9 **Abstract**

10 Paleoclimate reconstructions across Iceland provide a template for past changes in climate across the northern North Atlantic,  
11 a crucial region due to its position relative to the global northward heat transport system and its vulnerability to climate change.  
12 The roles of orbitally driven summer cooling, volcanism, and human impact as triggers of local environmental changes in the  
13 Holocene of Iceland, remain debated. While there are indications that human impact may have reduced environmental  
14 resilience during Late Holocene summer cooling, it is still difficult to resolve to what extent human and natural factors affected  
15 Iceland's Late Holocene landscape instability. Here, we present a continuous Holocene fire record of northeastern Iceland  
16 from proxies archived in Stóra Viðarvatn sediment. We use pyrogenic polycyclic aromatic hydrocarbons (pyroPAHs) to trace  
17 shifts in fire regimes, paired with continuous biomarker and bulk geochemical records of soil erosion, lake productivity, and  
18 human presence. The molecular composition of pyroPAHs and a wind pattern reconstruction indicate a naturally driven fire  
19 signal that is mostly regional. Generally low fire frequency during most of the Holocene significantly increased at 3 ka and  
20 again after 1.5 ka BP, before known human settlement in Iceland. We propose that shifts in vegetation type caused by cooling  
21 summers over the past 3 kyr, in addition to changes in atmospheric circulation, such as shifts in North Atlantic Oscillation  
22 (NAO) regime, led to increased aridity and biomass flammability. Our results show no evidence of faecal biomarkers  
23 associated with human activity during or after human colonisation in the 9<sup>th</sup> century CE. Instead, faecal biomarkers follow the  
24 pattern described by erosional proxies, pointing toward a negligible human presence and/or a diluted signal in the lake's  
25 catchment. However, low post-colonisation levels of pyroPAHs, in contrast to an increasing flux of erosional bulk proxies,  
26 suggest that farming and animal husbandry may have suppressed fire frequency by reducing the spread and flammability of  
27 fire-prone vegetation (e.g., heathlands).

28 Overall, our results describe a fire frequency heavily influenced by long term changes in climate through the Holocene. They  
29 also suggest that human colonisation had contrasting effects on the local environment by lowering its resilience to soil erosion  
30 while increasing its resilience to fire.

## 31 1 Introduction

32 Iceland is highly sensitive to most mechanisms controlling the evolution of Holocene climate in the North Atlantic, from  
33 millennial (e.g., shifts in deep water formation and ocean current positions) to sub-decadal timescales (e.g., variability of the  
34 North Atlantic Oscillation) (Harning et al., 2021; Mjell et al., 2016; Moossen et al., 2015; Petit et al., 2020). Recent lake  
35 sedimentary records in Iceland (Alsos et al., 2021; Geirsdóttir et al., 2009a, 2013, 2019, 2020; Harning et al., 2016, 2020;  
36 Hiles et al., 2021; Larsen et al., 2011, 2012; Richter et al., 2021) draw a comprehensive picture of Icelandic environments  
37 during the Holocene (last 11.7 kyr). These Holocene paleoclimate reconstructions derived from lake sediments in Iceland show  
38 first-order millennial trends that reflect orbitally-driven changes in Northern Hemisphere summer insolation, and millennial to  
39 sub-millennial changes that are primarily impacted by northern North Atlantic ocean circulation and to a part by local  
40 volcanism (e.g., Flowers et al., 2008; Geirsdóttir et al., 2013, 2020; Harning et al., 2018b; Larsen et al., 2012). These Holocene  
41 climate reconstructions further indicate a major shift from occasional to increasingly severe landscape instability and soil  
42 erosion occurring at least 300 years before the acknowledged settlement of Iceland (ca 870 CE; The Book of Icelanders  
43 “Íslendigabók”, by Ari Thorgilsson, 12<sup>th</sup> century CE, e.g., Smith, 1995), suggesting that human impact had a secondary role  
44 to climate by lowering the resilience of the environment to an already ongoing naturally driven erosion (e.g., Bates et al., 2021;  
45 Geirsdóttir et al., 2009b, 2020). The ability to generate high-resolution Holocene terrestrial climate records, along with  
46 Iceland’s relatively short settlement history, makes Iceland an ideal location to attempt disentangling the impact of natural  
47 climate variability and human activities on the changes in the local landscape during the Late Holocene.

48 In this study, we use multiple organic proxies from a Holocene sediment core from the Stóra Viðarvatn lake in northeast  
49 Iceland to investigate the effects of natural and anthropogenic drivers on the local Icelandic environment. First, we focus on  
50 tracing the evolution of fire regimes using pyrogenic polycyclic aromatic hydrocarbons (pyroPAHs; Lima et al., 2005). Fires  
51 can have a significant impact on ecosystems, affecting vegetation patterns, nutrient cycling, and wildlife habitat (e.g.,  
52 Goldammer and Furyaev, 1996). The frequency, intensity, and spatial extent of fires can provide insights into past climate and  
53 environmental conditions (e.g., Marlon, 2009; Power et al., 2008) and, to our knowledge, there are no such records for the  
54 Holocene in Iceland, while limited data is available for the surrounding regions (Chen et al., 2023; Marlon et al., 2013; Segato  
55 et al., 2021; Zennaro et al., 2014). Second, as fire frequency can be influenced by human activities as well (e.g., Marlon et al.,  
56 2009, 2013; Zennaro et al., 2015), we also analyse faecal markers of human presence (Vázquez et al., 2021). By analysing  
57 these biomarkers from deglaciation to present, we can define their natural, pre-settlement background levels and thus  
58 potentially trace anthropogenic impact on the local environment, pinpointing human arrival in the lake catchment.

59 Finally, by coupling fire and human presence biomarker records with established proxies for environmental change (e.g., soil  
60 erosion and primary productivity, e.g., Argiriadis et al., 2018; Geirsdóttir et al., 2013; Gross, 2017), we test what control  
61 natural and/or human factors had on the evolution of the Holocene landscape in Iceland.

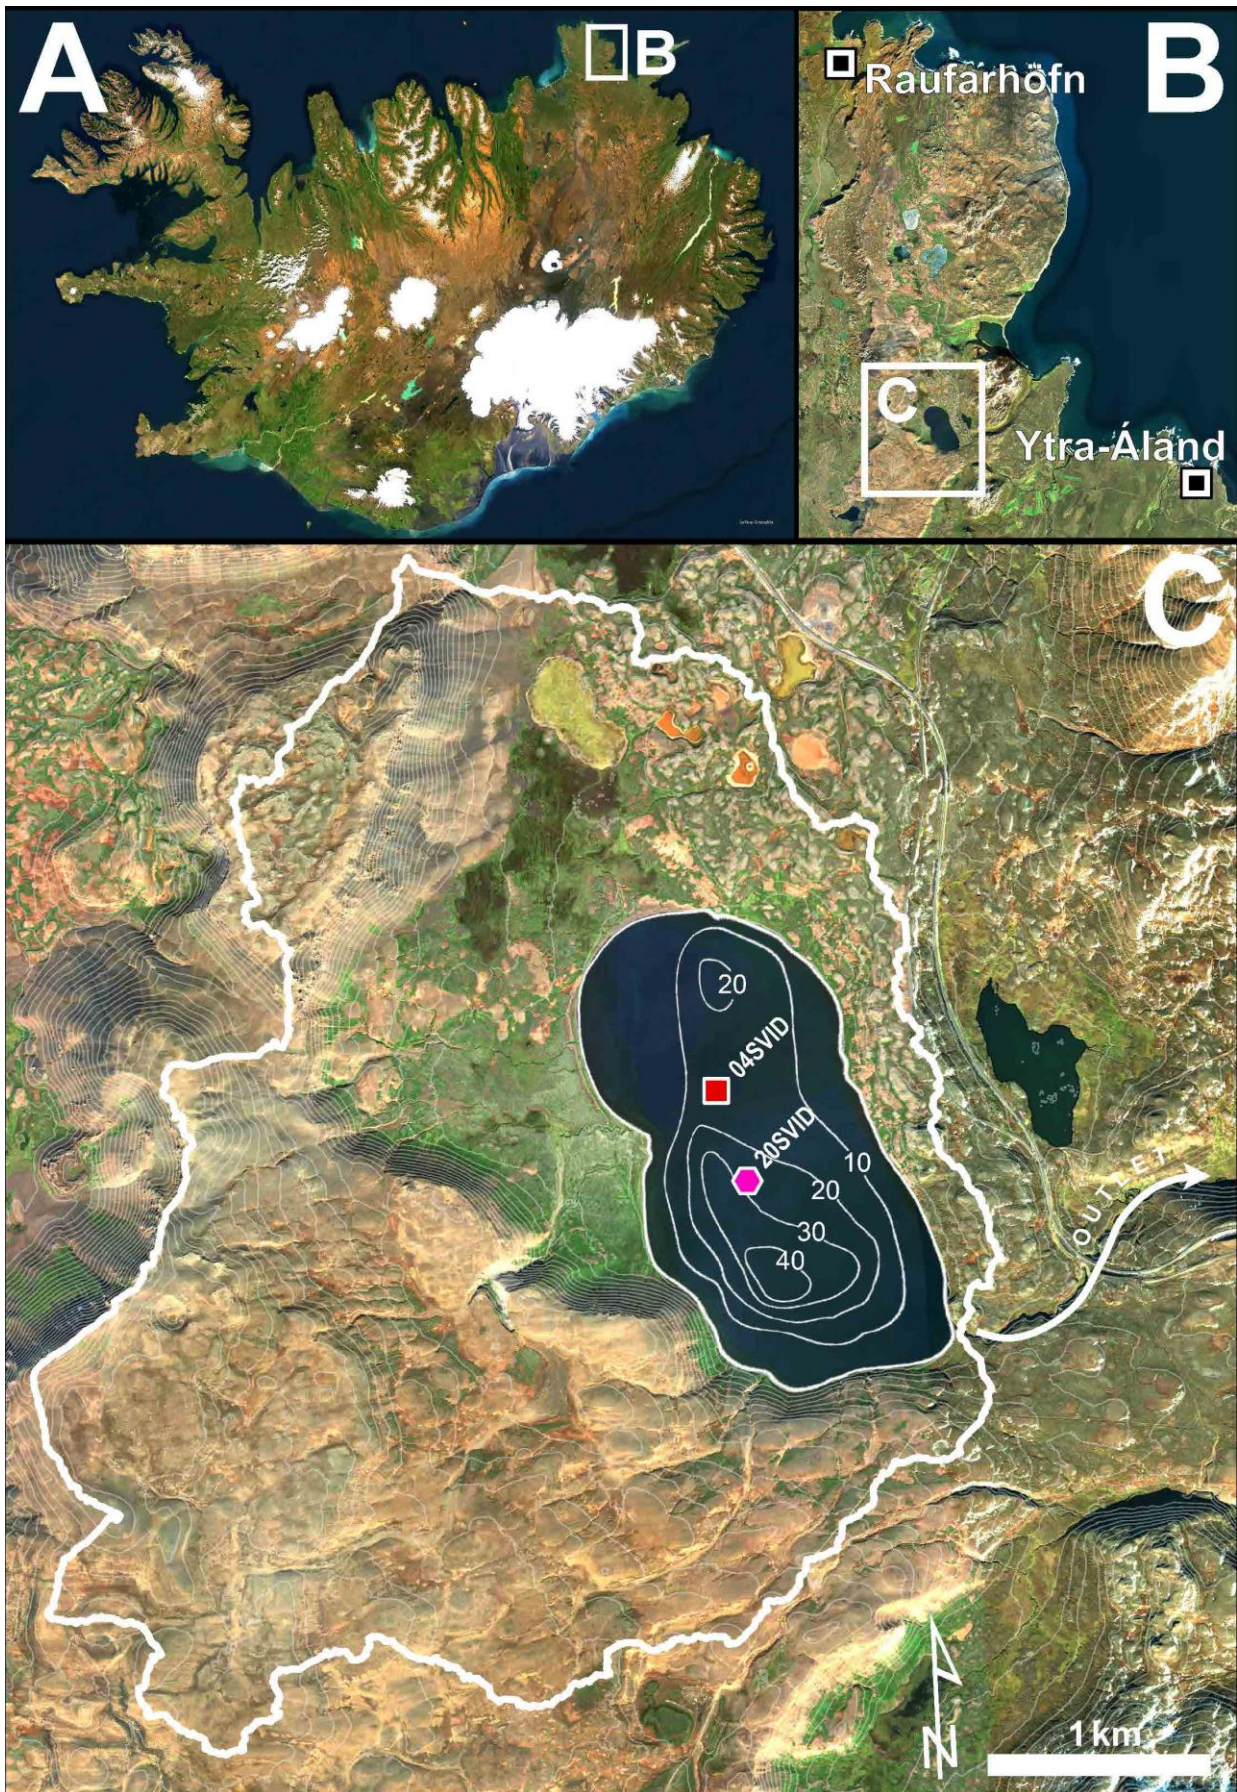

## 62 2 Methods

### 63 2.1 Study site

64 Stóra Viðarvatn (SVID) is a lake (2.6 km<sup>2</sup> surface area) located in NE Iceland (Fig. 1A-B) at an elevation of 151 m asl. SVID  
65 has a maximum depth of 48 m, a catchment area of 17 km<sup>2</sup> (including the lake surface), and a volume of ca 3.6×10<sup>7</sup> m<sup>3</sup> (this  
66 study, based on data from the National Land Survey of Iceland, Landmælingar Íslands, 2023; Axford et al., 2007). The lake is  
67 surrounded by Quaternary age basaltic lavas and glacial hyaloclastites formed by subglacial eruptions, as well as some  
68 Holocene soil with several mm-cm thick tephra layers (Hjartarson and Sæmundsson, 2014). The nearby Raufarhöfn station  
69 (Icelandic Meteorological Office, 2022) provides weather data for the 1961–1990 CE interval: mean annual temperature is  
70 2 °C with a maximum in July-August (8 °C), while the lake surface is usually frozen between November and March; mean  
71 annual precipitation is 733 mm a<sup>-1</sup> with lowest values occurring in May (28 mm) and the highest in October (ca 86 mm),  
72 suggesting a lake-water residence time between five and nine years.

73 In February 2020, we recovered a 8.93 m long core 20-SVID-02 (66.236867° N; -15.837837° E; 1C) from 17.4 m water  
74 depth near the centre of the lake (Harning et al., 2023). The sediment was retrieved in seven drives of ~150 cm each, using  
75 lake ice as a coring platform. The core was subsequently stored in a cool room (4 °C) at the Institute of Arctic and Alpine  
76 Research, University of Colorado Boulder, where it was subsampled. Previously, two studies have analysed an 8 m long core  
77 (04-SVID-03; 1C) retrieved in February 2004 to trace Holocene temperature (Axford et al., 2007) and δ<sup>18</sup>O from chironomid  
78 remains, as well as the δD, δ<sup>13</sup>C, δ<sup>15</sup>N of total organic matter (Wooller et al., 2008) at a 1–0.2 kyr resolution.

79

80 Figure 1: (A) Study area in NE Iceland; (B) Location of the Raufarhöfn climatological station and Ytra-Áland site (Karlsdóttir et  
 81 al., 2014), which are 20 km NNW and 13 km ESE from Stóra Viðarvatn (SVID), respectively; (C) Location and catchment area of  
 82 the Stóra Viðarvatn lake: 20-SVID-02 core is marked by a pink hexagon and an older 04-SVID-03 core by a red square (Axford et  
 83 al., 2007); SVID bathymetry (10 m isolines) is reported by Axford et al. (2007); watershed catchment and contour lines (10 m) are  
 84 calculated via ArcGIS (Esri, 2023) based on digital elevation models provided by the National Land Survey of Iceland; basemap  
 85 sourced from Esri.

## 86 2.2 Tephrochronology

87 Our sediment core chronology takes advantage of the geochemical fingerprints of visible Icelandic tephra layers and their  
88 correlation to marker tephra of known age. Thirteen tephra layers were sampled along the vertical axis, sieved to isolate glass  
89 fragments between 125 and 500  $\mu\text{m}$ , and embedded in epoxy plugs. At the University of Iceland, individual glass shards were  
90 analysed on a JEOL JXA-8230 electron microprobe using an acceleration voltage of 15 kV, beam current of 10 nA, and a  
91 beam diameter of 10  $\mu\text{m}$ . The international A99 standard was used to monitor for instrumental drift and maintain consistency  
92 between measurements. Tephra origin was then assessed using major oxide compositions, following the systematic procedures  
93 outlined in Jennings et al., 2014 and Harning et al., 2018a. Briefly, based on  $\text{SiO}_2$  wt% vs total alkali ( $\text{Na}_2\text{O} + \text{K}_2\text{O}$ ) wt%, we  
94 determined whether the tephra volcanic source is mafic (tholeiitic or alkalic), intermediate and/or rhyolitic. From here, we  
95 objectively discriminate the source volcanic system through a detailed series of bi-elemental plots produced from available  
96 compositional data on Icelandic tephra. Source eruption was then determined using the geochemical fingerprint and relevant  
97 stratigraphic information. See supplemental information for complete major oxide compositions and bi-elemental plots.  
98 Using the 13 marker tephra layers of known age (Table 1), we generated a Bayesian age model using the R package rbacon  
99 2.5.7 (Blaauw and Christen, 2011; R Core Team, 2020) and default model functions (Fig. 2). We used the ‘slumps’ function  
100 for the thicker tephra layers (e.g., Hekla 3 and Hekla 4) to reflect their instantaneous deposition on geologic timescales.

## 101 2.3 Sample preparation and analysis

102 At the University of Colorado Boulder, we retrieved a total of 196 sediment core samples at an average spacing of 4.5 cm,  
103 providing a temporal resolution of decadal to centennial time scales. We freeze-dried samples for 24–48 hours, and ground  
104 and homogenised them (mean weight 1.5 g, range 0.6–6.6 g) using an agate mortar and pestle. Using 13–70 mg of sediment,  
105 we measured total carbon (TC), total nitrogen (TN), and  $\delta^{13}\text{C}$  (relative to VPDB) on an elemental analyser linked to a Thermo  
106 Delta V isotope ratio mass spectrometer (EA-IRMS) in the Earth Systems Stable Isotope Laboratory at the University of  
107 Colorado Boulder; samples were analysed against a suite of secondary laboratory standards that are extensively calibrated to  
108 international standard reference materials to correct for size, blank-mixing, linearity and drift effects (Harning et al., 2018b).  
109 We did not decalcify samples as the contribution of inorganic carbon to TC in Icelandic lake sediment is considered to be  
110 negligible (see par. 5.1; Geirsdóttir et al., 2020). We analysed 9–11 mg of sediment for biogenic silica by Diffuse Reflectance  
111 Fourier Transform Infrared Spectrometry (FTIRS) on a Bruker Vertex 70 with a Praying Mantis diffuse reflectivity accessory  
112 (Harrick) and report values in FTIRS - Fourier Transform Infrared Spectroscopy absorbance units (e.g., Harning et al., 2018b).  
113 We processed 86 selected samples for organic biomarker analyses. We extracted 0.4–2 g of dry sediment with an accelerated  
114 solvent extractor (Dionex ASE350). Sample size, matrix, and richness in organic compounds greatly varied along the core and  
115 initial tests occasionally showed coloration in the sample extract even after 4–5 cycles, likely due to the persistence of organics.  
116 Thus, to maintain consistency in lipid yields throughout the core, we used dichloromethane (DCM):methanol (MeOH) 9:1 for  
117 six cycles of five minutes (static time), 100 °C, and 1,500 psi. After extraction, we spiked the total lipid extract (TLE) with  
118 1000 ng of 3-methyl-heneicosane (CAS#: 6418-47-9, Sigma-Aldrich), 20 ng of p-terphenyl (CAS#: 92-94-4, TCI), and 50 ng  
119 of pregnanol ( $5\beta$ -Pregnan-3 $\alpha$ -ol, CAS#: 4352-07-2, Steraloids) as internal standards for the quantification of *n*-alkanes, PAHs,  
120 and sterols, respectively. We concentrated the TLE under a gentle flow of nitrogen and then mixed it with HCl-activated copper  
121 shots to remove elemental sulphur as copper sulphide precipitates. We then filtered the samples through a  $\text{NaSO}_4$ -packed  
122 Pasteur column to remove any residual water and copper sulphide and concentrated them under  $\text{N}_2$ . We subsequently  
123 separated the TLE into six chromatographic fractions using a Pasteur pipette packed with silica gel (60–200  $\mu\text{m}$  - 60 A) and  
124 solvents of increasing polarity. We calculated the column’s dead volume (DV) with *n*-hexane, and then eluted samples with  
125 1.5 DV of *n*-hexane (F1), 2 DV of *n*-hexane:DCM 4:1 (F2), 1.5 DV of DCM (F3), 2 DV of DCM:acetonitrile (F4), 1.5 DV of  
126 acetonitrile (F5), and 3 DV of MeOH (F6). We derivatised fraction F4, containing the sterols/stanols, using TMS-BSTFA  
127 (Supelco) and pyridine (50:50) at 70 °C for 15 minutes, then dried under  $\text{N}_2$  and redissolved it in *n*-Hexane. We added 1 ng of

128 p-terphenyl D<sub>14</sub> (CAS: 1718-51-0, Sigma-Aldrich) and 50 ng of 5 $\alpha$ -cholestane (CAS: 481-21-0, Sigma-Aldrich) to fractions  
129 F2 (PAHs) and F4 (sterols), respectively, as injection standards to check the recovery and quantification consistency of  
130 analyses.

131 We analysed the *n*-alkanes, PAHs, and sterols using a Thermo Scientific Trace 1310 gas chromatograph (GC) equipped with  
132 a PTV inlet and a Restek glass liner interphase to a TSQ8000-Evo triple quadrupole mass spectrometer (MS). We used a 60  
133 m DB1 column (DB-1MS, 0.25 mm, 0.25  $\mu$ m film thickness, Agilent, USA) to separate *n*-alkanes and a DB-5 column (DB-  
134 5MS, 0.25 mm, 0.25  $\mu$ m film thickness, Agilent, USA) for PAHs and sterols, and He (1.2 ml min<sup>-1</sup>) as a carrier gas. For *n*-  
135 alkane analysis, we injected samples in splitless mode at 65 °C and the PTV was ramped to 400 °C at 3 °C s<sup>-1</sup> and held for 5  
136 min. The GC oven temperature was programmed from 60 °C to 220 °C (25 °C min<sup>-1</sup>) and then to 315 °C (2.5 °C min<sup>-1</sup>, held  
137 13 min). *n*-Alkanes were analysed in full scan (50–600 m/z) using the following MS conditions: 300 °C EI source at 70 eV  
138 electron energy, 50 uA emission current, and 15 V electron lens voltage, with a transfer line at 315 °C. For PAH analysis, all  
139 samples were injected in splitless mode at 45 °C and the PTV was ramped to 400 °C at 11.6 °C s<sup>-1</sup> and held for 2 min. The GC  
140 oven temperature was programmed from 60 °C (held 1 min), to 150 °C (40 °C min<sup>-1</sup>), to 320 °C (3 °C min<sup>-1</sup>, held 15 min). MS  
141 conditions were as follows: 250 °C EI source at 70 eV electron energy, 50 uA emission current, and 15 V electron lens voltage,  
142 with a transfer line at 320 °C. For sterol/stanol analysis, all samples were injected in splitless mode at 90 °C, evaporated at  
143 100 °C (0.1 min), and the PTV was ramped to 400 °C at 8 °C s<sup>-1</sup> and held for 1 min). The GC oven temperature was programmed  
144 from 80 °C (held 1 min), to 200 °C (20 °C min<sup>-1</sup>), to 320 °C (5 °C min<sup>-1</sup>, held 20 min). MS conditions were the same as for *n*-  
145 alkanes. PAHs and sterols/stanols were analysed in selected reaction monitoring (SRM) using the collision energies and mass  
146 transitions reported in Table A1 and Table A2).

## 147 **2.4 Analysis of air parcel back-trajectory patterns**

148 To define the potential regional extent of airborne PAHs arriving to SVID's catchment area, we traced the back-trajectory of  
149 air parcels using HYSPLIT (hybrid single particle lagrangian integrated trajectory; Draxler et al., 1998; Stein et al., 2015).  
150 Using a modified version of an R script originally developed to trace precipitation patterns (Caves Rugenstein and  
151 Chamberlain, 2018), we analyse data from the NOAA Global Data Assimilation System (GDAS; resolution 1° by 1°) at a six  
152 hours frequency tracing back trajectories for three days (72 h) and two weeks (336 h) during two years characterised by  
153 opposite North Atlantic Oscillation (NAO; Hurrell et al., 2003) configuration (2009-2010, NAO-; 2013-2014, NAO+; NOAA,  
154 2023). PAHs deposition, which is enhanced by low temperatures, occurs not only via precipitation but in dry conditions as  
155 well (Arellano et al., 2018; Feng et al., 2017; Golomb et al., 2001; Halsall et al., 2001). Thus, we present data for air parcel  
156 trajectories that did and did not produce precipitation within six hours from the endpoint (SVID), initialising the trajectories  
157 at four different altitudes: 1000, 1500, 2000 m asl (water vapour usually advects within an altitude of 2 km; Bershaw et al.,  
158 2012; Lechler and Galewsky, 2013; Wallace and Hobbs, 2006), and 150 m asl (SVID surface elevation).

## 159 **3 Background on proxies**

### 160 **3.1 Polycyclic aromatic hydrocarbons (PAHs)**

161 We use pyrogenic PAHs (pyroPAHs) as tracers for the frequency/intensity of fire episodes, and the PAH perylene as a biogenic  
162 PAH related to terrestrial organic matter input. PAHs are semi-volatile compounds that can be of pyrogenic, petrogenic, or  
163 biogenic origin (Kozak et al., 2017; Lima et al., 2005). Low molecular weight (LMW; see Table A1 for group definition)  
164 PAHs in their non-alkylated form (Page et al., 1999; Yunker et al., 2002) constitute the majority of the PAHs produced by the  
165 combustion of plant biomass, while the relative amount of high molecular weight (HMW) PAHs increases along with higher  
166 fire temperatures (McGrath et al., 2003). LMW PAHs tend to be airborne and show high aqueous solubility and higher  
167 volatility, whereas HMW PAHs are usually in a solid phase (associated to either soot or char), show lower volatility, and are

likely sourced locally (Hoffmann and Wynder, 1977; Junk and Ford, 1980; Karp et al., 2020; Lammel et al., 2009; Lima et al., 2005; Purushothama et al., 1998). Thus, low contributions of HMW PAHs in environmental samples are often considered indicative of either low temperature fires (e.g., Denis et al., 2012) or a distal source, while high relative amounts generally point toward a more local signal. Finally, perylene is a 5-hexa-ring PAH often detected in aquatic sediments and considered to be mostly of in situ biogenic origin, probably from precursor compounds present in saprophagous and mycorrhizal fungi (e.g., Aizenshtat, 1973; Jiang et al., 2000; Slater et al., 2013; Wang and Huang, 2021), and thus likely linked to higher organic matter content and terrigenous input (Guo and Liao, 2020; Hanke et al., 2019).

### 3.2 Sterols/stanols as markers of plant sources and animal digestion

Stanols are saturated isomers of sterols (e.g., Patterson, 1971). When the bacterially mediated reduction of sterol double bonds occurs in an open environment (e.g., soil), it leads almost exclusively to the production of 5 $\alpha$  stanol isomers. When the reduction of sterols occurs in the animal's digestive tract, their enteric bacterial flora maximises the production of 5 $\beta$  stanols (Hatcher and McGillivray, 1979; Murtaugh and Bunch, 1967). Humans (and partially other omnivores and carnivores) maximise the production of coprostanol (5 $\beta$ -cholestan-3 $\beta$ -ol) through the saturation of animal derived cholesterol (5-encholest-3 $\beta$ -ol). Ruminants such as sheep and cattle, on the other hand, maximise the production of 5 $\beta$ -stigmastanol and 5 $\beta$ -campestanol (Leeming et al., 1996, 1994) from plant derived sterols like stigmasterol, sitosterol, and campesterol (e.g., Goad, 1977; Goad and Goodwin, 1966; Pancost et al., 2002). Higher/lower ratios of coprostanol and its derived epimer epicoprostanol (5 $\beta$ -cholestan-3 $\alpha$ -ol; McCalley et al., 1981; Quirk et al., 1980; Wardroper et al., 1978) to 5 $\beta$ -stigmastanol or 5 $\beta$ -campestanol are considered to be a proxy for higher/lower faecal input from human sources relative to ruminant sources, and have been widely applied to samples from modern/ancient sewage material and manured soil (e.g., Birk et al., 2012; Bull et al., 2001, 2002; Cordeiro et al., 2008; Evershed et al., 1997; He et al., 2018; Lerch et al., 2021; Simpson et al., 1999; Tyagi et al., 2009).

### 3.3 *n*-Alkanes

Plants synthesise *n*-alkanes and other *n*-alkyl lipids as part of their waxy coating with a characteristic strong odd-over-even chain length predominance (Eglinton and Hamilton, 1967), which is summarised by their higher carbon preference index (CPI; Bray and Evans, 1961; Marzi et al., 1993). In contrast, lower CPI values are usually indicative of petrogenic, algal, or bacterial sources (Grimalt and Albaigés, 1987; Han and Calvin, 1969). Aquatic sources such as macrophytes and mosses (e.g., *Sphagnum*) maximise their leaf wax *n*-alkane production at mid-length homologues (C<sub>21–25</sub>), while terrestrial plants (e.g., grasses, sedges, trees, shrubs) are generally skewed toward longer homologues (C<sub>27–31</sub>), allowing for use of source discriminating ratios and indices such as the aquatic plant index (P<sub>aq</sub>, Ficken et al., 2000) and average chain length (ACL, Gagosian and Peltzer, 1986).

### 3.4 Bulk geochemistry proxies

Aquatic and terrestrial catchment productivity, flux of inorganic sediments, and organic matter preservation are the main factors determining the level of total organic carbon content in lacustrine sediments (Meyers and Ishiwatari, 1993). The molar carbon to nitrogen ratio (C/N) in plant tissue varies between aquatic plants and phytoplankton (<10) and terrestrial plants and bryophytes (>10; Meyers, 1994). Thus, increases in C/N are usually interpreted as an increased catchment erosion and input of terrestrial organic matter and/or as a relative decrease of aquatic plant productivity (Fernández-Martínez et al., 2021; Kaushal and Binford, 1999; Meyers, 1997; Meyers and Teranes, 2001; Rieger et al., 1979). Shifts in the abundance of diatom derived biogenic silica (BSi) can trace lake productivity (Colman et al., 1995; Conley, 1988; Conley and Schelske, 2002). The conservation potential of diatom frustules is strongly related to sedimentation rate, with higher rates leading to better preservation. When sedimentation rates are considered relatively constant, shifts in BSi can reflect qualitative changes in

208 spring/summer temperature in high-latitude lakes, such as Iceland (Geirsdóttir et al., 2009a; McKay et al., 2008). The stable  
 209 isotopic composition of carbon ( $\delta^{13}\text{C}$ ) can trace shifts in the relative contribution of organic matter sources, with terrestrial  
 210 plants (but also bryophytes) and associated soils showing more  $^{13}\text{C}$ -depleted values (ca -32‰ to -25‰), aquatic plants  
 211 exhibiting more  $^{13}\text{C}$ -enriched values (ca -20‰ to -10‰), and freshwater algae and phytoplankton showing a wider isotopic  
 212 range (Meyers, 1994; Prokopenko et al., 1993; Rundel et al., 1979; Smith and Epstein, 1971; Geirsdóttir et al., 2020 and refs  
 213 therein). The physical mixing or stratification of a lake water column can also influence the carbon isotopic signature of aquatic  
 214 sources (Hernández et al., 2011).

## 215 4 Results

### 216 4.1 Age model

217 Based on major oxide composition and stratigraphical information, we identified 13 marker tephra layers of known age (Table  
 218 1). Our Bayesian tephra age model shows nearly constant sediment accumulation rates throughout the Holocene (Fig. 2).  
 219 There is increased uncertainty in age control between the G10ka tephra series and Kverkfjöll/Hekla 6200 due to fewer marker  
 220 tephra layers being present. However, the Late Holocene, particularly during the historical period of settlement, features  
 221 numerous tephra layers that result in substantially lower age estimate uncertainty.

222  
 223 **Table 1: Marker tephra layers of known age identified in 20-SVID-02 and used to develop the age model.**

Composite depth (cm)	Tephra layer ID	Layer age (a BP)	Reference
31.5	Bárðarbunga-Veiðivötn 1717	233 ± 2	Thorarinsson (1974)
42.0	Grímsvötn 1619?	352 ± 2	Thorarinsson (1974)
56.0 – 57.0	Veiðivötn 1477	473 ± 2	Larsen et al. (2002)
70.0	Hekla 1300	650 ± 10	Thorarinsson (1967)
82.5	Hekla 1104	846 ± 10	Thorarinsson (1967)
102.2	Kverkfjöll	1125 ± 50	Óladóttir et al. (2011)
242.5 – 248.5	Hekla 3	3010 ± 54	Dugmore et al. (1995)
344.0 – 345.0	Hekla 4	4200 ± 42	Dugmore et al. (1995)
414.0 – 414.5	Kverkfjöll	5200 ± 100	Óladóttir et al. (2011)
503.2	Kverkfjöll and Hekla	6200 ± 100	Óladóttir et al. (2011)
815.0	G10ka Series (top)	9900	Óladóttir et al. (2020)
853.5	G10ka Series (bottom)	10400	Óladóttir et al. (2020)
886.5	Askja S	10830 ± 57	Bronk Ramsey et al. (2015)

To facilitate the interpretation of downcore records, we present and discuss data (1) divided into nine time intervals (I–IX; Table 2) representing the most distinguishable periods of variability with respect to background values, and (2) separately for the sections preceding and following the G10ka tephra series (Óladóttir et al., 2020). We tried analysing some material from the G10ka series (a very thick tephra unit; Óladóttir et al., 2020) but the yields of organics were too low to be reliable (as expected; its contents are almost 100% inorganic). Thus, here we only included one sample at the bottom limit of the G10 ka tephra series and one at the upper limit.

**Table 2: Age intervals (approximate) and descriptions of the nine subdivisions of the 20-SVID-02 record used in this study.**

Interval	Age (ka BP)	Description
I	10.85–10.63	Potential Preboreal cooling
II	10.63–10.40	Pre-Boreal warming
III	10.4–9.9	G10 ka tephra series
IV	9.9–8.8	Early Holocene warming (rebound after G10 ka event)
V	8.8–7.5	Early Holocene instability (8.2 ka event?)
VI	7.5–3.0	Middle Holocene plateau and trend inversion
VII	3.0–1.3	Late Holocene cooling
VIII	1.3–0.25	Medieval period and Little Ice Age
IX	0.25–present	End of LIA and contemporary warming

238 **4.2 Bulk geochemistry**

239 The C/N ratio (Figs. 3-4B) ranged from ~1 to ~9.5, showing lowest values at the beginning of the record (I). At ca 10.63 ka BP, C/N increased sharply and reached mid-range values (5-6), remaining relatively stable throughout most of the remaining  
 240 Holocene (IV–VI), except for two drops, after the G10ka Series tephra and between 8.8 and 7.75 ka BP (V). In the last 2 kyr, C/N values steadily increased, leading to the highest values in the most recent portion of the record. The two periods with  
 241 decreased C/N values, as well as the initial increase (I to II), generally paralleled the behaviour of the total carbon (Figs. 3-4E), biogenic silica (Figs. 3-4H), and  $\delta^{13}\text{C}$  (Figs. 3-4D) records. TC increased steadily throughout the Holocene from ~0%  
 242 while BSi rapidly increased at the beginning of the record (30 to 90) to then stabilise at 110–120 for more than 5 kyr (V–VI). Both records peaked at ca 3.5 ka BP (2.8%, TC; ~160, BSi max) and temporarily dropped between ca 3 and 2.25 ka BP.  
 243 Subsequently, TC increased to its maximum value (3.6%, modern) while BSi decreased in a stepwise manner, reaching its  
 244 lowest value of the last 10 kyr (~50) at ca 0.2 ka BP. The  $\delta^{13}\text{C}$  record showed the most  $^{13}\text{C}$ -enriched values (-20‰) in the  
 245 oldest interval (I); it then decreased (to -26‰, modern) steadily throughout the Holocene, except for two major drops to its  
 246 most depleted values (ca -27‰) during periods II and V.

### 264 4.3 $n$ -Alkanes

265 We detected  $n$ -alkane homologues from  $C_{19}$  to  $C_{33-35}$  (Fig. A3) in most samples, with a total sum that ranged from 0.3 to 50  
 266  $\mu\text{g g}^{-1}$  (700–4000  $\mu\text{g g}^{-1}$  TC; Figs. 3-4A). The 10.8 to 4.2 ka BP interval showed relatively low and stable values ( $\sim 5 \mu\text{g g}^{-1}$ );  
 267 concentrations roughly doubled from 4 to 1.5 ka and then again after 0.5 ka BP, reaching its maximum value at the end of the  
 268 record. The CPI showed a stable odd-over-even predominance (3 to 6.5) through the whole record, except for low values (1 to  
 269 3) seen in the interval preceding the G10ka Series tephra (Figs. 3F-4I). The most abundant homologues were  $C_{23-27}$  (45%) in

270 the 10.8 to 3 ka BP interval and  $C_{29-31}$  (40%) in the last 3 kyr. This regime change was highlighted by a shift in  $P_{aq}$  from  
 271 relatively high values (up to 0.8; avg. 0.6) through the early-mid Holocene to lower values (down to 0.2; avg. 0.3) after 3 ka  
 272 BP (Fig. 4G).

#### 273 4.4 Faecal sterol/stanols

274 We detected the three main faecal stanols: the plant derived  $5\beta$ -stigmastanol was ~5–10 times more abundant (up to 3-500 ng  
 275  $g^{-1}$ ; Figs. 5-6A) than coprostanol + epi-coprostanol (10-30 ng  $g^{-1}$ ; Figs. 5-6B). The oldest interval (I) showed the lowest  
 276 concentrations for all three stanols, while the following interval (II) displayed high (highest for coprostanol and epi-  
 277 coprostanol) concentrations. All three stanols showed low and stable concentrations between ~9.5 and 7.5 ka BP, gradually  
 278 increased from ~7.5 ka BP before reaching a relative maximum around 1.5 ka BP (VII), dropping again during interval VIII,  
 279 and peaking during the last 200 to 300 years (IX). Parent sterols ( $\beta$ -sitosterol,  $\beta$ -stigmasterol, except cholesterol) and the  $\alpha$ -  
 280 stanol isomers, follow patterns similar to the  $\beta$ -stanols throughout the Holocene, but with 10 to 100 times higher concentrations  
 281 (Fig. A2).

282

283 **Figure 5: Sterols/stanols from the pre-G10ka Series tephra interval (pink vertical band) of 20-SVID-02 core. (A, red)  $5\beta$ -stigmastanol**

 288 concentration on g of dry sample (full line) and on g of TC (dotted line); (C, black) β-sitosterol to 5α-stigmastanol ratio; (D, yellow)  
 289 β-sitosterol concentration; (E, light blue) 5α-stigmastanol concentration. Red dotted line marks the conventional age (870 CE) of the  
 290 settlement of Iceland (Landnám). Black vertical dashed lines mark an arbitrary subdivision of 20-SVID-02 record into nine intervals  
 291 (Table 1).

#### 292 4.5 Polycyclic aromatic hydrocarbons (PAHs)

293 PAHs were present in all samples and generally in higher concentrations in more recent compared to older samples (Fig. A1).  
 294 Perylene (Figs. 3-4C), which accounts for more than 97% of detected PAHs, maintains low concentrations (0–20 ng g<sup>-1</sup>) from  
 295 10.5 to 4–3 ka BP. A first increase to 0.5–1.5 μg g<sup>-1</sup> occurred between 3.5 and 2.8 ka BP, followed by a decrease loosely coeval  
 296 to the decrease in TC and BSi (VII). After ca 1.5 ka BP, perylene increases to a maximum value (~6 μg g<sup>-1</sup>, ca 0.15 ka BP),  
 297 which generally matches the pattern of TC. The second most abundant compound was phenanthrene (0.01–31.1 ng g<sup>-1</sup>),  
 298 followed by pyrene (0.1–11.5 ng g<sup>-1</sup>) and fluoranthene (0.01–17.6 ng g<sup>-1</sup>). The least abundant PAHs were naphthalene,  
 299 acenaphthylene and acenaphthene. However, since the detection of these three low molecular weight compounds could have  
 300 been influenced by evaporation losses during sample preparation, their reported concentrations are likely to be underestimated.  
 301 Given the overwhelming dominance of perylene and its likely biogenic rather than pyrogenic origin, we removed it from total  
 302 PAHs abundance calculations to provide a record with features that were not apparent in perylene's trend. In terms of total  
 303 pyroPAHs abundance, we observe five distinguishable intervals (Fig. 7A). First, a 3 kyr-long interval (~80 years average  
 304 temporal resolution) starting at ca 10.5 ka BP displays a relatively stable low concentrations (< 5 ng g<sup>-1</sup>, SD σ = 2.3). The only  
 305 exception is a point taken within the G10ka Series tephra (up to 10 ng g<sup>-1</sup>) at ca 10 ka BP. Second, from ~7.5 to 2.9 ka BP  
 306 (~320 years average temporal resolution), the total PAHs concentration increases from ~5 to 10 ng g<sup>-1</sup>, although with enhanced  
 307 variability (σ = 3.7). Third, led by the increase of low molecular weight PAHs (LMW, Fig. 7B), during the 2.9 to 0.7 ka BP  
 308 interval, values fluctuate (σ = 7.5) between ~10 and 20 ng g<sup>-1</sup>, with two major peaks reaching 45 and 35 ng g<sup>-1</sup> at ~2.7 to 2.3  
 309 ka BP and 1.5 to 1.3 ka BP, respectively. Fourth, between 0.7 and 0.3 ka BP there is a relatively brief although clear drop (~10  
 310 ng g<sup>-1</sup>, σ = 1.5), led by both LMW and MMW PAHs. In the last 250 years we observe a sharp, 10-fold increase in PAHs  
 311 concentration leading to the highest recorded values (~200 ng g<sup>-1</sup>). When normalised for TC (Fig. A1), the absolute values  
 312 increase 10 to 100-fold, but the patterns do not substantially change.

313

314 **Figure 7:** PAHs record of the 20-SVID-02 core. (A, black) sum of pyrogenic PAHs concentrations; (B, fuchsia low, (orange) medium, and (blue) high molecular weight pyrogenic PAHs concentration. Red dotted line marks the conventional age (870 CE) of the settlement of Iceland (Landnám). Vertical pink band marks the G10ka Series Tephra. Black vertical dashed lines mark an arbitrary subdivision of 20-SVID-02 record into nine intervals (Table 1).

#### 318 4.6 HYSPLIT

319 We calculated a total of 11,392 air trajectories, which we split by year, season, dry (i.e., not associated with precipitation), or precipitation bearing trajectories (Fig. A4). Most trajectories, even for two weeks intervals, show air parcels originating mostly from Iceland and surrounding areas of the North Atlantic, regardless of season or NAO configuration, while the contribution from nearby terrestrial regions (potential PAHs sources) such as Greenland, British Isles, or Scandinavia is negligible. As the marine environment is not conducive to combustion nor redeposition of particulates, this implies a dominantly Icelandic signal for PAH production.

325 Since wildfires are concentrated in the relatively dryer, snow-free summer season (McCarty et al., 2021), we focus particularly on the JJA air trajectory data (Fig. 8). These results show that: (1) 95% of back-trajectories originate from Iceland and its nearby waters; (2) 90% of back-trajectories originate within 100–150 km radius from SVID; (3) dry trajectories more likely originate inland relative to precipitation carrying trajectories; (4) 95% of trajectories from a NAO- year tend to be confined to northern Iceland while during a NAO+ year trajectories more commonly originate from inland; (5) these patterns are consistent even when scaled from three days to two weeks intervals (Fig. A4).

331

332 **Figure 8:** HYSPLIT back trajectories of air parcels for 2010 (NAO-) and 2013 (NAO+), annual and summer (JJA). Trajectories are  
 333 calculated on a two-weeks (336 h) interval at a 6-hour frequency; "precip" indicates trajectories that produced precipitation within  
 334 6 h from the SVID endpoint, while "dry" trajectories did not. Contour colours indicate the frequency at which air parcels part of a  
 335 trajectory travel above a certain area.

## 337 5.1 Primary aquatic production vs erosion/terrestrial input

338 In Icelandic lacustrine environments,  $\delta^{13}\text{C}$  and C/N are generally considered proxies for the relative contribution of terrestrial  
 339 vs aquatic organic matter and shifts in primary productivity, as total carbon is virtually solely of organic origin (e.g., Geirsdóttir  
 340 et al., 2009a). Iceland's bedrock is dominantly comprised of basaltic bedrock, including the catchment of SVID (Hjartarson  
 341 and Sæmundsson, 2014), meaning there is negligible carbonate available. Although some dissolved inorganic carbon (DIC)  
 342 has been measured in Icelandic rivers, it is greatly outweighed by organic carbon (Kardjilov et al., 2006), whereas the amount  
 343 of inorganic carbon measured in soils is negligible (Mankasingh and Gísladóttir, 2019). This is important to consider as SVID  
 344 has no river inflow and water inflow is dominated by runoff from the catchment through soil. In addition, while there is some  
 345 evidence for the transport of Saharan dust to Iceland within the last decade (Varga et al., 2021), there is currently no evidence  
 346 of such transport during the Holocene. Additional pools of inorganic carbon from aquatic invertebrates, such as ostracods, are  
 347 also considered to be negligible (Alkalaj et al., 2019). Ostracods crystallise their shells in very close equilibrium to the carbon  
 348 isotopes of DIC (Decrouy, 2012), which for Iceland is notably enriched relative to bulk organic matter carbon isotopes  
 349 (Sveinbjörnsdóttir et al., 2020). If ostracods were a substantial contributor to the total carbon pool, we would expect lake  
 350 sediment carbon isotopes to deviate significantly from modern terrestrial and aquatic plant carbon isotope values. As Icelandic  
 351 lake sediment bulk geochemistry is consistent with the fields of modern plants (see Geirsdóttir et al., 2020), inorganic carbon  
 352 from aquatic invertebrates are not considered a significant contributor to the total carbon pool.  
 353 In addition, in SVID, the similarity of the C/N record to the perylene curve reinforces its significance as a proxy for terrigenous  
 354 input.

## 355 5.1.1 11-7.5 ka BP: Postglacial warming

356 Deglaciation in the NE of Iceland set in between 15 and 13 ka BP and proceeded in a stepwise fashion, with two main glacier  
 357 re-advances at ca 12.7 (Younger Dryas) and 10.9 ka BP (Preboreal; Geirsdóttir et al., 2009b; Norðdahl and Pétursson, 2005).  
 358 Our record captures sediment below the Askja S tephra layer ( $10.83 \pm 0.57$  ka BP, Bronk Ramsey et al., 2015), showing ice-  
 359 free conditions and the start of organic sedimentation by 10.85 ka BP at SVID's location. Except for the oldest sample, high  
 360  $\delta^{13}\text{C}$  and low TC values indicate a primarily aquatic source of carbon during the oldest interval (I) (Fig. 3). This suggests an  
 361 absence of substantial terrestrial vegetation, consistent with a postglacial landscape and possibly a cooler climate associated  
 362 with the Preboreal period.

363 TC, BSi, and C/N increase suddenly at ca 10.65 ka BP, maintaining higher values for two-three centuries (vice versa for  $\delta^{13}\text{C}$ ),  
 364 indicating an enhanced terrestrial input likely resulting from a retreating glacier, development of soil and vascular plants, and  
 365 generally warming conditions (Fig. 3). After the G10ka Series tephra, all proxy values decrease, likely due to the destructive  
 366 impact of substantial volcanic ash fallout on both terrestrial and aquatic vegetation and related water chemistry alteration (e.g.,  
 367  $\delta^{13}\text{C}$  dropping due to acidification; Kilian et al., 2006) (Fig. 4). Following the volcanic event, all proxies increase at ca 9.75 ka  
 368 BP, whereas terrestrial- relative to aquatic-sourced carbon temporarily increase (ca 8.7–7.5 ka BP). The observed decrease in  
 369  $\delta^{13}\text{C}$  (and, partially, C/N) between 8.7 and 7.5 ka BP is identified in other Icelandic lake sediment records between 8.8 and 7.9  
 370 ka BP (e.g., Eddudóttir et al., 2018; Geirsdóttir et al., 2013; Harning et al., 2018b; Larsen et al., 2012) and has been attributed  
 371 to the likely impact of meltwater pulses into the northern North Atlantic due to the retreating Laurentide ice sheet and/or local  
 372 effusive volcanic eruptions (Geirsdóttir et al., 2013; Larsen et al., 2012).

373 The total sum of *n*-alkanes ( $\text{C}_{19-35}$ ; Fig. 4A), which is heavily controlled by  $\text{C}_{29}$  and  $\text{C}_{31}$  (Fig. A3), increases throughout the  
 374 Holocene similar to the pattern described by C/N and perylene as a result of an increased terrigenous input. As inferred by  
 375 high CPI values, most *n*-alkanes in SVID originate from plants (terrestrial and possibly also aquatic) through the Holocene  
 376 record (Fig. 4I). The relatively low CPI values in the oldest interval (I) indicate a negligible contribution from plant sources

377 (relative to phytoplankton) to the carbon pool, which is consistent with a still cold, relatively barren, deglacial environment.  
378 The CPI curve shows a similar but opposite pattern to the  $\delta^{13}\text{C}$  record until ca 8 ka BP, reinforcing  $\delta^{13}\text{C}$  as a proxy mostly  
379 controlled by terrigenous input (*n*-alkanes from aquatics show lower CPI values than terrestrial plants; e.g., Bray and Evans,  
380 1961; Duan et al., 2014; Eglinton and Hamilton, 1967; Li et al., 2020). The reason for the change in the relationship between  
381 CPI and  $\delta^{13}\text{C}$  (which become positively correlated after 8 ka BP) is unclear. While it matches the timing of increasing  
382 temperatures (Axford et al., 2007; Fig. 10D) and *Betula* expansion in the region (Karlsdóttir et al., 2014; Fig. 10E), its  
383 interpretation is complicated by the fact that CPI can also be influenced by factors such as changes in mean annual precipitation,  
384 seasonality, plant community, and algal productivity (Li et al., 2020).

### 385 **5.1.2 7.5-4.2 ka BP: Mid-Holocene Plateau and trend inversion**

386 Overall, all proxies suggest that the interval between ~7.5 and 4.2 ka BP, was characterised by relatively stable climatic  
387 conditions, generally warmer (Axford et al., 2007) and wetter (Moossen et al., 2015) than both the preceding and following  
388 periods. These conditions likely led to an enhanced primary productivity within the lake, as suggested by high values of BSi,  
389  $P_{\text{aq}}$ , CPI, and pollen inferred vegetation communities (Eddudóttir et al., 2016; Karlsdóttir et al., 2014). In fact, modelled  
390 reconstructions of Icelandic vegetation cover throughout the Holocene show the highest values during this interval (Ólafsdóttir  
391 et al., 2001). In particular, partly due to the retreat/disappearance of most glaciers, between 50% and 60% of Iceland was likely  
392 covered in vegetation, of which a quarter was birch forest, throughout the mid-Holocene, with two peaks, one at the Holocene  
393 Thermal Maximum (8–7 ka BP) and one at ~3.5 ka BP (Ólafsdóttir et al., 2001). The warm and moist climate, paired with the  
394 expansion of vegetation, may have stabilised the local environment, reducing erosion. Such stability is consistent with the low  
395 C/N, Perylene, and *n*-alkanes values throughout this interval.

396 Though this four thousand year period is broadly categorised by stability, a more detailed view reveals important inflection  
397 points in the long term trends of many proxies. For example, while some proxies keep increasing (e.g., TC, and summer  
398 temperature, Axford et al., 2007), some stop rising and remain relatively flat throughout this interval (e.g., C/N, Perylene),  
399 while others even invert their trends ( $\delta^{13}\text{C}$ ,  $P_{\text{aq}}$ , CPI). Another trend inversion occurred around 5 ka BP with the inception of  
400 neo-glaciation in Iceland when glaciers started to expand again (Geirsdóttir et al., 2019). This could be interpreted as a slow  
401 inertial response of the local environment to the decreasing NH summer insolation, likely reducing its resilience to short term  
402 events such as volcanic eruptions and NAO shifts, until some kind of threshold was finally reached around 4 ka BP (Geirsdóttir  
403 et al., 2013, 2019).

### 404 **5.1.3 4.2 ka BP: Increased erosion in a cooling climate**

405 Our SVID proxy datasets generally agree with previous work using bulk geochemistry proxies in Icelandic lakes, which  
406 collectively point toward decreasing primary productivity and increasing landscape instability in response to declining  
407 Northern Hemisphere summer insolation (e.g., Geirsdóttir et al., 2013, 2019; Harning et al., 2018b, 2020; Larsen et al., 2012).  
408 The decreasing trend in  $\delta^{13}\text{C}$  is generally anticorrelated with the TC curve, indicating that TC is increasingly controlled by  
409 terrestrial input. BSi, TC, and C/N values drop or invert their trend after ca 4 ka BP, consistent with a general decrease in  
410 productivity. This is possibly related to a combination of decreasing moisture and/or summer temperatures (Axford et al.,  
411 2007), and the effect of the Hekla 4 volcanic event, pushing the local environment beyond a threshold (Eddudóttir et al., 2017).  
412 Absolute amounts of *n*-alkanes also increase starting at 4 ka (Fig. 4A), led by an increase in *n*-C<sub>29</sub> (Fig. A3), typical of terrestrial  
413 plants. The ratio between the mid- and long-chain homologues (aquatic plant index or  $P_{\text{aq}}$ ; Ficken et al., 2000) is often  
414 interpreted as a proxy for a wetter/drier environment. However, this is likely an oversimplification as questions remain about  
415 the relationship between *n*-alkane chain length and vegetation source, particularly for aquatic plants which are often a minor  
416 component of the leaf wax pool in Arctic lakes (Dion-Kirschner et al., 2020; Hollister et al., 2022). Nevertheless, when coupled  
417 to the concentration data of *n*-alkanes (Fig. 4A; Fig. A3),  $P_{\text{aq}}$  can here be more safely interpreted as indicative of lower/higher

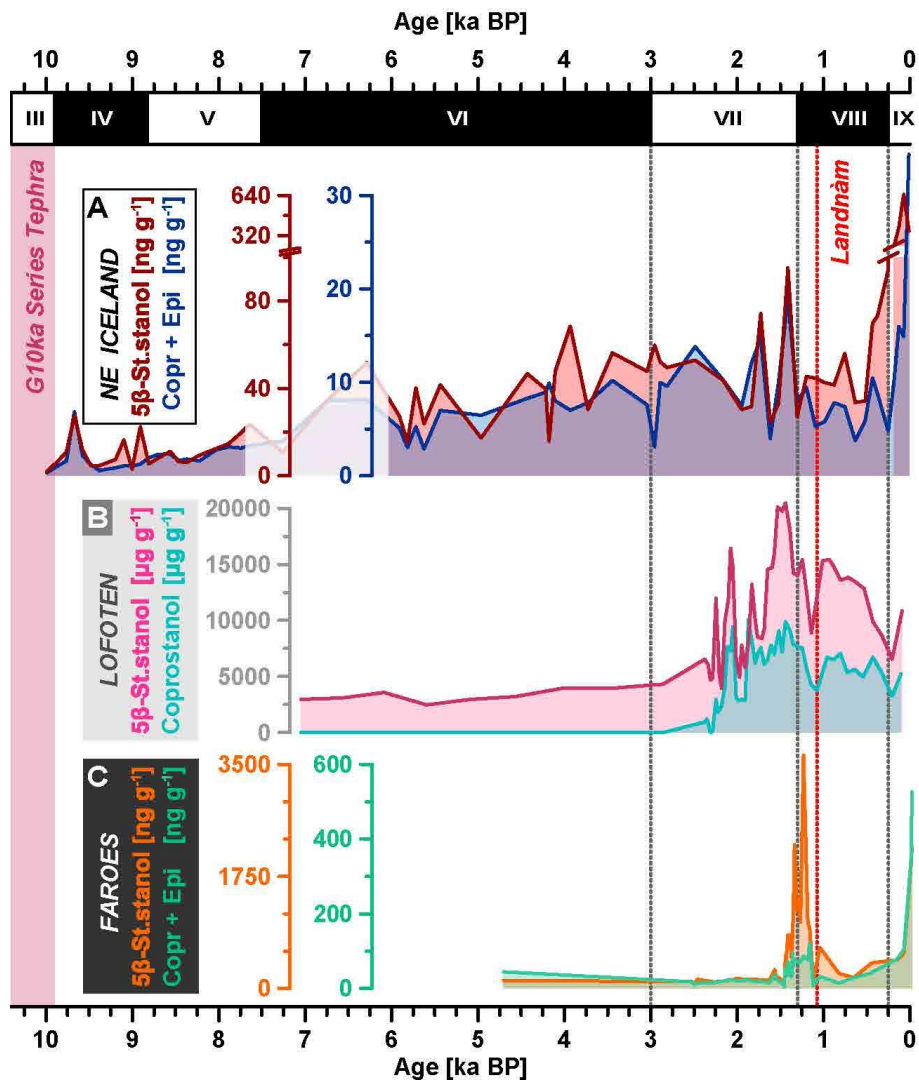

418 terrigenous input. The SVID record (Fig. 4H; Sect. 3.3) shows higher  $P_{aq}$  values (mean 0.6) during the 10.8 to 4-3 ka BP  
419 interval, indicating an environment with significant aquatic plant production and likely limited erosion/in-wash. The record  
420 then switches abruptly to lower values (mean 0.3) at 3 ka BP, highlighting a shift toward greater in-wash of terrestrially derived  
421 material.

422 The massive Hekla 3 eruption (the most severe Hekla eruption of the Holocene; ~3,010 a BP; Larsen, 1977; Larsen and  
423 Eiríksson, 2008), was likely the cause, or at least the trigger, of this abrupt shift at 3 ka BP in most SVID proxy records,  
424 particularly the ones related to primary production and erosion (Larsen et al., 2011). In fact, the volcanic fallout likely killed  
425 terrestrial plants by burning, root suffocation, and reduced photosynthesis (e.g., Ifkirne et al., 2022; Mack, 1981; De Schutter  
426 et al., 2015), and had likely similar effects on aquatic flora as well, also through increased turbidity and acidity of lake waters  
427 (e.g., Ayris and Delmelle, 2012). The subsequent reduced coverage of terrestrial plants likely exposed the soil to increased  
428 erosion, resulting in more terrestrial in-wash (as reflected by a sudden perylene peak), skewed toward the inorganic components  
429 of soil (as reflected by a sudden drop in TC and *n*-alkanes lasting roughly a century). The increased terrestrial in-wash would  
430 have further reduced primary productivity within the lake, as suggested by the drop in BSi. At the same time, the short C/N  
431 peak and the major drop in  $P_{aq}$  seem to indicate that the productivity and contribution of terrestrial plants remained higher than  
432 aquatic sources (Larsen et al., 2011). The post-3 ka trend is temporarily interrupted by what appears to be a partial rebound in  
433 primary productivity (BSi increases too) and diminished in-wash of terrestrial material until ca 1.5 ka BP, whereafter it  
434 continues to decline.

## 435 **5.2 Is there geochemical evidence for human settlement in the SVID catchment area?**

436 In paleoclimate studies, relative shifts to above natural background levels of  $\beta$ -stanols have been used as a proxy for human  
437 settlement, marking the appearance of humans and domesticated animals in specific areas of the world (Shillito et al., 2020;  
438 Sistiaga et al., 2014), often in lake catchments (Battistel et al., 2016; Callegaro et al., 2018; Raposeiro et al., 2021; Sear et al.,  
439 2020; Vachula et al., 2019, 2020). This method has detected the arrival of Viking settlers in other Nordic regions, such as in  
440 the Lofoten islands in northern Norway (D'Anjou et al., 2012, Fig. 9B) and in the Faeroe Islands (Curtin et al., 2021, Fig. 9C).  
441 However, SVID sterol/stanol records show no evident human signals at or around the time of colonisation (i.e., 9<sup>th</sup> century CE,  
442 ca 1.1 ka BP). While a relative maximum of sterol/stanol concentrations found at ca 1.4 ka BP resembles the timing of an  
443 earlier-than-colonisation stanol signal found in the Faeroes (Curtin et al., 2021), as well as an analogous signal in the Lofoten  
444 Islands (D'Anjou et al., 2012), we cannot confidently interpret this peak as indication of human presence as its amplitude is  
445 comparable in magnitude to the inherent variability in the record (i.e., low signal to noise ratio).

446

447 **Figure 9: Holocene sub-Arctic records of faecal stanols in North Atlantic Islands.** (A) 5β-stigmastanol (dark red) and sum of  
 448 coprostanol and epi-coprostanol (dark blue) from core 20-SVID-02, NE Iceland (this study); (B) 5β-stigmastanol (pink) and  
 449 coprostanol (light blue) from cores LILA09-LILC09 from Lilandsvatnet lake, Lofoten Islands (D’Anjou et al., 2012); (C) 5β-  
 450 stigmastanol (orange) and coprostanol + epi-coprostanol (green) from core EI-D-01-15 from Eiðisvatn lake, Faroe Islands (Curtin  
 451 et al., 2021).

452 The lack of a clear anthropogenic faecal biomarker signal could be explained by either (1) a scarce/null incidence of human  
 453 activities in the catchment (unlikely, given the archaeological evidence in nearby areas; Gísladóttir et al., 2012; Lebrun et al.,  
 454 2023) and/or by (2) dilution of the signal due to the relatively large size of the lake paired to a small catchment. The sterol/stanol  
 455 records show a general increase throughout the Holocene (Fig. A2) in a pattern that matches the C/N, *n*-alkanes and perylene  
 456 trends, suggesting that the primary driver of SVID’s sterol signal is likely landscape instability and soil erosion rather than  
 457 human/ruminant presence. Furthermore, ratios of sterols to their derived 5β-5α stanols can trace redox conditions in various  
 458 environments (e.g. Andersson and Meyers, 2012; Canuel and Martens, 1993; Jaffé et al., 1996; Routh et al., 2014) and thus,  
 459 potentially, human presence in a lake catchment, as anthropogenic activities tend to mobilise more soil and increase in-wash  
 460 of organic material, fostering reducing conditions (Argiriadis et al., 2018). In SVID, the stanol values (5β-5α) are consistently  
 461 lower than their respective sterol precursors, suggesting a generally oxidising environment throughout the Holocene (Fig. 6).  
 462 The only exception to this trend is in the earliest part of the record (ca 10.8–10.6 ka BP; Fig. 5), indicative of a more reducing  
 463 environment, though not linked to an increased organic input (low TC values), but more likely to lake stratification with  
 464 deglacial water sinking at the bottom of the lake (Sugiyama et al., 2021).

### 465 5.3 Holocene fire frequency

466 Pyrogenic PAHs are considered a reliable proxy for fire frequency on a local scale, within and around a catchment (Denis et  
467 al., 2012). Although other factors can influence the PAH signal in sedimentary archives (e.g., accumulation rates, degradation;  
468 Stogiannidis et al., 2015), we interpret SVID pyroPAHs data as a record of NE Iceland fire history through the Holocene.

469 The trend in pyroPAHs does not match the erosional signal described by bulk geochemical proxies and *n*-alkanes, suggesting  
470 that soil erosion is not a mechanism for Holocene pyroPAHs variability. We exclude chemical degradation as a source of the  
471 signal, as PAHs are relatively stable molecules on long time scales (e.g., Johnsen et al., 2005). In fact, the ratio between low  
472 molecular weight (more prone to chemical degradation and leeching) and high molecular weight PAHs (as defined in Fig. A5)  
473 remains above 1 in most samples. Similarly, the pyrene/coronene ratio shows high and stable values throughout the record,  
474 indicating good preservation, with no significant degradation or preferential removal of less recalcitrant PAHs such as pyrene  
475 (Fig. A5 and refs therein).

476 The pyroPAH record presents two peaks at ca 2.8 and 1.5 ka BP, both predating acknowledged human settlement. PyroPAH  
477 values subsequently drop (VIII) and increase again in the last two centuries reaching maximum values in the present (Fig. 7A).  
478 Analysing PAH data subdivided in molecular weight classes (see 3.1; Table A1; Fig. 7B) can help explain these two features  
479 as well as the general trend. HMW pyroPAHs show low and stable relative contributions ( $12\pm 7\%$  of total pyroPAHs) through  
480 the whole record and rise to 70% in the last 200 years. This trend, paired with increased pyroPAH concentrations, is consistent  
481 with the burning of coal/oil, the use of internal combustion engines, and increased human presence (Abas and Mohamad, 2011;  
482 Kozak et al., 2017). MMW pyroPAHs show relatively stable concentrations through most of the record (until ca 0.2 ka BP).  
483 Their relative abundance ( $\sim 68\pm 35\%$ ) slowly decreases through the Holocene, proportionally to the increase of LMW  
484 pyroPAHs ( $\sim 20\pm 16\%$ ). The latter, which are predominantly present in the gaseous phase (Karp et al., 2020), peak at 3–2.8 and  
485 1.5 ka BP, and substantially control the shape of the pyroPAH record (Fig. 7A-B). Together, the (1) low and stable values of  
486 HMW pyroPAHs, the (2) stable MMW values, and the (3) increasing/peaking values of LMW pyroPAHs are consistent with  
487 a general increase in the frequency of low temperature fires (e.g., peat fires or crawling fires) at a regional level. While the  
488 Hekla 3 event (3.01 ka BP, the largest rhyolitic eruption during the Holocene; Larsen, 1977; Larsen and Eiríksson, 2008)  
489 occurs just before the first pyroPAH peak, it is unlikely to be its unique or even main cause. However, in an environment such  
490 as Iceland, is legitimate to ask if the several and frequent eruptions might have influenced the PAHs' natural background and  
491 if this is detectable in our records. As discussed below, we are confident that volcanic eruptions have had no significant direct  
492 impact on the amount and distribution of PAHs in the SVID archive.

493 Volcanic activity does produce PAHs (both in the gaseous and in the particulate phases) but generally their long term  
494 contribution is considered negligible, particularly in the modern world where the main PAHs source is the burning of fossil  
495 fuels (Guiñez et al., 2020; Kozak et al., 2017).

496 Overall, due to the high temperatures involved, volcanic eruptions tend to produce medium-high molecular weight PAHs in  
497 gases and particulates (Guiñez et al., 2020; Ilyinskaya et al., 2017). Volcanic layers can contain pyrogenic (unsubstituted but  
498 also alkylated) PAHs with a molecular weight distribution resembling modern fossil fuel combustion, dominated by  
499 unsubstituted forms (Murchison and Raymond, 1989) as well as traces of nitro- and oxy-PAHs (Guiñez et al., 2020). We do  
500 not see this distribution in any of our samples, not even when they include parts of tephra layers. This suggests that (1) either  
501 our sampling method does not capture volcanic layers (maybe due to its resolution) or that (2) there is no such signal in the  
502 SVID archive.

503 Regarding the first hypothesis (sampling method not capturing volcanic PAHs), Kozak et al. (2017) analysed the impact of  
504 2010 and 2011 Icelandic eruptions in Svalbard (Arctic Norway), finding high abundances of 4-5 ring PAHs in volcanic mud,  
505 great variations in the contribution of different eruptions to the total PAHs detected in sampled surface water, significant  
506 increases in the total abundance of PAHs during eruption years, but also that this increase in PAHs abundance as well as shifts  
507 in PAHs distribution do not seem to last beyond the eruption years. Considering the temporal resolution of our record (max

10-50 years), it is unlikely that any eruption would have impacted it significantly: from a geological point of view, eruptions tend to be short-living, and unless they relate to a massive event sustained over a long period of time, they are unlikely to have a strong impact on a sample that represents 10-50 years of sedimentation. No discernible correlation arose between the PAHs curve and the detected tephra, the only exceptions being the Hekla 3 and, to a lesser extent, the Hekla 4 tephra layers. However, these major volcanic events, besides marking the beginning of major shifts in most proxies, correlate to the initial phase of major shifts in low (and not high nor medium) molecular weight PAHs. This suggests that, if a connection between these two eruptions and PAH shifts exists, it must be indirect and, more likely, the two events acted as a general destabilising factor in an environment already subjected to increasing cooling and erosion.

The only possible example of an increased PAH concentration due to volcanic sources could come from the sample obtained from the lower limit of the G10ka series tephra (Fig. 7), which has a different composition (mostly inorganic) compared to the rest of the organic-rich samples in our record. In fact, HMW PAHs seem to spike here, even if they still exhibit an overall lower concentration than LMW PAHs; this could be due to its massive nature (Óladóttir et al., 2020).

Regarding the second hypothesis (missing signal of volcanic PAHs), it is possible that no detectable volcanic PAHs were present in the SVID archive due to (1) its geographical location, relatively far from volcanic sources and formations (Hjartarson and Sæmundsson, 2014), and (2) the same nature of Icelandic volcanic eruptions, which are characterised by relatively low-viscosity basaltic lava rather than highly explosive pyroclastic flows (Thordarson and Höskuldsson, 2008), thus reducing the chance of ash production and deposition, particularly in distal locations such as SVID.

The effects of tephra fallout on vegetation and related PAH deposition, seem to be quite short lived, with fires events likely coeval to the eruption and vegetation recovering within a few decades (Eddudóttir et al., 2017; Pickarski et al., 2023), while SVID pyroPAH peaks are clearly led by increases in LMW PAHs on a longer timescale.

Notably, this shift in fire regime at ca 3 ka BP in Iceland falls within a wider pattern of increasing fire frequency emerging from the analysis of several Holocene fire records throughout Europe (Marlon et al., 2013). This is linked to either an increase of cultivated land (fire was used to clear land for agriculture) and/or, particularly in Europe, to increasing aridity (Marlon et al., 2013). We hypothesize that the latter is the most probable explanation for the shifts in NE Icelandic fire regimes as discussed in Section 5.4.

#### 5.4 Regional drivers of precipitation and their role on fire frequency

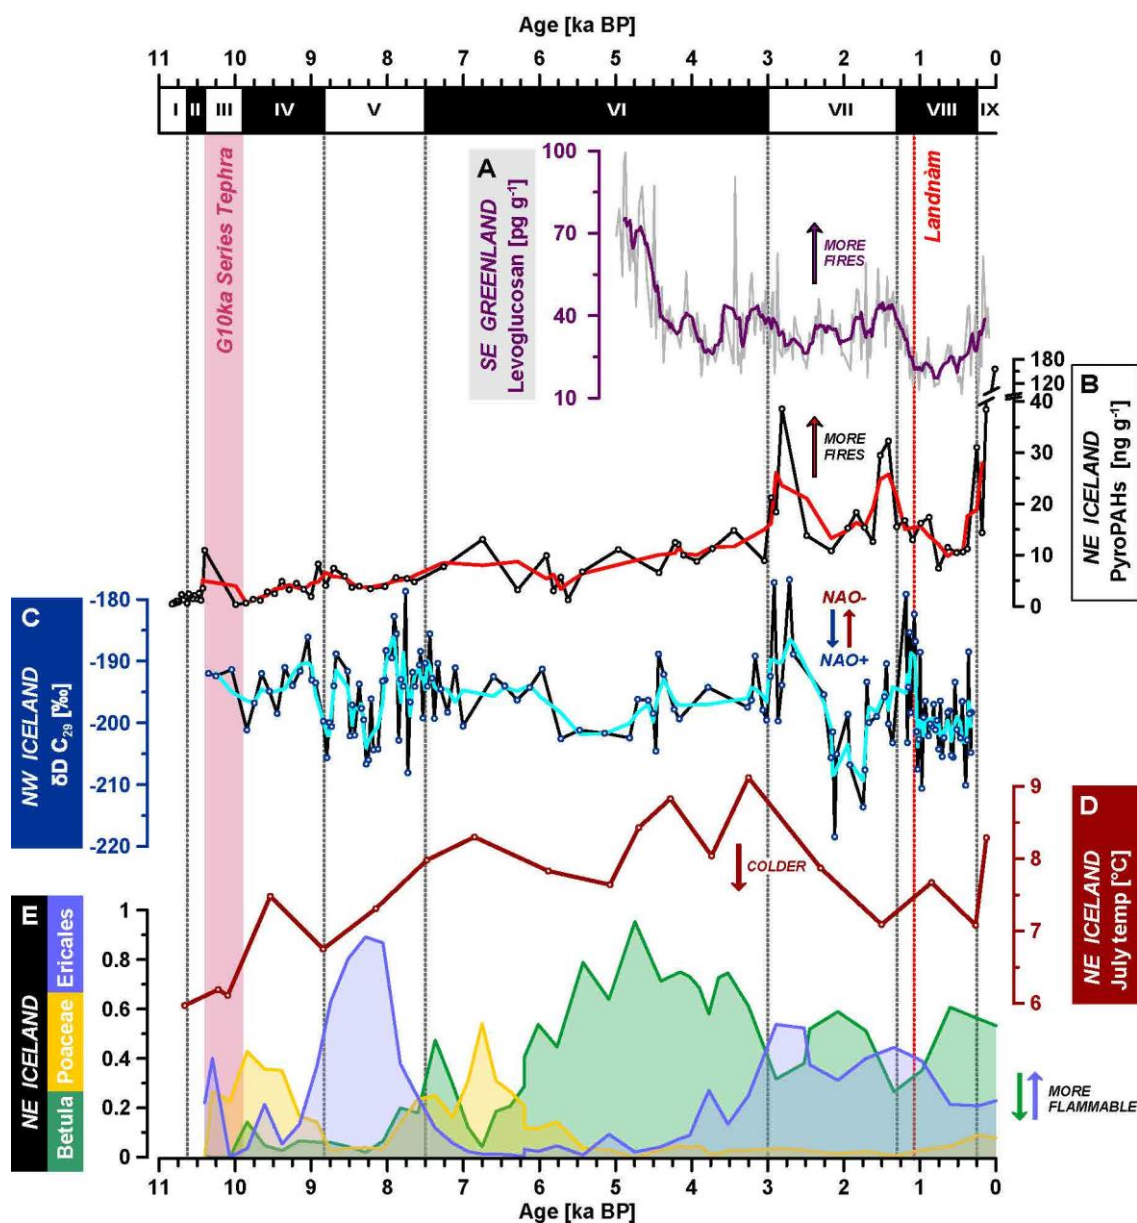

Fuel moisture content and, more generally, environmental moisture, are the main variables controlling flammability in vegetational communities typical of temperate/sub-arctic regions (Marino et al., 2010; Plucinski et al., 2010; Santana and Marrs, 2014). The North Atlantic Oscillation (NAO; Hurrell et al., 2003) modulates the intensity of the westerly storm track and thus the amount and source of precipitation in Iceland. Its positive mode (NAO+) brings intervals of higher precipitation resulting in a wetter (and often warmer) climate than NAO- intervals, which are characterised by weaker westerlies, stronger northerly winds, and drier (and often colder) conditions (Hurrell, 1995; Trouet et al., 2009). Major changes in precipitation regimes usually lead to changes in the hydrogen stable isotopic value of environmental water ( $\delta D$ ; Dansgaard, 1964) which translate into shifts in the  $\delta D$  of plant waxes (e.g., *n*-alkanes; Sachse et al., 2012). This relationship has been calibrated in various environments, including the Arctic (e.g., Berke et al., 2019; Bush et al., 2017; McFarlin et al., 2019; Thomas et al., 2016) and applied for paleo-precipitation reconstructions (e.g., Ardenghi et al., 2019; Niedermeyer et al., 2016; Tierney et al., 2017; Wilkie et al., 2013). A  $C_{29}$  *n*-alkane  $\delta D$  record from a fjord core in NW Iceland (Fig. 10C; Moossen et al., 2015) describes a relatively stable NAO+ configuration (wetter - more D-depleted) throughout the Holocene, and two major shifts toward NAO- (drier - less D-depleted) conditions at ca 3–2.5 and 1.5–1.0 ka BP, matching the timing of first SVID pyroPAH peak and at least partially overlapping to the second one. A similar correlation of fire frequency shifts to NAO- configurations has recently been suggested for other Arctic sites, particularly in Svalbard (Chen et al., 2023).

Biomass typology (i.e., the kind of vegetation on site) also influences fuel flammability (Chandler et al., 1983; Fernandes and

550 Cruz, 2012; Santana et al., 2011; Scarff and Westoby, 2006). In Iceland, many plant taxa appeared shortly after deglaciation  
551 (e.g., Alsos et al., 2021; Harning et al., 2023). Increasing summer temperatures led to the expansion of thermophilic woody  
552 plant taxa (e.g., birch) during/after the Holocene Thermal Maximum (e.g., Eddudóttir et al., 2016; Geirsdóttir et al., 2022;  
553 Karlsdóttir et al., 2014). Since ~6 ka BP, the birch woodland in the NE region has evolved into more open heathland and  
554 peatland, until the birch population decreased around 3 ka BP (Roy et al., 2018), along with a general temperature decrease  
555 (Axford et al., 2007). In this context, at Ytra-Áland (Fig. 1B), two major drops in *Betula* pollen coeval to two increases in  
556 Ericales (heather's order) pollen closely follow the NAO- shifts at 3 and 1.5 ka BP (Fig. 10E; Karlsdóttir et al., 2014).  
557 Heathlands, especially in low moisture conditions, are associated with higher flammability, particularly high sustainability  
558 (i.e., how well the combustion proceeds). Thus, heathlands are prone to longer, more stable fires, and with an increased  
559 potential for igniting higher canopy elements and underlying peat layers (Plucinski et al., 2010; Rein et al., 2008; Santana and  
560 Marrs, 2014). More frequent, more stable, slow crawling fires involving dense bushes and peat would increase the amount of  
561 pyroPAHs produced and deposited in the region while skewing their distribution toward LMW components (George et al.,  
562 2016; Iinuma et al., 2007; Siao et al., 2007), as observed in the SVID pyroPAH signal (Fig. 7). Lastly, the observed shifts in  
563 pyroPAHs are unlikely to be the result of a change in their source area. Our back-trajectory analysis reveals that more air  
564 parcels originate over Iceland or in the surrounding North Atlantic (Fig. 8). The analysis further reveals that trajectories with  
565 terrestrial origins are more likely in NAO+ than NAO- regimes. As such terrestrial trajectories would be the ones responsible  
566 for bringing combustion products to SVID, we might therefore expect a stronger pyroPAH signal during NAO+ intervals.  
567 However, our results display the opposite trend, with the initial increase in pyroPAH abundances at ~3 ka occurring during an  
568 NAO- mode and their subsequent drop occurring during a strong NAO+ interval. Thus, the late Holocene increase in pyroPAHs  
569 in SVID is likely to record a substantial increase in local fires (driven by vegetation change and NAO-modulated aridity) rather  
570 than a shift in the compounds' sources.

571 Overall, SVID pyroPAH signal describes a major shift from a relatively stable (i.e., low fire frequency) early and mid-Holocene  
572 environment to a dryer late-Holocene environment at ca 3 ka BP, naturally more prone to long term persistence of low  
573 temperature wildfires. This is likely the result of the combination of (1) recorded cooling and related shifts in vegetational  
574 communities, (2) NAO- shifts and associated dryer conditions.

575

576 **Figure 10: Regional comparison of climatic, fire, and vegetation records.** (A, purple) levoglucosan concentrations from the RECAP  
 577 ice core, south-eastern Greenland (Segato et al., 2021); (B, black) sum of pyrogenic PAHs concentrations – red line indicates a 3  
 578 points running average; (C, blue) stable isotopic composition of hydrogen of sedimentary *n*-alkanes from marine core MD99-2266  
 579 off the coast of NW Iceland (Moossen et al., 2015) – cyan line indicates a 3 points running average; (D, red) chironomid derived  
 580 temperatures from core 04-SVID-03 (Axford et al., 2007); (E) pollen percentages of *Betula* (green), *Poaceae* (yellow), and *Ericales*  
 581 (blue) in a peat section from the Ytra-Åland site, NE Iceland (Karlsdóttir et al., 2014).

## 582 5.5 Evidence for a human influence on fire frequency?

583 Unlike other proxies, pyroPAHs return to background levels after reaching high values at 1.5 ka BP, and then remain low  
 584 through the Medieval Warm Period (ca 900–1200 CE) and most of the Little Ice Age (1300–1900 CE), before peaking again  
 585 in the last 150–200 years. A similar drop in fire markers (anhydrosugars) is also observed in eastern Greenland (Segato et al.,  
 586 2021; Fig. 10A). Low pyroPAHs levels during an interval of known human presence in Iceland suggests that human activities  
 587 might have curbed regional fire frequency, thus modulating the natural signal, which would have otherwise remained relatively  
 588 high due to the persistence of colder conditions and more flammable plant communities (regardless of NAO shifts). In fact,  
 589 while increased pressure from grazing lowered environmental resilience to soil erosion (e.g., Bates et al., 2021; Eddudóttir et  
 590 al., 2016; McGovern et al., 2007), it likely also decreased fuel flammability (which is dependent on the amount of dead  
 591 biomass; Davies and Legg, 2011; Santana and Marrs, 2014) in the predominant heathland environment (Lake et al., 2001).  
 592 Additionally, the creation of farmland and pastureland at the expenses of areas with woody vegetation and heathland likely  
 593 reduced the extent of the biomes naturally prone to fires. This reduction of local wood availability is reflected in changes of

594 foraging habits, as settlers shifted to relying more heavily on more abundant fuel sources such as peat and turf, as well as other  
595 marine derived substances (e.g., seal oil, seaweed; Bold, 2012), while driftwood and imported wood (from Europe or North  
596 America, often with ad hoc expeditions) satisfied most of the need for timber (e.g., Bold, 2012; Edvardsson, 2010; Mooney,  
597 2016; Pinta, 2021; Sveinbjarnardóttir et al., 2007). A general mechanism for fire suppression due to the expansion of cultivated  
598 land has already been proposed for global data (Marlon et al., 2013), but assumed to be likely asynchronous in different regions  
599 and strongly influenced by local climatic, environmental, and social conditions.

600 We speculate that the drop in fire markers in Iceland from the reduction in wildfire risk due to husbandry and farming exceeded  
601 the production of fire markers due to human necessities (e.g., warming), resulting in an overall suppressed fire signal. This  
602 would also be consistent with the low population density, which started to increase only in the 1800s CE (Iceland Statistical  
603 Service, 2023; Jónsson and Magnússon, 1997), matching the coldest interval of the Little Ice Age and the sharp rise in HMW  
604 pyroPAHs. From this perspective, the pressure of human activities would have fostered erosion through decreased  
605 environmental resilience while, at the same time, suppressing natural fire frequency.

## 606 **6 Conclusions**

607 Our multiproxy analysis of Holocene sediments from Stóra Viðarvatn provides new insight into the coupled vegetation, fire,  
608 erosion, and climate regimes of NE Iceland:

- 609 • Bulk geochemistry proxies show that the general climatic evolution of NE Iceland is primarily driven by summer  
610 insolation: an initial deglacial warming followed by a relatively warm and stable climate until ca 4–3 ka BP, after which  
611 declining summer temperatures result in accelerating catchment erosion.
- 612 • Faecal biomarkers, traditionally linked to human activities, do not show an elevated signal at or around colonisation (9<sup>th</sup>  
613 century CE). Instead, faecal biomarkers roughly trace the erosional signal described by bulk geochemical proxies. This  
614 may result from a combination of (1) low local anthropogenic pressure (although sparse settlements existed a few km  
615 from the study area), and (2) signal dilution, due to the large lake size and its relatively small watershed. Therefore, we  
616 urge caution when interpreting faecal biomarkers as unequivocal proxies of human presence, particularly when highly  
617 sensitive analytical tools like the one used in this study are involved.
- 618 • PyroPAHs carry a regional (mostly confined to northern and north-eastern Iceland) and predominantly natural signal  
619 (i.e., controlled by parameters such as precipitation and moisture availability, vegetation typology and flammability).  
620 After generally low fire frequency throughout most of the Holocene, we observe major regime changes at 3 ka and 1.5  
621 ka BP, before known human colonisation in Iceland. During this interval, the distribution of pyroPAHs point toward a  
622 regional increase in low temperature fire frequency. This can be linked to a change in vegetation typology driven by the  
623 cooling of the last 4 to 3 kyr, coupled to major shifts in atmospheric circulation (i.e., NAO regimes) that led to increased  
624 aridity and thus flammability. Finally, low levels of pyroPAHs characterise the time following known human  
625 colonisation, before rising again (but with a molecular composition more distinctive of fossil fuels) in the last ~200 years.  
626 This suggests that human activities, particularly husbandry and farming, may have suppressed fire frequency by reducing  
627 the range and flammability of environments more prone to fire, effectively modulating the natural signal while decreasing  
628 the resilience of the local environment to soil erosion.

630

631 Figure A1: Concentration curves of all 20-SVID-02 pyrogenic PAHs recovered in this study. All concentrations are expressed as ng  
 632 per g of dry sample, except for the last curve (red-dotted) which is in ng per g of TC. Note that several vertical axes have been  
 633 adjusted to minimise the rise in the last 2–3 centuries. Compounds are listed in chromatographic order and grouped by molecular  
 634 weight through colour shading (LMW in magenta; MMW in orange; HMW in blue).

635

636 **Figure A2:** Concentration curves of all 20-SVID-02 faecal sterol/stanols of interest recovered in this study. All concentrations are  
 637 expressed as ng per g of dry sample. Note that several vertical axes have been adjusted to minimise the rise in the last 2–3 centuries.  
 638 Compounds are grouped and colour shaded by structure (cholesterol and stanol derivatives in blue purple; sito-stigma-  
 639 sterols and stanols in red orange; campesterol and campestanol in green).

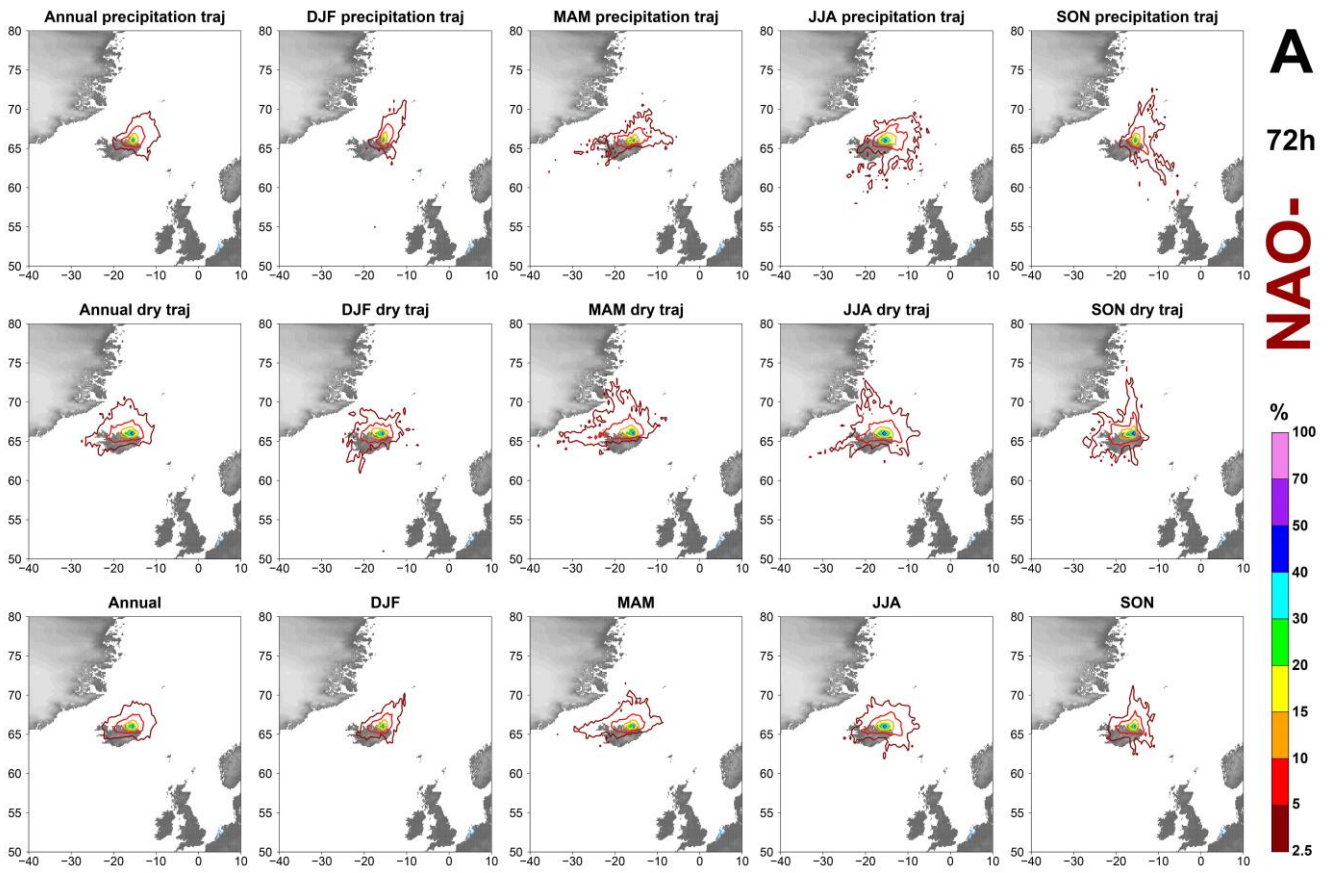

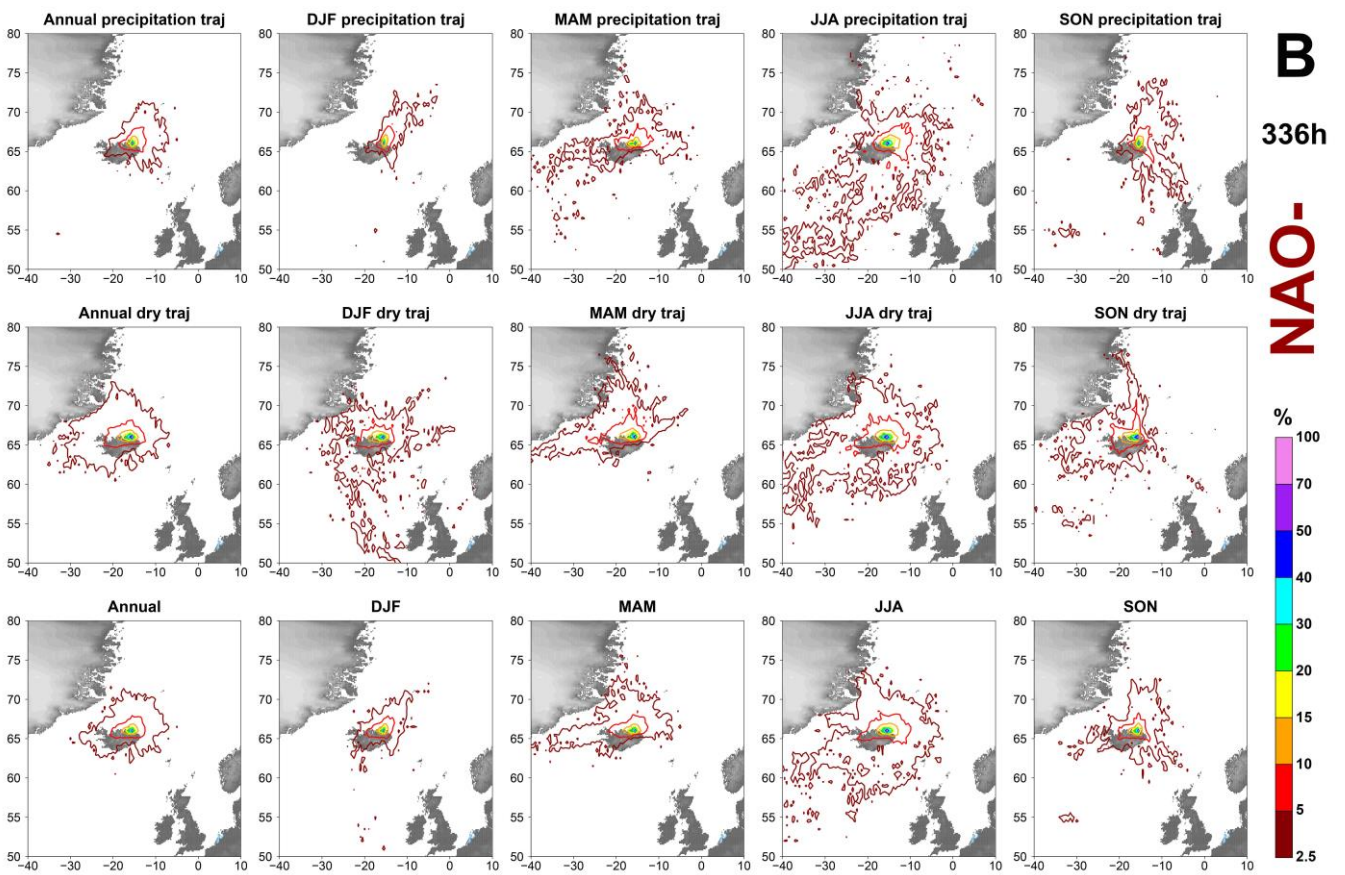

640

641 Figure A3: Concentration curves of all 20-SVID odd-numbered *n*-alkane homologues from *n*-C<sub>19</sub> to *n*-C<sub>35</sub> recovered in this study.  
 642 All concentrations are expressed as ng per g of dry sample.

646

647 **Figure A4:** HYSPLIT back trajectories of air parcels for December 2009 to November 2010 (NAO-) and May 2013 to April 2014  
 648 (NAO+, except for October 2014). Trajectories are calculated on a three days (72 h, A-C) and a two weeks (336 h, B-D)  
 649 intervals at a 6 hours frequency; “precipitation” (top) indicates trajectories that produced precipitation within 6 h from the SVID endpoint,  
 650 “dry” (middle) vice versa; bottom plots are the sum of “precipitation” and “dry” trajectories. Contour colours indicate the frequency  
 651 at which air parcels part of a trajectory travel above a certain area.

652

653

Figure A5: PAH indices used as an indication of PAH preservation.

654

The L/H index (black) is a ratio between low and high molecular weight unsubstituted PAHs, defined as  $L/H = (\text{Phenanthrene} + \text{Anthracene} + \text{Fluoranthene} + \text{Pyrene}) / (\text{Benzo[a]anthracene} + \text{Chrysene} + \text{Benzo[k]fluoranthene} + \text{Benzo[a]pyrene} + \text{Indeno[1,2,3,c,d]pyrene} + \text{Dibenzo[a,h]anthracene} + \text{Benzo[g,h,i]perylene})$  (Magi et al., 2002; Stogiannidis et al., 2015 and refs. therein).

657

658

The Pyrene-Coronene index (orange) defined as  $\text{pyrene} / (\text{pyrene} + \text{coronene})$  is based on the assumption of an higher preservation potential of the HMW coronene over the lighter, more soluble pyrene (Denis, 2016; Denis et al., 2017; May et al., 1978); higher, more stable values point toward good preservation for both HMW and LMW PAHs.

659

**Table A1: Polycyclic aromatic hydrocarbons (PAHs) analysed in this study. Pyrogenic PAHs are grouped into low, medium, and high molecular weight. Elution order and SRM transitions are reported for each compound.**

Elution order	Group	Compound name	Mass	Product mass a/b	Collision energy
1		Naphthalene*	128	128/102	8
2		Acenaphthylene*	152	152	8
3	LMW	Acenaphthene*	154	153/154	8
4		Fluorene	166	166	8
5		Phenanthrene	178	178	8
6		Anthracene	178	178	8
7		Fluoranthene	202	202	8
8		Pyrene	202	202	8
11	MMW	Retene	234	234/219	8
12		Benzo[a]anthracene	228	228	8
13		Triphenylene	228	228	8
14		Chrysene	228	228	8
15	HMW	Benzo[k]fluoranthene	252	252	8
16		Benzo[j]fluoranthene	252	252	8
17		Benzo[a]pyrene	252	252	8
19		Indeno[1,2,3-C,D]pyrene	276	276	8
20		Dibenzo[a,h]anthracene	278	278	8
21		Benzo[g,h,i]perylene	276	276	8
22		Coronene	300	300	8
18		Perylene**	252	252	8
9		p-Terphenyl D14 (IS)	244	244	8
10		p-Terphenyl (IS)	230	230	8

\* Compound(s) difficult to quantify correctly and thus excluded from final sums.

\*\* Non-pyrogenic PAH.

664

**Table A2: Faecal sterols and stanols analysed in this study. Elution order and SRM transitions are reported for each compound.**

Elution order	Name	Detailed name	CAS #	Quantitative qualitative	Mass	Product Mass	Collision Energy
1	Pregnanol (IS)	5 $\beta$ -pregnan-3 $\alpha$ -ol	4352-07-2	Q q	361 361	215 191	10 10
2	5 $\alpha$ -Cholestane (IS)	5 $\alpha$ -cholestane	481-21-0		372	217	10
3	Coprostanol	5 $\beta$ -cholestan-3 $\beta$ -ol	360-68-9	Q q	370 460	215 215	10 10
4	Epi-Coprostanol	5 $\beta$ -cholestan-3 $\alpha$ -ol	516-92-7	Q q	370 460	215 215	10 10
5	Cholesterol	5-en-cholest-3 $\beta$ -ol	57-88-5	Q q	368 458	145 129	20 50
6	Cholestanol	5 $\alpha$ -cholestan-3 $\beta$ -ol	80-97-7	Q q	370 460	215 215	10 10
7	5 $\beta$ -Campestanol	24R-methyl-5 $\beta$ -cholestan-3 $\beta$ -ol	33947-18-1	Q q	384 474	215 215	10 10
8	5 $\beta$ -Stigma(sito)stanol	24R-ethyl-5 $\beta$ -cholestan-3 $\beta$ -ol	4736-91-8	Q q	383 488	147 215	20 10
9	Campesterol	24R-methyl-5-en-cholest-3 $\beta$ -ol	474-62-4	Q q	382 472	255 129	5 50
10	5 $\alpha$ -Campestanol	24R-methyl-5 $\alpha$ -cholestan-3 $\beta$ -ol	474-60-2	Q q	384 474	215 215	10 10
11	$\beta$ -Stigmasterol	24S-ethyl-5,22E-dien-cholest-3 $\beta$ -ol	83-48-7	Q q	394 484	255 211	5 20

13	5 $\alpha$ -Stigma(sito)stanol	24R-ethyl-5 $\alpha$ -cholestan-3 $\beta$ -ol	83-45-4	Q q	383 488	147 215	20 10

668 **8 Data availability**

669 All raw data will be available on the NOAA National Centers for Environmental Information  
670 (<https://www.ncei.noaa.gov/access/paleo-search/study/38503>).

671 The data will also be made available upon request.

672 **9 Author contributions**

673 GHM, ÁG and JS conceptualized research and obtained financial support for the NSF project ILLUME (Iceland landscape  
674 reconstruction using molecular proxies); GHM, ÁG, JHR, DJH, and NA participated in the field campaign to retrieve the  
675 sediment core; JS and GHM provided laboratory and analytical infrastructure; NA, DJH, and BRH processed all sediment  
676 samples; NA performed method development and sample analysis. TT and DJH performed the tephra analysis and developed  
677 the age model; NA performed the HYSPLIT analysis; NA wrote the manuscript draft, except for the age model paragraph  
678 (DJH); GHM, ÁG, JS, DJH, and JHR reviewed and edited the manuscript.

679 **10 Competing interests**

680 The authors declare that they have no conflict of interest.

681 **11 Acknowledgements**

682 We kindly thank Sveinbjörn Steinþórsson and Þór Blöndahl for lake coring assistance at Stóra Viðarvatn. We thank Dr. Jamie  
683 McFarlin (INSTAAR and University of Wyoming), Dr. Nadia Dildar (INSTAAR), Dr. Sebastian Kopf (INSTAAR), and  
684 Katelyn Eaman for their invaluable analytical support in the lab; Dr. Thomas Marchitto (INSTAAR) for providing access to  
685 the clean room used for sampling; Jeremy Caves Rugenstein (Colorado State University) for sharing his expertise on  
686 HYSPLIT; and Karl Painter and Isaiah Castro for helping with biogenic silica analyses.

687 **12 Financial support**

688 This work was supported by the National Science Foundation grant ARC1836981 to GHM, ÁG, JS, and TT, and by a  
689 University of Iceland grant to ÁG.
