 4.1.1 Stratigraphic trends

The complete set of rock magnetic data is reported in Supplementary Table S2 (online dataset, Maron et al., 2023) and Fig. A1. Bulk susceptibility ( $\chi$ ) increases from  $\sim 2 \times 10^{-8}$  to  $\sim 5 \times 10^{-8}$  SI between 41 and 44 meters, then it decreases around the NRB up to  $\sim 46$  meters to increase again up to  $\sim 48$  meters (Fig. 2A), indicating an increase of more susceptible ferromagnetic minerals (likely magnetite). There are two major peaks in  $\chi$  at  $\sim 44$  m and  $\sim 30$  m, with several minor peaks from 0 to 25 m  
135 (Fig. 2A). The mean values of IRM<sub>1T</sub> and ARM, respectively  $5.9 \times 10^{-5}$  and  $2.6 \times 10^{-6}$  Am<sup>2</sup>/kg, suggest relatively small but detectable quantities of ferromagnetic minerals. The IRM<sub>1T</sub> curve shows a general increasing trend between 10 to 30 meters and a further increase with two peaks at  $\sim 40$  and  $\sim 47$  meters, close to the NRB (Fig. 2B).

140 **Figure 2. Lithostratigraphy and rock magnetic parameters of the Pignola-Abriola section. From left to right: a) low-field magnetic susceptibility  $\chi$  at 1 kHz of frequency; b) saturation IRM at 1 T; c) ARM acquired with an AC field of 100 mT under a bias DC field of 0.1 mT; d) ARM/IRM<sub>T</sub> ratio; e) S-Ratio; f) HIRM; g) Hematite contribution from IRM unmixing. Thick black/red line: local regression smoothing (LOESS).**

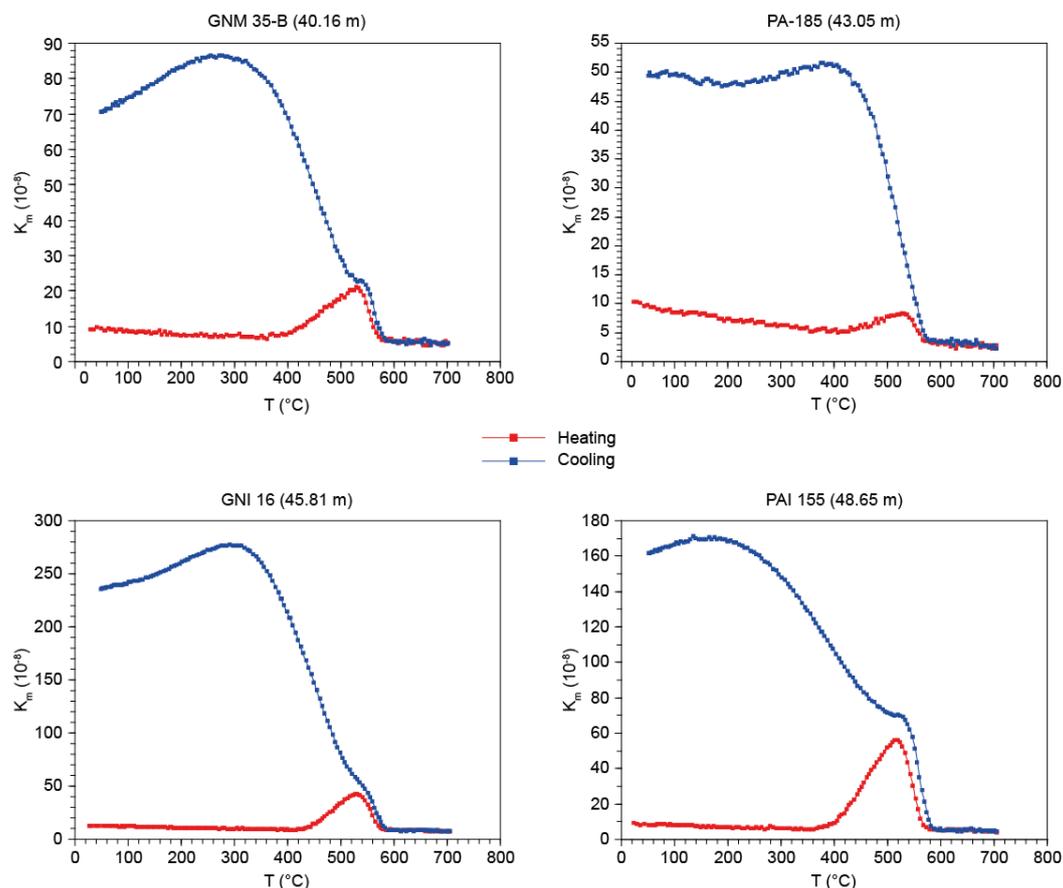

The ARM curve shows a similar trend in the lower part of the section (10-30 m), but higher values between 35 and 45 meters that decrease while approaching the NRB (similarly to the  $\chi$  curve), showing peaks that mirror the  $IRM_{IT}$  curve (Fig. 2C).

145 In the lower part of the section (up to 15-17 m), a relevant increase of high coercivity phases is shown by the S-Ratio (Fig. 2E) and HIRM (Fig. 2F), correlative to an increase in the coercivity of remanence ( $H_{cr}$ ; Figure A1). Similarly, an increase of high coercivity minerals is recognized few meters above the NRB, between ~46 and ~50 meters (Fig. 2E, F). The presence of resedimented calcarenites in this interval suggests that the increased quantity of hard coercivity minerals could be due to enhanced detrital input.

#### 150 4.1.2 Magnetic mineralogy

Previous analysis of thermal demagnetization of three-axis IRM (Maron et al., 2015) indicates that this high-coercivity fraction is hematite. The preserved magnetostratigraphic record in the Pignola-Abriola section (Maron et al., 2015) supports the primary origin of this hematite (together with magnetite). Moreover, the application of the elongation/inclination statistical method of Tauxe and Kent (2004) provided a flattening factor of 0.6 typical of detrital grains (Maron et al., 2015).

155

**Figure 3.** Heating-cooling curves of susceptibility against temperature ( $\chi$  vs.  $T$ ) of representative samples from the Pignola-Abriola section (see text for discussion). Curves were obtained using Cureval software by AGICO.

The  $\chi$  vs. T diagrams performed in Ar atmosphere show the presence of magnetite in both the heating and cooling curves (Curie temperature:  $T_C \approx 580$  °C; Fig. 3) and the neoformation of magnetite possibly from the conversion of mineral precursors (see below). Hematite is not clearly visible in our  $\chi$  vs. T diagrams (possibly due to its very low  $\chi$ ) albeit it was observed in Pignola-Abriola samples using IRM thermal decay experiments (Maron et al., 2015).

A peak of susceptibility appearing between  $\sim 400$  and  $500$  °C in the heating curve (peak susceptibility  $[\chi_H]$ /room temperature susceptibility  $[\chi_R]$  ranging from 4 to 50) is interpreted as due to mineralogical transformation during heating rather than a Hopkinson peak (Hopkinson, 1889; Dunlop, 1974; King and Ranganai, 2001; Dunlop and Özdemir, 2007; Dunlop, 2014) where  $\chi_H/\chi_R$  should not exceed 2.2 (e.g., Dunlop, 2014). The presence of pyritized radiolarians (Bazzucchi et al., 2005; Rigo et al., 2005; Giordano et al., 2010; Maron et al., 2015) indicate that pyrite could be the precursor mineral that alters into magnetite. Oxidation of iron sulfides is reported in both oxidizing (air) and inert (Ar) atmosphere (e.g., Li and Zhang, 2005; Wang L. et al., 2008) starting at  $\sim 400$  °C (Weaver et al. 2002). Ferromagnetic iron sulfides seem to be rare in the Pignola-Abriola section (see also Maron et al., 2015). The  $\chi$  vs.  $IRM_{1T}/\chi$  diagram (Larrasoña et al., 2007) indicates that most of the samples are in the range of magnetite ( $IRM_{1T}/\chi < 15$  kA/m), with only ten samples apparently containing also greigite (Fig. 4). Iron-bearing clay minerals (see the following paragraph 4.2) can also be involved in the formation of new magnetite through heating.

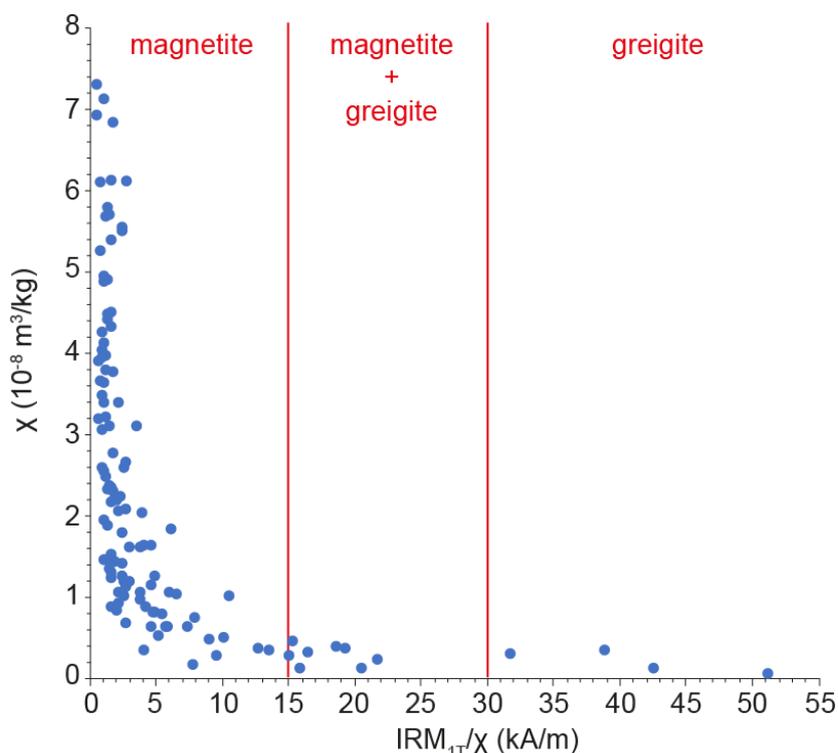

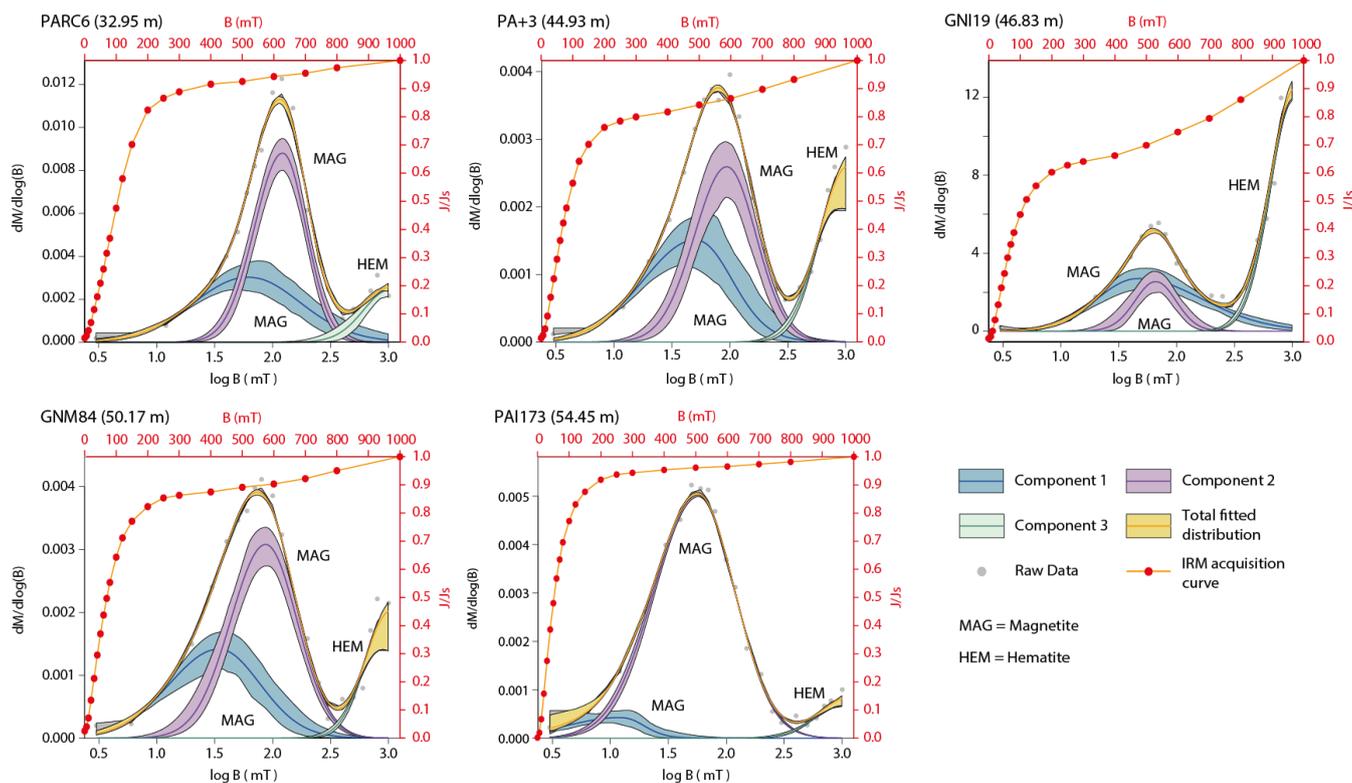

Figure 4. The  $\chi$  vs.  $IRM_{1T}/\chi$  plot (Larrasoña et al., 2007) indicates that almost the most of the samples lack of ferromagnetic iron sulfides (greigite, pyrrhotite), with a tenth of them showing dominant greigite or a mixture of magnetite and greigite.

175 The unmixing of IRM acquisition curves reveals at least two low coercivity components that can be attributed to magnetite (Fig. 5, Tab. 1) and a high coercivity component that can be attributed to hematite (Fig. 5, Tab. 1). The trend of hematite contribution as presented in Fig. 2G mirrors the HIRM and S-Ratio curves. The total contribution of magnetite is higher between ~25 m to ~40 m, and decreases up-section while fluctuating in a series of pulses (Fig. 2H).

180 **Figure 5.** IRM unmixing and acquisition curves of representative samples from the Pignola-Abriola section. Unmixing has been obtained using MaxUnmix online software (Maxbauer et al. 2016).

### 4.1.3 Magnetic grain size

ARM values are generally higher in single domain (SD) magnetite grains (Egli and Lowrie, 2002), thus a decrease in ARM could be associated to an increase in magnetite granulometry but also to an increase of high coercivity minerals less susceptible to ARM. The grain-size sensitive parameter  $ARM/IRM_{1T}$  shows a decrease in grain-size between ~38 and ~42 m just below the NRB (Fig. 2D). The trend of the  $ARM/IRM_{1T}$  curve mostly resemble the ARM curve, especially in the 35-45 m interval, suggesting that grain size plays a major role in ARM intensity than mineralogy. To test the reliability of the  $ARM/IRM_{1T}$  parameter as grain-size indicator, we calculate the  $ARM/IRM$  ratio with IRM acquired at the same field as ARM (100 mT), in order to exclude the influence of high coercivity minerals from the  $ARM/IRM$  ratio. The results show that the trend of  $ARM/IRM_{100mT}$  is mostly similar to both the  $ARM/IRM_{1T}$  and ARM trends (Fig. A2). Thus, we can confidently use the  $ARM/IRM_{1T}$  as a grain-size proxy.

Sample	Component	Contribution (%)	$B_{1/2}$ (mT)	DP
PARC6 (32.95 m)	1	34.4	60	2.9
	2	47.9	113	1.7
	3	17.6	1291	2.0
PA+3 (44.93 m)	1	28.0	39	2.4
	2	33.4	89	1.9
	3	38.6	1317	2.1
GNI19 (46.83 m)	1	28.4	68	2.9
	2	10.5	65	1.5
	3	61.1	1071	1.7
GNM84 (50.17 m)	1	29.0	30	2.5
	2	46.3	82	1.9
	3	24.7	1122	1.7
PAI173 (54.45 m)	1	6.5	7	2.2
	2	80.2	51	2.2
	3	13.3	1667	2.3

**Table 1. Ferromagnetic components from IRM unmixing.**

The hysteresis curves, corrected for ubiquitous paramagnetic signals (Fig. 6A), yielded parameters that place most of the samples between the SD-MD and SP-SD mixing curves of magnetite on a modified Day et al. (1977) plot (Dunlop, 2002a, 2002b) (Fig. 6B). We also plot in Figure 6B the hematite+magnetite mixing line of Liu et al. (2019) and the SD-MD greigite mixing line of Roberts et al. (2011), none of which seem to describe the data distribution of our samples, characterized by a more complex magnetic mineralogy.

#### 4.1.4 Summary

In summary, rock magnetism experiments indicate that magnetite and hematite are the main ferromagnetic minerals of the Pignola-Abriola sedimentary sequence, with minor amounts of iron sulfides as possibly suggested by the  $\chi$  vs. T curves (Fig. 3). In general, magnetite appears to be widespread, as suggested by the hysteresis data (Fig. 6). The amount of hematite appears to be quite variable along the section, showing a major increasing trend from 15 to 17 m followed by a decreasing trend up to 23 m and finally a set of rapid oscillations across the NRM between 39 and 50 m (Fig. 2E, F, H). As suggested by previous data (Maron et al., 2015), this hematite is detrital in origin. As indicated by the ARM/IRM<sub>1T</sub> curve (Fig. 2D), the magnetite grains size is quite stable along the section, except for a slight increase of finer-grained magnetite between 38 and 42 m, possibly related to higher occurrence of authigenic (microbial?) magnetite.

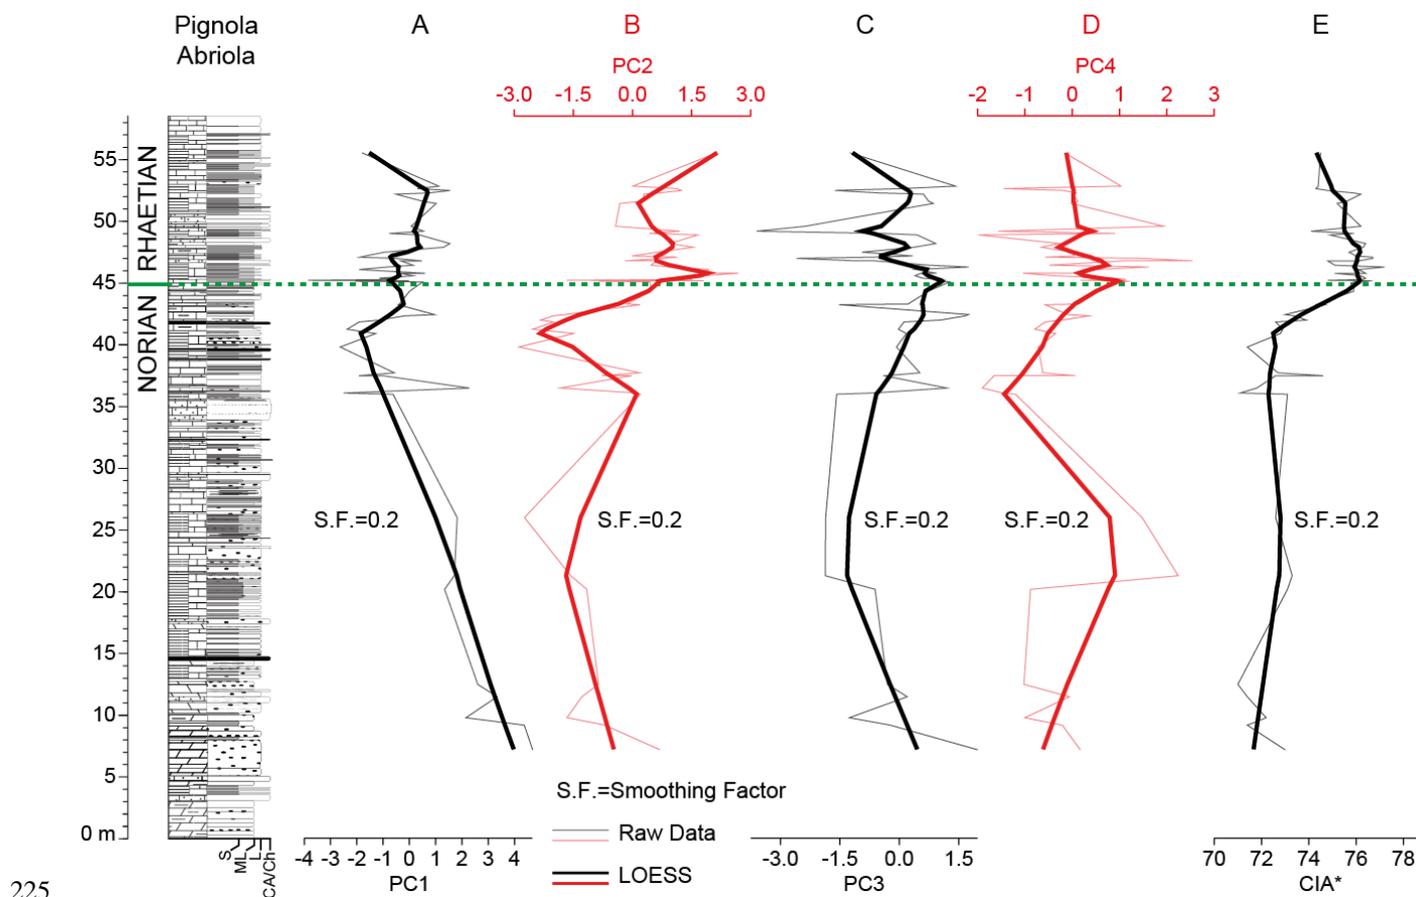

## 4.2 Geochemistry

215 The major element data obtained for the 56 shale samples of the Pignola-Abriola section are listed in Supplementary Tab. S3  
 (online dataset, Maron et al., 2023). In this study, we employed the Chemical Index of Alteration (CIA; Nesbitt and Young,  
 1982) to measure degree of chemical weathering in hinterland from major oxides. Values of CIA indicate the extent of  
 decomposition of feldspar minerals, which are the most abundant mineral group in the UCC. Following the previous study  
 (Casacci et al., 2016), we used a modified form of the CIA equation (Eq. 4) in which CaO is omitted from the denominator  
 220 because of the high carbonate content of the study units, which makes it difficult to determine accurately the amount of non-  
 carbonate CaO in each sample:

$$CIA^* = \frac{Al_2O_3}{Al_2O_3 + Na_2O + K_2O} \times 100 . \quad (4)$$

Stratigraphic variations in CIA\* values are shown in Fig. 7. The CIA\* values begin to increase from 40 m to the top of the  
 section. The value reaches its maximum from 45 m, at the NRB.

225

**Figure 7.** Stratigraphic variations in PC scores, CIA\* (Casacci et al., 2016), and  $\delta^{13}C_{org}$  curve (Zaffani et al., 2017) in the Pignola-Abriola section. Thick black/red line: local regression smoothing curve (LOESS).

### 4.3 Principal component analysis

230 Tab. 2 lists the component loadings for the studied samples. PCA showed that the first four principal components explain 79.8% of the total variance in the dataset with their high eigenvalues ( $> 1.0$ ). The loadings of PC1 show strong negative values (less than  $-0.80$ ) for Si and Al, with subordinate negative values for Mg ( $-0.63$ ), Na ( $-0.60$ ), and Fe ( $-0.58$ ). PC2 is characterized by high negative loadings for K ( $-0.80$ ) and Mg ( $-0.57$ ), and a high positive loading of Na ( $0.62$ ). PC3 has a prominent negative loading for Ca ( $-0.90$ ) with high negative loadings for P ( $-0.58$ ) and Mn ( $-0.45$ ). The loadings of PC4  
 235 displayed the opposite direction between Mn ( $-0.65$ ) and P ( $0.67$ ) with the low loadings of the others.

	PC1	PC2	PC3	PC4
Si <sub>EF</sub>	-0.82	0.47	-0.03	0.14
Al <sub>EF</sub>	-0.86	0.07	0.21	0.35
Fe <sub>EF</sub>	-0.58	-0.25	-0.01	-0.03
Mn <sub>EF</sub>	-0.47	-0.16	-0.45	-0.65
Mg <sub>EF</sub>	-0.63	-0.57	-0.04	0.13
Ca <sub>EF</sub>	0.09	0.09	-0.90	-0.03
Na <sub>EF</sub>	-0.60	0.62	-0.17	-0.05
K <sub>EF</sub>	-0.33	-0.85	0.12	-0.17
P <sub>EF</sub>	0.13	-0.35	-0.55	0.67
Eigenvalue	1.69	1.37	1.19	1.02
Proportion	31.7	20.8	15.6	11.7
Cumulative Proportion	31.7	52.5	68.2	79.8

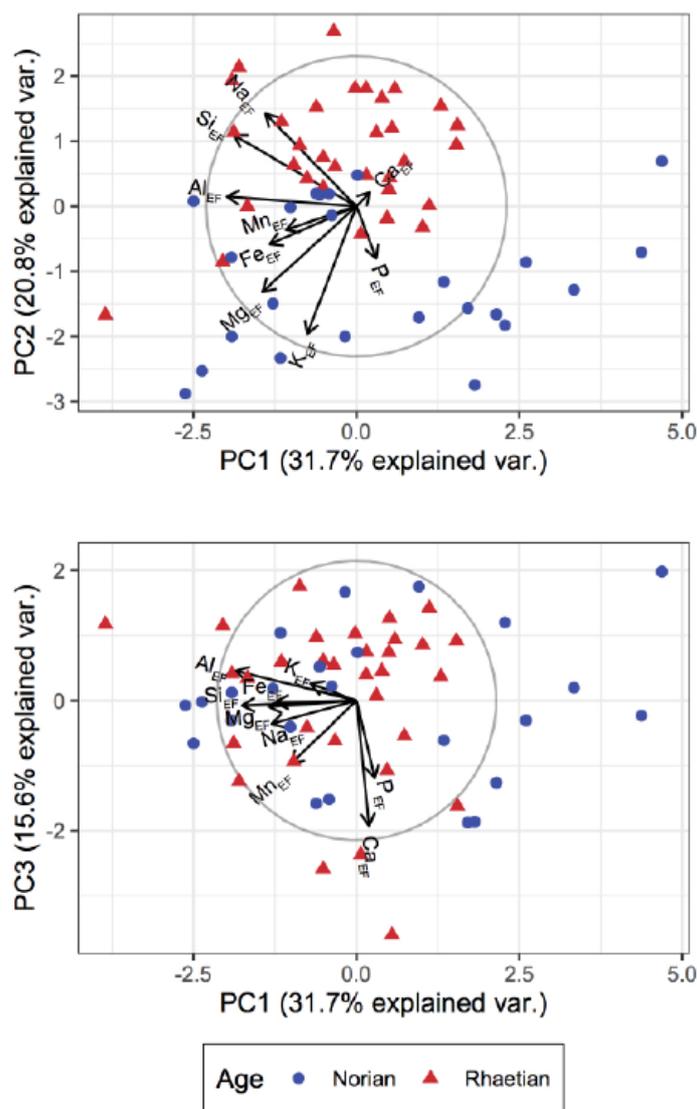

**Table 2. Principal component loadings calculated from the major element contents of the shales.**

The PC1 scores represent the compositional variations associated with terrigenous detrital materials because of the same directions in the relatively strong loadings for Al, Si, Mg, Na, and Fe. The strong PC1 loadings in Al and Si relative to Mg, Na, and Fe (Fig. 8) reflect the typical order of element mobility during weathering (Goldich, 1938; Middelburg et al., 1988; Pokrovsky et al., 2005). These elemental behaviors in the PC1 axis indicate the intensity of chemical weathering. The PC3 axis explains the calcium carbonate accumulation because the loadings show a prominent negative loading for Ca and the stratigraphic trend in PC3 is largely similar to those in Ca<sub>EF</sub> (Fig. A1; Supplementary Table S3 in online dataset, Maron et al., 2023). Similar negative loadings for Mn and P suggest this relates to precipitation of Mn and P into carbonate minerals at  
 245 the time of deposition or during burial diagenesis (e.g., Price and Sellwood, 1994), as reported from multivariate statistical analyses of a Rhaetian carbonate–clastic deposit in the northwestern Tethys (Onoue et al., 2022).

Although the interpretations for PC2 and PC4 need to be verified by mineralogical and organic geochemical data in future studies, the character of each loading might be interpreted as follows. The PC2 axis might indicate crystallographic structural changes in clay minerals between illite and smectite groups (Brigatti et al., 2006) because of the opposite direction between  
 250 K and Mg (interlayer cations for illite and chlorite) and Na (exchangeable cation for smectite) (Fig. 8). The positive scores

for PC4 could be explained by the preservation of organic matter under reducing conditions. Phosphorous is transferred to the sediment mainly as organically bound P, most of which is subsequently liberated through re-mineralization of organic matter (Algeo and Ingall, 2007). Organic-bound P is expected to be preserved under suboxic conditions where Mn is reduced to Mn(II) and forms soluble cations (Algeo and Li, 2020); this explains the opposite direction between P and Mn in PC4.

255

**Figure 8.** Compositional biplots obtained from the major element contents of the shales in the Pignola-Abriola section. Relative directions and lengths of the arrows indicate loadings for the PC axes. Each variance (var.) is represented as a proportion in this dataset.

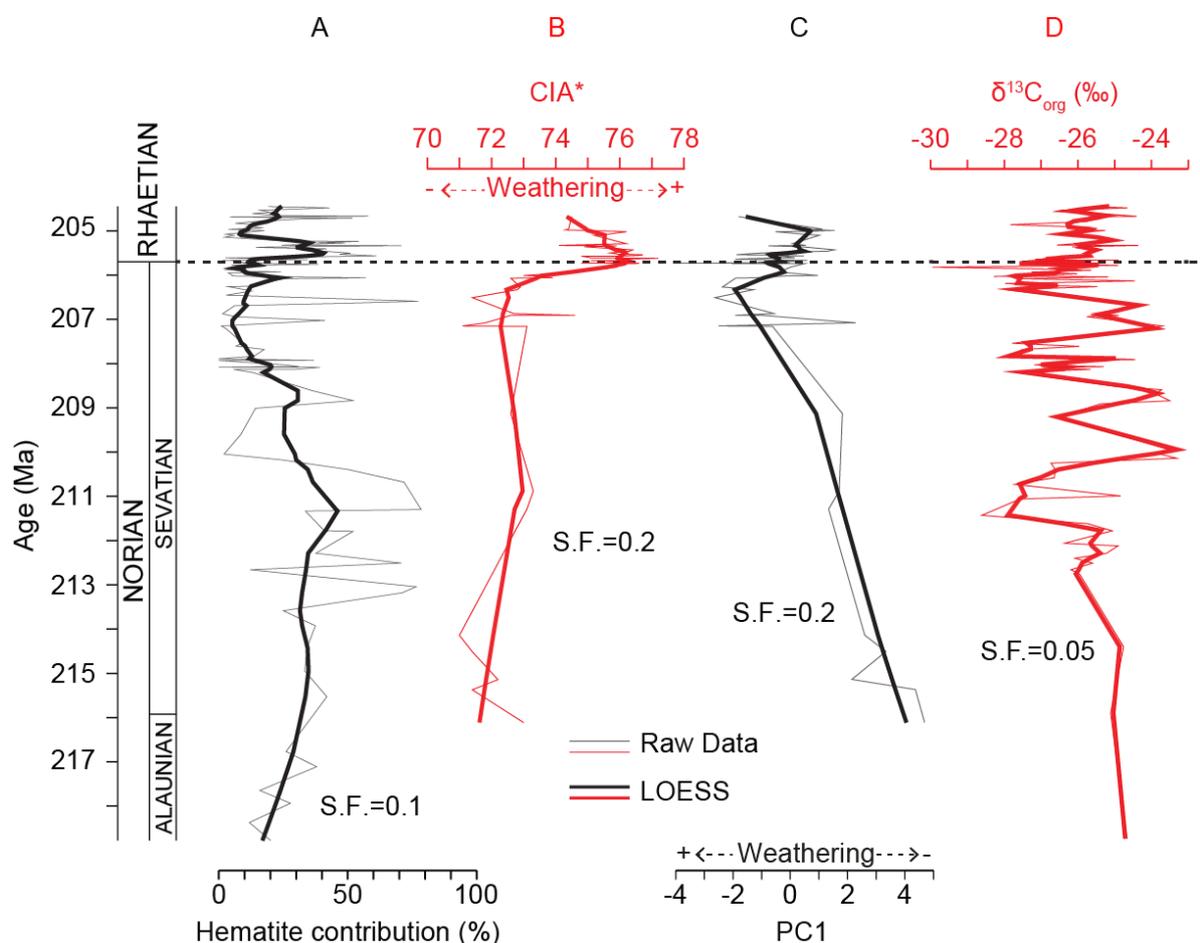

## 5 Discussion

### 260 5.1 Long-term weathering trends

Rock magnetic data (Fig. 9A) show a long term increasing trend of detrital hematite from at least ~217 Ma in the Alauanian to ~211 Ma in the middle Sevatian followed by an ensuing long term decreasing trend of detrital hematite up to ~207-206 Ma in the latest Sevatian.

As hematite is a relevant component of soils (e.g., Ambrosi et al., 1986; Hernández-Quiroz et al., 2012; Haldar, 2013; Best, 265 2015), relative increases/decreases in detrital hematite are here interpreted as indicating increases/decreases in weathering of silicates (see also discussion below).

270 **Figure 9.** Main rock magnetic and geochemical proxies for environmental interpretation: A. contribution of hematite (in percentage), B. Chemical Index of Alteration (CIA\*), C. PC1 (weathering of silicates from PCA), D.  $\delta^{13}\text{C}_{\text{org}}$  curve (from Zaffani et al., 2017). Vertical scale is in Ma, following the age model for the Pignola-Abriola section of Maron et al. (2015). Thick black/red line: local regression smoothing curve (LOESS).

## 5.2 Rapid weathering oscillations

Weathering becomes again more intense albeit oscillatory starting just below the NRB and continuing in the earliest Rhaetian, where hematite shows a rapid increase and PC1 and CIA\* reach respectively their lowest and the highest values (Fig. 9A-C). A transient peak in weathering occurs at the NRB occurs close to a major negative excursion of  $\delta^{13}\text{C}_{\text{org}}$  (Fig. 9D). PC2 scores (Fig. 7B) may also support the interpretation that continental chemical weathering was accelerated at the NRB. The PC2 scores exhibits an abrupt increase to positive scores that begins in the latest Norian (Fig. 7B) and reaches its maximum in the earliest Rhaetian, which may represent a change in the major clay mineral composition from illite to smectite due to the increased precipitation around the hinterland areas. In fact, illite and chlorite are generally formed in the early stages of chemical weathering under dry and cold conditions, whereas smectite is formed under warm and humid conditions (e.g., Fürsich et al., 2005, Nakada et al., 2014).

## 6 Possible causes of the Norian long-term weathering trends

### 6.1 Premises

Silicate weathering followed by carbonate deposition is regarded as the main negative feedback mechanism to stabilize  $p\text{CO}_2$  levels and conjoint surface temperatures (Walker et al., 1981). Typically, global  $\text{CO}_2$  input from volcanic degassing and metamorphic reactions and output from silicate weathering (and carbon burial) are in dynamic equilibrium, stabilizing global climate (Walker et al., 1981). However, there are some mechanisms that can perturb this balance on various time scales. A large igneous province (LIP), if emplaced rapidly (e.g., within 1 Myr or less), can cause a transient extra  $\text{CO}_2$  input triggering rapid global warming that in turn accelerates global weathering to handle the extra  $\text{CO}_2$  input, returning the climate system to pre-stress conditions on relatively rapid time scales ( $\sim 10^5$  yr). When a mafic LIP and/or orogenically uplifted mafic rocks enter *via* plate tectonics the equatorial belt of high humidity and temperatures, they are subject to enhanced weathering that may continue even though global  $p\text{CO}_2$  and temperatures decrease, muting temporarily the ‘Walker thermostat’ and paving the way to global cooling (Kent and Muttoni, 2008; 2013 and references therein). Similarly, removing uplifted mafic rocks from the equator may trigger climate to rebound toward warmer states (Kent and Muttoni, 2008; 2013). Conditions of enhanced weathering and global cooling may in theory occur also at mid-latitudes, provided however that an equatorial-type climate develops at least seasonally, as described for example by the dynamic theory of monsoons. These paleogeographic conditions that may perturb the  $\text{CO}_2$  input-output balance on time scales of  $10^6$  yr are of course dependent also on factors such as extent of mafic rocks that undergo weathering under equatorial or monsoonal climate, their composition (Ca-rich mafic rocks weather more efficiently than other igneous rocks), degree of exposure due to uplifting/orogenesis/LIP topography, degree of burial under regolith cover, etc (Kent and Muttoni, 2013 and references therein).

## 6.2 Interpretation

The increase of weathering (increase of hematite input) observed in the Alaunian-early Sevatian at Pignola-Abriola is in temporal agreement with the rise of  $^{87}\text{Sr}/^{86}\text{Sr}$  observed in the Pizzo Mondello section and interpreted as related to a phase of increasing (global) weathering in the Late Triassic (Onoue et al., 2018) (Fig. 10). We are not aware of any LIP that transited across the equatorial belt of Pangea in the Carnian-Norian. The Angayucham LIP with an age of  $214 \pm 7$  Ma (Ernst and Buchan, 2001; Prokoph et al., 2013) is a possible candidate but if it was part of Wrangellia it was located in the southern hemisphere in the Late Triassic (Kent and Irving, 2010). An alternative candidate for enhanced weathering is represented by the Cimmerian orogen that developed relatively rapidly in the Late Triassic along the southern margin of Eurasia at mid northern latitudes (e.g., Muttoni et al., 2009) possibly under a monsoonal-type climate (Onoue et al., 2018).

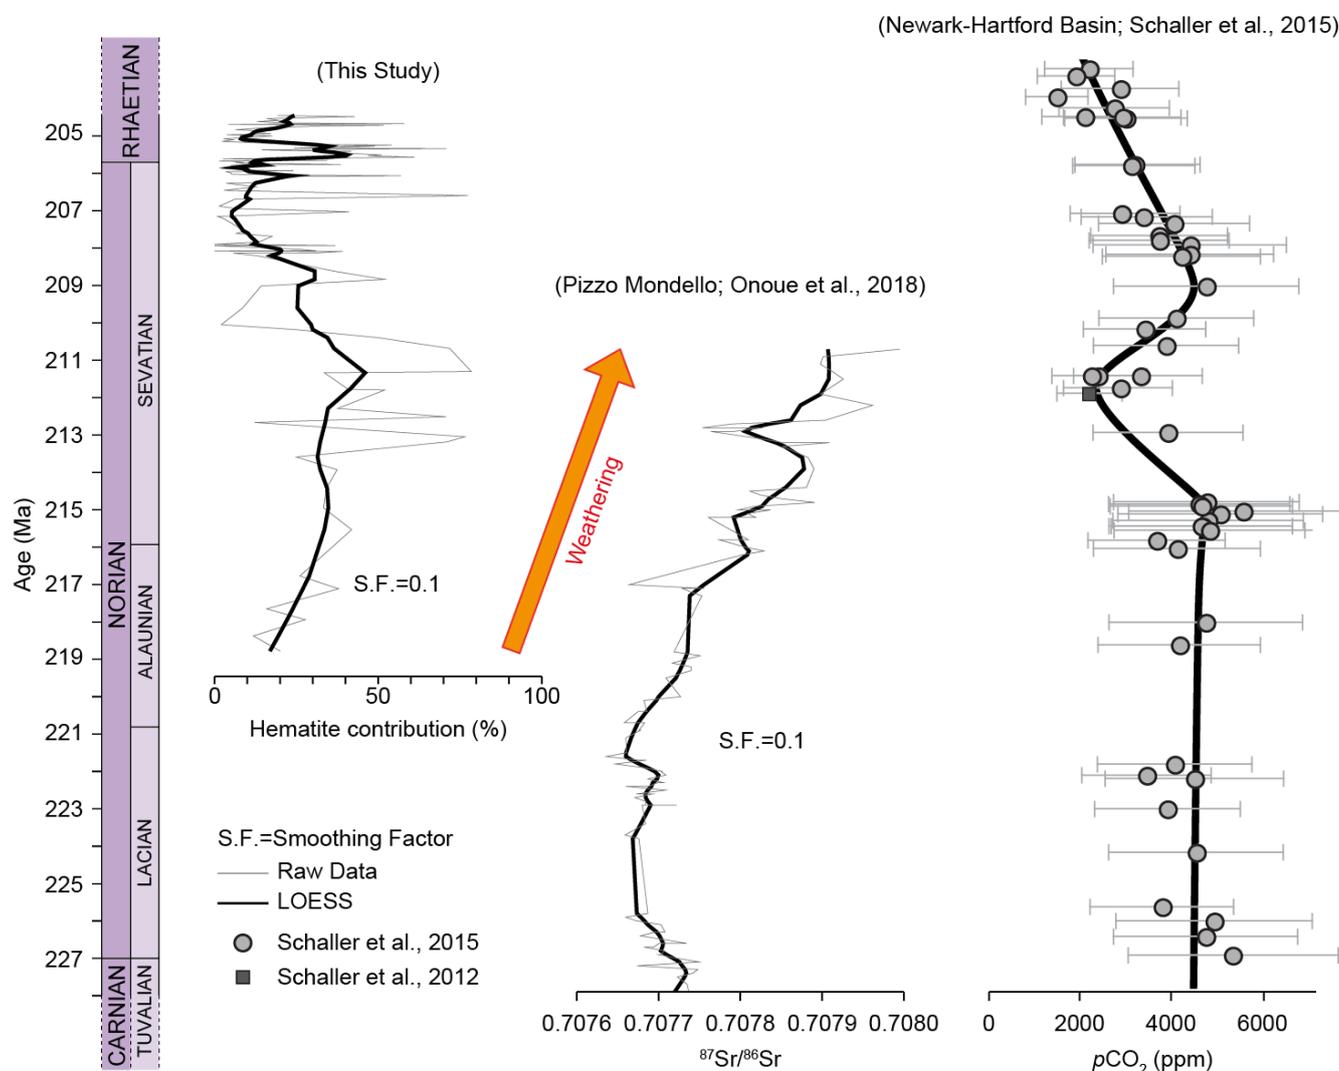

The Cimmerian is a multi-phase orogenetic event that occurred essentially in the Late Triassic and involved the accretion of different terranes with each other and ultimately with the Asian margin. Several slices of ultramafic rocks mark the complex Cimmerian suture from Pamir in the east to Turkey in the west. For example, the Bashgumbaz Complex of Pamir, comprised of mafic-ultramafic lithologies, obducted during the collision between the Central and Southern Pamir terranes, resulting in the Cimmerian orogeny in this part of Asia (Zanchetta et al., 2018). Recent petrographic and detrital zircon U-Pb data indicate a coeval accretion of the Central and Southern Pamir terranes to Northern Pamir (southern margin of Asia) by the end of the Triassic (Villareal et al., 2020). More to the west, geologic data indicate onset of collision of the Iran terrane with Eurasia in the Middle-Late Triassic followed by a main Cimmerian uplift phase at around the Triassic-Jurassic boundary (Wilmsen et al., 2009). Further to the west, high-pressure metamorphic rocks in northwest Turkey are interpreted as part of a larger Triassic mafic complex (Nilufer unit) accreted during the latest Triassic to the active margin of Eurasia, resulting in Cimmerian orogeny in northern Turkey (Okay et al., 2002). In summary, even though the geologic record is still discontinuous due to the complex geology of the Asian margin, there seems to be plenty of evidence for accretion/obduction/uplift of crustal elements locally enriched in mafic (highly weatherable) lithologies during multiphase Cimmerian deformation in the Late Triassic that may in part justify the observed Alaunian-Sevatian increased weathering trend.

In Sevatian levels of the Newark-Hartford Basin of North America, Schaller et al. (2015) observed a drop in atmospheric  $p\text{CO}_2$  starting at  $\sim 215$  Ma (incidentally at the time of the Manicouagan impact at  $215.40 \pm 0.16$  Ma; Jaret et al., 2018) with a minimum centered at  $\sim 212$  Ma followed by a rebound to higher  $p\text{CO}_2$  values at  $\sim 209$  Ma and a second long-term  $p\text{CO}_2$  decreasing trend up to the Rhaetian (Fig. 10). According to Schaller et al. (2015), the cause of the  $\sim 5$  Myr Sevatian drop and rebound in  $p\text{CO}_2$  is unclear, while the general decrease of  $p\text{CO}_2$  from high Carnian-Norian levels to low Rhaetian levels was interpreted as due to increased weathering of silicate rocks entering the tropical-equatorial belt during the northward displacement of Pangea in the Late Triassic. We speculate that the  $\sim 5$  Myr Sevatian  $p\text{CO}_2$  drop and rebound could be related at least in part to the onset and demise of weathering of mafic lithologies exposed (and then buried under regolith?) during

335 one or more of the several phases of obduction/uplift that characterized the multiphase Cimmerian orogeny, albeit we do not exclude the effects of the northward motion of Pangea *sensu* Schaller et al. (2015).

The  $p\text{CO}_2$  curve of Schaller et al. (2015) shows an ensuing decreasing trend in late Sevatian-Rhaetian levels, albeit we notice that the record is discontinuous in the 207-205 Ma interval (Fig. 10). The Pignola-Abriola record shows fluctuating values of weathering in the latest Sevatian-earliest Rhaetian (Fig. 10). The origin of these high-frequency fluctuations is at present unclear but tectonic processes involving plate motion (Cimmeria, Pangea) are ruled out as they work on longer time scales.

340

Figure 10. Curve of hemateite contribution from Pignola-Abriola compared to the  $^{87}\text{Sr}/^{86}\text{Sr}$  curve from Pizzo Mondello (Onoue et al., 2018) and to the latest Carnian to early Rhaetian portion of the  $p\text{CO}_2$  curve from the Newark-Hartford Basin (Schaller et al., 2015). See text for discussion.

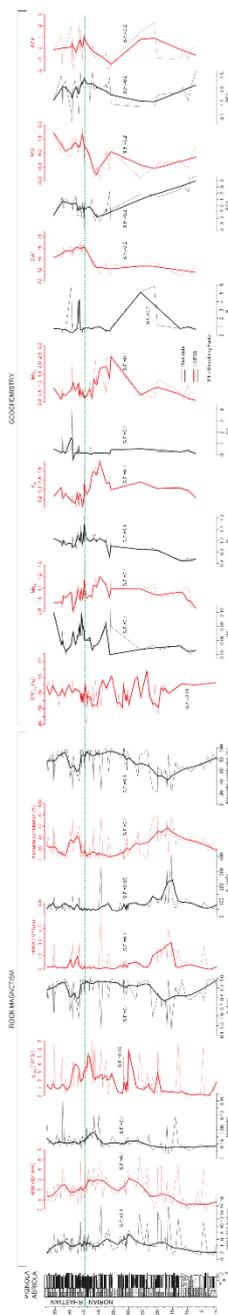

## 7 Conclusions

345 Both rock magnetic and geochemical data from the Pignola-Abriola section, in particular the hematite contribution from IRM unmixing and S-Ratio, CIA\*, and PC1, reveal trends in weathering rates. In particular:

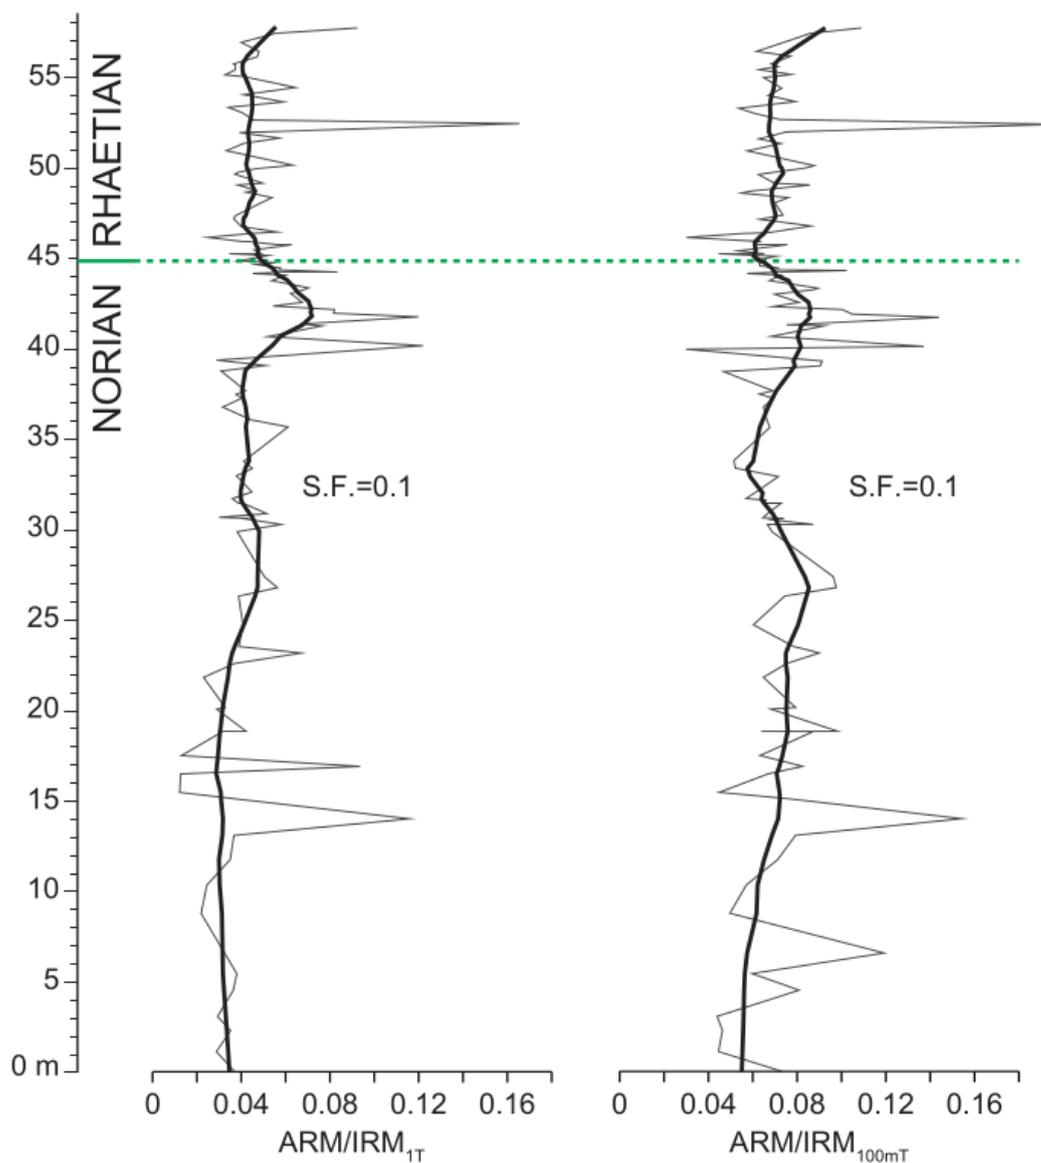

- We observed a long-term (~6 Myr long) increase of chemical weathering during the Alaunian-Sevastian (from ~217 to ~211 Ma) broadly coeval with the Sr trend from Pizzo Mondello. This trend is followed by a long-term (~5 Myr long) decrease of chemical weathering up to the latest Sevastian (~207-206 Ma). These trends are broadly paralleled  
350 by a decrease and increase in  $p\text{CO}_2$  (Schaller et al., 2015). These conjointly observed trends were possibly controlled by the weathering of the Cimmerian orogeny at mid-latitudes possibly under a monsoonal-type climate (Onoue et al. 2018), and/or by the northward drift of Pangea across the equatorial belt (Schaller et al., 2015).
- We observed fluctuating but generally high values of weathering across the NRB (~205.7 Ma), starting in the latest Sevastian (~206.5 Ma) and ending in the earliest Rhaetian (~205 Ma). The peak in weathering at the NRB is also  
355 marked by a  $\delta^{13}\text{C}_{\text{org}}$  negative excursion. The origin of these high-frequency oscillations has still to be determined.

## Appendix A

**Figure A1.** Curves of all the rock magnetic and geochemical parameters used in this paper. A local regression smoothing curve (LOESS, thick black/red line) has been calculated for each parameter using PAST software (Hammer et al., 2001).

**Figure A2.** Comparison of  $ARM/IRM_{1T}$  and  $ARM/IRM_{100mT}$  curves as a test for the contribution of high coercivity phases and grain size on the ARM over IRM ratio. A local regression smoothing curve (LOESS, thick black line) has been calculated for both curves using PAST software (Hammer et al., 2001).

## 365 **Data availability**

Rock magnetic and geochemical data are hosted on the Mendeley data repository:  
<https://data.mendeley.com/datasets/bmbt8t2ywj/1>.

## **Author contributions**

The authors declare they contribute to the manuscript as follows: conceptualization by MM, SS and MR; writing of the  
370 original draft by MM; investigation by MM, TO, HS, GM and MR; formal analysis by MM, TO, KS, HS and MR;  
visualization by MM; resources by MM, TO, SS, GM and MR; data curation by MM, TO, KS, HS and MR; review and  
editing by TO, SS, KS, HS, GM and MR; methodology by MM, TO, and KS; funding acquisition by TO, SS and MR;  
supervision by SS; project administration by SS and MR.

## **Competing interests**

375 The authors declare that they have no conflict of interest.

## **Financial support**

This study has benefited from financial support of MIUR – Ministero dell’Istruzione, dell’Università e della Ricerca (grant  
number: PRIN 2017W2MARE) to Manuel Rigo and Sara Satolli, and of the Japan Society for the Promotion of Science  
(grants numbers: JP19H00711 and JP20H00203) to Tetsuji Onoue.
