Abstract.

Tipping elements, including the Antarctic Ice Sheet (AIS), are Earth system components that can reach critical thresholds due to anthropogenic emissions. Increasing our understanding of past warm climates can help to elucidate the future contribution of the AIS to emissions. The mid-Pliocene warm period (mPWP, 3.3-3.0 million years ago) serves as an ideal benchmark experiment. During this period, CO₂ levels were similar to present-day (350-450 ppmv), but global mean temperatures were 2.5-4.0 degrees higher. Sea-level reconstructions from that time indicate a rise of 10-20 meters compared to the present, highlighting the potential crossing of tipping points in Antarctica. In order to achieve a sea-level contribution far beyond 10 m not only the West Antarctic Ice Sheet (WAIS) needs to largely decrease, but a significant response in the East Antarctic Ice Sheet (EAIS) is also required. A key question in reconstructions and simulations is therefore which of the AIS basins retreated during the mPWP. In this study, we investigate how the AIS responds to climatic and bedrock conditions during the mPWP. To this end we use the Pliocene Model Intercomparison Project, Phase 2 (PlioMIP2) general circulation model ensemble to force a higher-order ice-sheet model. Our simulations reveal that the West Antarctic Ice Sheet experiences collapse with a 0.5 K oceanic warming, the Wilkes basin shows retreat at 3 K oceanic warming, although higher precipitation rates could mitigate such a retreat. Totten glacier shows slight signs of retreats only under high oceanic warming conditions (greater than 4 K oceanic anomaly). We also examine other sources of uncertainty related to initial topography and ice dynamics. We find that the climatologies yield a higher uncertainty than the dynamical configuration, if parameters are constrained with PD observations and that starting from Pliocene reconstructions lead to smaller ice-sheet configurations due to hysteresis behaviour of marine bedrocks. Ultimately, our study concludes that cliff instability is not a prerequisite for the retreat of Wilkes basin. Instead, a significant rise in oceanic temperatures can initiate such a retreat. Our research contributes to a better understanding of Antarctic tipping points and the likelihood of crossing them under future emission scenarios.

1 Introduction

Sea level has been rising since the beginning of the 20th century due to ocean expansion and melting of glaciers and ice sheets (Frederikse et al., 2020). Sea level will continue to rise by the end of this century and very likely far beyond that period depending on the future emission pathways followed (IPCC AR6; Masson-Delmotte et al. (2021)). The Antarctic Ice Sheet (AIS) plays a major role in future sea-level projections, as it is the largest ice sheet on Earth, with a total volume of ~58 meters of sea-level equivalent (mSLE; Morlighem et al. (2020)). Nonetheless, assessment of its future contribution using ice-sheet models is subject to a very large uncertainty, mainly due to our poor understanding of ice-sheet-related physical processes that are difficult to quantify (Seroussi et al., 2020; van de Wal et al., 2022). From a tipping point perspective, modeling studies suggest that the AIS exhibits three potential critical thresholds (Armstrong McKay et al., 2022): a collapse of the West Antarctic Ice Sheet (WAIS), which is likely to occur below 2 degree of warming since pre-industrial era; a collapse of the marine basins in the East Antarctic Ice Sheet (EAIS) with a tipping point between 2-4 degrees; and a fully melted EAIS, probably above 8 degrees of global warming. In this study we will mainly focus on the internal feedback mechanisms that can lead to a collapse of the marine basins in the WAIS and EAIS.

The WAIS, as well as many regions of the EAIS, lies on marine bedrock (i.e. below sea level) with a retrograde slope and is therefore thought to be subject to the Marine Ice Sheet Instability (MISI; Schoof (2007)). MISI is a positive feedback mechanism by which marine ice sheets are unstable under retrograde bed-slopes, since the ice flux at the grounding line is directly proportional to the ice thickness. If the grounding line retreats into pronounced bed-slopes, MISI can be initiated. Such a retreat can be triggered by the melting of ice shelves. Although ice shelves do not directly contribute to sea-level rise, they can help reduce inland ice velocities due to the buttressing effect (Fürst et al., 2016; Sun et al., 2020). The thinning of ice shelves, either by increased oceanic melt (Rignot et al., 2013), hydrofracturing (Robel and Banwell, 2019) or ice damage (Lhermitte et al., 2020) leads to a reduction of the buttressing effect and consequently trigger grounding-line retreat. Therefore, one key question regarding the AIS tipping points is if there is a temperature threshold at which AIS ice shelves are not large enough to provide the necessary buttressing effect to the interior of the ice sheet, triggering MISI and eventually leading to a collapse of its marine regions.

Sea-level reconstructions suggest that AIS marine regions indeed collapsed during past warmer periods, highlighting the importance of the assessment of Antarctic tipping points (Rohling et al., 2014, 2019). One of these warmer periods is the mid-Pliocene Warm Period (3.3-3.0 Ma). This period was characterized by atmospheric CO₂ concentrations similar to the present day (PD) values (350-450 ppmv), although with significantly warmer global temperatures (2.5-4 K; Haywood et al., 2016) which could reach up to 8 K at high latitudes due to polar amplification (Fischer et al., 2018). Sea-level reconstructions of that period show high uncertainty, yet they suggest that sea level was 5-25 meters higher than today. The highest global estimated sea-level contribution during the Pliocene comes from Hearty et al. (2020) with reconstructions in the South African coast far above 30 meters of sea-level rise. Dumitru et al. (2019) reconstruct a total of 25 meters of sea-level rise (23.4 mSLE from ice sheets and 1.6 meters from thermal expansion) from caves in Mallorca. On the other hand, Richards et al. (2022), Moucha and Ruetenik (2017) and Grant et al. (2019) obtain a lower range (from 8-20 meters of sea-level rise), although these results, rather

55 than from in-situ measurements, are obtained from model reconstructions. Such high sea-level stands point to a substantial contribution of continental ice sheets. Even if the Greenland Ice Sheet was entirely absent, it is still necessary to account for an Antarctic contribution that exceeds the 7 mSLE. Thus, it is very likely that Antarctic tipping points were exceeded during the mPWP, making this an ideal benchmark period for assessing AIS stability in warmer climates.

Ice-sheet modeling studies also suggest a wide range of Antarctic contributions to sea-level rise during the mPWP. Dolan et al. (2018) forced three ice-sheet models with climates from seven Atmosphere-Ocean General Circulation Model (AOGCM) produced in the frame of the first stage of the Pliocene Model Intercomparison Project (PlioMIP1). They showed that, although climatologies can lead to important differences, the largest source of uncertainty is the ice-sheet model used, stressing the importance of analyzing the sources of structural uncertainty for every model. Golledge et al. (2017) simulated two Antarctic states (allowing in one case for melting at the grounding line) and performed an analysis with varying climatic conditions. They found a mean AIS contribution of 8.6 mSLE (9.7 mSLE if melting at the grounding line is allowed). Yan et al. (2016) investigated Antarctic sea-level uncertainty in their ice-sheet model to model parameters and climatic sensitivities. They found a mean Antarctic contribution of 5.6 mSLE but parameter uncertainty in their model ensemble shows a spread of 10.8 mSLE. Finally, Berends et al. (2019) simulated a total sea-level rise of 8–14 mSLE during the late Pliocene accounting for the contribution from all ice sheets.

70 The largest simulated Antarctic sea-level contributions at the mPWP are provided by the studies of DeConto and Pollard (2016) and DeConto et al. (2021), with simulated means of 11.3 mSLE and 17.8 mSLE, respectively. In both cases, they performed a large ensemble analysis testing parameters that affect ice-shelf sensitivity, like maximum calving and the hydrofracturing rate on ice shelves. In these studies, the large contribution is due to the inclusion of the so-called Marine Ice Cliff Instability (MICI), a potential positive feedback mechanism that affects marine terminating glaciers. Marine cliffs that form at the ice front are thought to fail when their thickness exceeds a certain threshold. The retreat rate of marine cliffs increases with ice thickness (Crawford et al., 2021). Thus, if an ice front retreats and encounters a higher ice thickness upstream, the retreat rate increases, accelerating the grounding-line flux. Although the physics of such a mechanism are becoming more clear thanks to idealized experiments (Bassis et al., 2021; Crawford et al., 2021), its application to the AIS remains a matter of debate (Edwards et al., 2019).

80 One key question in Antarctic reconstructions and simulations is whether the Wilkes Basin retreated or not during the mPWP (Wilkes basin illustrated in Fig. 8 and Fig. S3). Today, the WAIS and the Greenland Ice Sheet (GrIS) sum up to make a total of 10 mSLE (Morlighem et al., 2017, 2020). Thus, in order to achieve a sea-level rise far beyond 10 mSLE, a significant response in the EAIS is required. Near-field sedimentological reconstructions suggest episodes of advance and retreat from the Wilkes Basin over the mPWP (Moucha and Ruetenik, 2017). From an ice-sheet modeling perspective, DeConto and Pollard (2016) and DeConto et al. (2021) achieved the most retreated EAIS, especially in the Wilkes Basin, due to the inclusion of MICI mechanism. Golledge et al. (2017) obtained a collapse of the Wilkes basin by warming the Pliocene climate by 2 degrees in the atmosphere and 1 degree in the ocean. Yan et al. (2016) also achieved a collapsed Wilkes Basin, but only for an additional 5 degrees oceanic warming. Dolan et al. (2018) and de Boer et al. (2014) only shows a collapsed Wilkes basin when the model is initialized with boundary conditions of the third phase of the Pliocene Research, Interpretation and Synoptic Mapping

90 (PRISM3), which include higher CO₂ concentrations than today and a different paleo ice-sheet geography and topography. In the transient simulation of Berends et al. (2019) only a WAIS collapse is achieved.

Our purpose here is to explore the AIS contribution to sea-level rise during the mPWP and to assess potential tipping points that can lead from a PD configuration to a mPWP state. Here we present the response of the Yelmo ice-sheet-shelf model to the mPWP climate simulated during the phase 2 of the PlioMIP project. The aim is to investigate parameter uncertainties of the ice-sheet model and their impact on the resulting simulations, as well as climatological uncertainties from the PlioMIP2 AOGCMs. The study is structured as follows: first we describe the ice-sheet model and the experimental setup (Section 2).
95 Then, the main results of the PlioMIP2-forced experiments are shown (Section 3). Our results are compared with those from other ice-sheet models and reconstructions. A discussion of our simulations (Section 4) is followed by the main conclusions (Section 5).

100 2 Methods and experimental setup

2.1 Yelmo ice-sheet-shelf model

For this study we use the Yelmo ice-sheet-shelf model with a horizontal resolution of 16 km with 20 terrain-following vertical layers. Yelmo is thermomechanically coupled and uses Glen's flow law with an exponent of $n=3$. Ice velocities are computed via the depth-integrated-viscosity approximation (DIVA; Goldberg (2011)). The DIVA solver replaces the horizontal velocity
105 gradients and effective viscosity by their vertical averages, which makes it computationally efficient, but still allows it to obtain results similar to other 3D higher-order models (Robinson et al., 2022). Here we will describe the most important features used in our experimental setup. Additional information on Yelmo is provided by Robinson et al. (2020).

Basal-drag law

Basal friction at the ice bed is represented with a regularized-Coulomb friction law

$$110 \quad \tau_b = c_b \left(\frac{|\mathbf{u}_b|}{|\mathbf{u}_b| + u_0} \right)^q \frac{\mathbf{u}_b}{|\mathbf{u}_b|}, \quad (1)$$

with basal velocity u_b . The regularization constant u_0 is set to 100 m/yr following Zoet and Iverson (2020), while q is the friction law exponent that determines the ice flow regime. The spatially variable basal friction coefficient c_b is defined as

$$c_b = c_f \lambda N \quad (2)$$

Here, c_f is a dimensionless field representing the basal properties of the base, such as soft/hard beds. Here we will use it for
115 calibration of the model. N is the effective pressure depending on the overburden pressure as in the formulation of Leguy et al. (2014). λ is a scaling factor which follows an exponential dependency with the bedrock height following Blasco et al. (2021).

This ensures that ice flows faster in marine regions due to softer soil properties. All parameter values are summarized in Table 1.

Grounding-line treatment

120 The grounding line is defined via the flotation criterion. In order to trace the grounding-line position accurately in transient
experiments it is necessary to use high resolution close to the grounding line (Pattyn et al., 2013). However, this leads to a
high computational cost and hinders studies that involve large timescales, such as paleoclimatic studies. In order to overcome
this problem, basal friction is scaled at the grounding-line points with its proportional grounded fraction. Given our coarse
125 resolution (16 km), we do not apply melting at the grounding line to avoid overestimation of the ocean-induced retreat in our
simulations (Seroussi and Morlighem, 2018).

2.2 Climatic forcing

Surface mass balance

Surface melt is computed via the Insolation-temperature melt (ITM) method (Pellicciotti et al., 2005; Van Den Berg et al.,
2008; Robinson et al., 2010). Daily surface melt is obtained from surface air temperature and absorbed insolation:

$$130 \quad M_{\text{srf}} = \frac{\Delta t}{\rho_w L_i} [\tau_a (1 - \alpha_s) S + c + \lambda_{\text{srf}} T_{\text{srf}}] \quad (3)$$

τ_a is the transmissivity of the atmosphere (i.e., the ratio between downward shortwave radiation at the land surface and at the
top of the atmosphere), ρ_w the density of pure water, L_i is the latent heat of ice, α_s the surface albedo of snow, S the insolation
at the top of the atmosphere and Δt the day length in seconds. λ_{srf} and c are parameters used to calibrate the AIS (Table 1). This
method accounts for the shortwave radiation and differences between snow and ice through the albedo effect (see Robinson
135 et al. (2010) for more details).

Atmospheric forcing

Atmospheric temperatures and precipitation fields are obtained either from observations and reanalysis or from climatic models.
In order to investigate the response of the AIS to the mPWP climate we use an anomaly method similar to Blasco et al. (2021):

$$T^{\text{atm}} = T_{\text{pd}}^{\text{atm}} + \Delta T_{\text{mod}}^{\text{atm}} \quad (4)$$

$$140 \quad P = P_{\text{pd}} + \delta P_{\text{mod}} \quad (5)$$

Here the subindex pd stands for present-day climate. These fields are obtained from the regional atmospheric climate model
RACMO2.3 (Van Wessem et al., 2014) forced with the ERA-Interim reanalysis data (Dee et al., 2011) and represent the temper-
ature difference and relative precipitation difference of the corresponding time period. The anomaly is computed between the

Pliocene experiment with 400 ppmv CO₂ and the pre-industrial experiment using 280 ppmv CO₂ from 12 different AOGCMs
145 in the frame of the PlioMIP2 (see Haywood et al. (2016) for more information on the experimental setup). In order to account
for surface temperature and precipitation changes in elevation, due to the Clausius-Clapeyron relation, a lapse rate correction
factor is applied, 0.008 K m⁻¹ for annual temperatures and 0.0065 K m⁻¹ for summer temperatures (Ritz et al., 1996; De-
Conto and Pollard, 2016; Quiquet et al., 2018; Albrecht et al., 2020). Figures 1 and 2 show the anomaly fields from the 12
AOGCMs used in this study scaled to sea level (elevation 0 meters).

150 Ocean forcing

Here we use a quadratic non-local sub-shelf melting by the ocean law for the Antarctic domain following a similar approach to
that of the ISMIP6 protocol (Jourdain et al., 2020). The quadratic non-local law not only includes local temperature changes,
but also the average over the ice-shelf basin. This parameterisation accounts for an additional overturning circulation below the
ice-shelf cavity which affects the total basal melt in a non-linear way (Favier et al., 2019). It reads as follows:

$$155 \quad M_{\text{quad-nl}} = \gamma_{\text{quad-nl}} \left(\frac{\rho_{\text{sw}} c_{\text{po}}}{\rho_i L_i} \right)^2 (T_o - T_f) |T_o - T_f| \quad (6)$$

where $\gamma_{\text{quad-nl}}$ represents the heat exchange velocity, ρ_{sw} and ρ_i the ocean water and ice densities respectively, c_{po} the specific
heat capacity of the ocean mixed layer, and L_i the latent heat of fusion of ice (Table 1). The freezing point temperature T_f at
the ice-shelf base is defined as:

$$T_f = \lambda_1 S_o + \lambda_2 + \lambda_3 z_b \quad (7)$$

160 z_b represents the ice-base elevation (negative below sea level), and the coefficients λ_1 , λ_2 , and λ_3 are respectively the
liquidus slope, intercept, and pressure coefficient (Table 1). Ocean temperature and salinity (T_f and S_o , respectively) are three
dimensional oceanic fields. PD fields are obtained from the ISMIP6 protocol. For computing the basal-melting rates at the
mPWP, the T_f and S_o fields are changed with an anomaly method analogous to equation 4. The resulting thermal forcing
field at the mPWP ($T_o - T_f$) is shown in Figure 3. Four of the 12 PlioMIP2 climate simulations did not provide oceanic data.
165 For those cases, a spatially homogeneous temperature anomaly field of one fourth of the atmospheric anomaly was applied,
following work by Golledge et al. (2015) and Taylor et al. (2012).

2.3 Experimental setup

Present-day spin up

First we perform an ensemble of 180 ice-sheet simulations for the AIS with different dynamic configurations under steady
170 PD climatic conditions using the . The ice-sheet dynamics, thermodynamics and topography are allowed to evolve freely.
This approach differs from other studies, where friction coefficients are optimized to simulate an AIS as close as possible

to observations. Instead, we prefer not to apply such an optimization, since it could bias our results towards PD conditions. Instead we use the more general friction coefficients that vary depending on the bedrock properties as described above.

We investigate uncertainty arising from three parameters that affect the ice dynamics: the exponent of the friction law q , the enhancement factor E_f and the friction coefficient c_f (Table 1). The friction exponent and coefficient affect the basal friction directly. The enhancement factor is a typical arbitrary scalar introduced in the Arrhenius equation to approximate the effect of an anisotropic flow. The simulations are run for 100 kyr to ensure equilibration at the PD. Only those simulations that match a realistic PD state (i.e. an ice volume difference of less than 1 mSLE and an extension difference of less than 2.5 times 10^5 km² compared to observations, indicating a deviation of only 2% from observed values) are considered for simulating the mPWP (31 of 180 simulations, see Fig. S1). Results of the ensemble experiments can be found in the Supplementary Material (Fig. S1). The present-day topography is taken from BedMachine v2 (Morlighem et al., 2020).

Paleo simulations

The 31 selected model versions are then used to simulate mPWP conditions with forcing from the 12 different AOGCMs. This gives a total of 372 simulations. These simulations are initialized from the end of the respective PD simulation and forced under steady mPWP conditions until they reach a new equilibrated state; after 30 kyr no significant changes are observed neither in ice volume nor ice area, (Figure S2). The background global sea level is set to 20 meters above PD for all simulations, representative of the highest estimates. Assuming a fixed and stable mPWP climatic state is a simplification compared to reality, since the AIS ice volume and climate vary throughout time (Yan et al., 2016; DeConto and Pollard, 2016; Golledge et al., 2017). However, this approach allows us to make use of the Pliocene AOGCM ensemble and to perform a straightforward comparison to gain insight into model sensitivities to climatic forcing.

3 Results

3.1 Ensemble simulations

The simulated ice volumes (in meters of sea-level equivalent, mSLE) and ice extensions at equilibrium are shown in Figures 4,5. All AOGCMs show a smaller AIS in terms of volume and extension with one exception (MIROC4m). Based on sea-level reconstructions, MIROC4m cannot be considered as realistic, nonetheless, we will discuss the potential reason for this unexpected behavior in the following sections. Over the remaining simulations, the simulated ice volume losses range from -1.8 mSLE (HadGEM3) to -9.6 mSLE (EC-Earth3.3). Ice extension ranges from 9.2 times 10^6 km² (EC-Earth3.3) to 10.9 times 10^6 km² (NorESM1-F). For reference, the PD grounded extension lies around 12.3 times 10^6 km², while an extension of around 10 times 10^6 km² represents a collapsed WAIS basin and even lower numbers indicate a retreat of marine basins in the EAIS. Compared to previous modeling studies, our simulations are well within modeling estimates and in the lower range of AIS volume responses (Figure 5a). No simulation reaches the upper limit of -11 mSLE set by DeConto et al. (2021, orange line), and just a few reach the upper limit of -7 mSLE set by DeConto et al. (2021, blue line). Results from Yan et al. (2016,

pink line) and Golledge et al. (2017, green line) are closer to our lower limit, whereas those of Berends et al. (2019, purple line) and Dolan et al. (2018, red line) are inside the range of our simulations and de Boer et al. (2015, brown line) simulates a lower contribution.

Figure 6 shows the ice-collapse probability for every AOGCM forcing applied (red: high probability of collapse, blue: low probability), determined from the 372-member ice-sheet model ensemble. All cases (with the exception of MIROC4m) show a collapsed WAIS, though in some cases this retreat is more pronounced ($10.1 \times 10^6 \text{ km}^2$; COSMOS) than in other cases ($10.8 \times 10^6 \text{ km}^2$; NorESM1-F). In the Wilkes basin, three AOGCM climates induce a retreat of the marine regions, though with different probabilities: low to medium in CESM1.0.5 and high in NorESM-L and EC-Earth3.3. Totten glacier shows a slight retreat only for CESM1.0.5. Some regions of the EAIS close to the Filchner-Ronne ice shelf also retreat in some cases, especially for EC-Earth3.3 and CCSM4-UofT. Generally less extended ice sheets lead to lower volumes, though it is not always the case (see simulations with HadGEM3 and MRI-CGCM2.3 forcing in Figure 5).

In order to assess the origin of mass loss for every AOGCM forcing we plot the mean ice thickness anomaly between the simulated PlioMIP2 and PD state (Figure 7). The ice thickness is practically always negative (red colors) in the WAIS, since it has collapsed in that region. Even MIROC4m shows a negative thickness anomaly, though smaller in magnitude. In contrast, the EAIS presents more complex behavior depending on the AOGCM forcing. A warmer atmosphere enhances precipitation. Thus, the interior of the EAIS gains volume for some AOGCMs (CCSM4-UofT, HadGEM3, IPSLCM5A, IPSLCM5A2). Nonetheless, if ocean temperatures are high enough, the Wilkes basin grounding-line retreat can be induced, leading to a lowering in ice thickness. This is the case for simulations forced by CESM1.0.5, EC-Earth3.3, NorESM-L. Simulations with COSMOS, NorESM1-F and MRI-CGCM2.3 show a slightly negative anomaly in the coastal regions of EAIS. Although it does not propagate further inland, it seems to compensate for inland accumulation, leading to a value close to zero. This spread in the EAIS and more specifically in the Wilkes basin points to an important role of the applied boundary conditions in the model response.

3.2 Tipping point analysis

Climatic forcing

We find in our study three potential sites prone to collapse: The WAIS through the Amundsen region, the Wilkes basin, and, on a smaller scale, the Totten basin. Since an increase in oceanic forcing is thought to be the main driver of MISI, we plot the ice extension of those basins with respect to the oceanic thermal forcing anomaly (Figure 8). In the case of the Amundsen region (Fig. 8a), we observe that all simulations show a collapsed WAIS with one exception, the MIROC4m model. Though this model result does not show realism in terms of sea-level equivalent, it shows interesting results in terms of tipping points in the Amundsen sea.

It is clear from Fig. 8a, that the even small temperature variation can lead to a collapse of the WAIS, but that changes in precipitation can play a key role for low temperatures. Since we want to focus on the tipping point and thus the minimal oceanic temperature anomaly that leads to a collapse of the Amundsen embayment, we focus on the four models that do not exceed

1 degree of oceanic anomaly: COSMOS (0.44 K), IPSLCM5A (0.92 K), IPSLCM5A2 (0.86 K) and MIROC4m (0.58 K). By plotting the relative precipitation against the thermal forcing anomaly (Fig. 8d), we find that MIROC4m shows a relative precipitation anomaly close to PD values, whereas the IPSLCM5A and IPSLCM5A2 precipitation anomaly lies around 85% of PD precipitation. Especially notable is the case of COSMOS, where the temperature anomaly is lower than MIROC4m, but also the precipitation, around 78%. Thus, we see that a thermal forcing below 0.5 K can lead to a collapse of the WAIS if precipitation stays below 80% of PD. Above 1 K anomaly we always find a collapsed WAIS even for precipitation rates close to PD (EC-Earth3.3). Nonetheless, it is important to mention that around 20-40% (Fig. 6) of the MIROC4m simulations show a collapsed Amundsen embayment, pointing to an important role of ice dynamics which will be discussed later.

We redo the same analysis with the Wilkes basin to investigate the tipping points that can lead to a collapse (Fig. 8b). Since the Wilkes basin also lies on a retrograde bedrock, we assume that thermal forcing is the main trigger. We find that the three AOGCMs that cause a collapse, namely EC-Earth3.3 (high probability), CESM1.0.5 (medium probability) and NorESM-L (high probability) simulate an oceanic anomaly above 3 K. Surprisingly, the model CESM1.0.5 which has the highest thermal forcing anomaly yields the highest uncertainty in the retreat (around 50%, Fig. 6). This can be explained partially by the precipitation anomaly, with three times more than PD rates (Fig. 8e). EC-Earth3.3 and NorESM-L have a similar thermal forcing anomaly with similar precipitation anomaly (around 130% of PD rates) and thus lead to similar results. Therefore, we conclude that a warming above 3 K can lead to an irreversible retreat of the Wilkes basin. Nonetheless, this retreat can be somewhat mitigated by basin-wide enhanced precipitation rates as seen in CESM1.0.5. In the next section we will analyze the potential role of ice dynamics for CESM1.0.5.

Finally we focus on Totten glacier, since it also shows signs of potential instabilities for CESM1.0.5 (Fig. 6). Redoing the same analysis for that basin (Fig. 8c,f), we find that CESM1.0.5 simulates the lowest ice extent in Totten due to a thermal forcing anomaly above 8 K. The other models do not show a significant retreat (extension above 90% of PD), even for thermal forcings close to 4 K. Thus, we conclude that for the Totten glacier, oceanic anomalies well above 4 K are needed to induce a retreat of the grounding line there.

Ice dynamics

Since we show that some basins collapse with certain probability for forcing from some AOGCMs, we focus our attention on the role of the ice dynamics in the ice retreat (Fig. S5). We plot the three main parameters influencing the ice flow that we permuted in our simulations (Enhancement factor E_f , friction law exponent q and friction coefficient c_f) for the two AOGCMs that showed a certain probability of collapse (CESM1.0.5 in the Wilkes and Totten basin, and MIROC4m in the Amundsen basin). For CESM1.0.5, we could not find any relationship between a Wilkes collapse and the dynamic configuration, except that lower enhancement factors simulated a more pronounced retreat than higher enhancement factors. On the other hand, for the Totten glacier we find that simulations with higher enhancement factors ($E_f=5$) never collapse, whereas simulations with lower values ($E_f=3$) always collapse. Intermediate values ($E_f=4$) show a regime with both states. Finally, no clear relationship is found for the MIROC4m model in the Amundsen region, except that neither an enhancement factor of $E_f=3$ nor a linear friction law ($q=1$) collapse.

270 3.3 Bedrock experiments

Some additional simulations were performed to test the effect of different topographic initial conditions on the final results. To avoid running the complete ensemble again, we took just the parameters from the ensemble that produced results closest to the mean value for every AOGCM forcing. We performed an additional set of imposing the Pliocene topography and ice-thickness configuration from PRISM4 (Dowsett et al. (2016); see Fig. S4). Figure 9 shows the the surface elevation of the simulated
275 AIS. In this case, all the simulations show a collapsed WAIS as well as Wilkes and Totten basin. These results are more in agreement with the reconstructions used for the PRISM4 boundary conditions and the highest range of sea-level estimates (sea-level contributions from 15 to 25 meters). Nonetheless, as we will discuss further, these results are biased towards a collapsed state, since growing on retrograde bedrock slopes is hampered. The existence of positive feedback mechanisms on marine retrograde bed slopes creates hysteresis behavior.

280 4 Discussion

4.1 Comparison with previous studies

We have presented a large ensemble forced with different climatologies for the mPWP. DeConto and Pollard (2016) and DeConto et al. (2021) also performed a large ensemble analysis but only explored the relationships between ocean temperature and sub-ice-shelf melt rates, hydrofracturing and maximum rates of marine-terminating ice-cliff failure. Yan et al. (2016) used
285 an ensemble to investigate parameters that affect the climatic conditions, rather than ice dynamics. de Boer et al. (2014) and Dolan et al. (2018) include several climatic outputs and ice-sheet models. Nonetheless, only one dynamic configuration was chosen for every ice-sheet model. Here we aimed to consistently investigate the role of both the mPWP climatology by testing different AOGCMs as well as uncertainties in the ice dynamics.

In total we simulate an Antarctic sea-level contribution of less than 10 meters if we start from PD conditions and use the
290 PD topography (Figure 5). Our results are in general agreement with many studies that start with PD initial conditions or evolve transiently towards the mPWP (de Boer et al., 2014; Yan et al., 2016; Golledge et al., 2017; Dolan et al., 2018; Berends et al., 2019). The greatest difference is with the studies from DeConto and Pollard (2016) and DeConto et al. (2021) due to their inclusion of the MICI mechanism. Without MICI, those studies only show a collapse of the WAIS and thus a sea-level rise of just 3 meters (Fig. S4a,b). However, it is worth mentioning, that these studies of DeConto and Pollard (2016) and
295 DeConto et al. (2021) apply an oceanic anomaly of 2 degrees warming with respect to PD at the mPWP. As shown in our study, with such a forcing we would not simulate a collapse of the Wilkes or Totten glacier retreat either, since at least a 3 degree oceanic warming anomaly is needed. Furthermore, Crawford et al. (2021), showed that the applied retreating rate for small cliffs was overestimated in DeConto and Pollard (2016). Other studies that achieve a collapse of the Wilkes basin do it either by increasing oceanic temperatures (Yan et al., 2016; Golledge et al., 2017) or adding melt at the grounding line (Golledge
300 et al., 2017). Though not focused on the Pliocene, the ABUMIP experiments showed that the removal of ice shelves also leads to substantial ice loss in Wilkes basin for most models, showing that its a highly vulnerable and uncertain region (Sun et al.,

2020). Our results support a collapse of the Wilkes basin for an oceanic anomaly of 3 K and a retreat of the Totten glacier for an oceanic anomaly of 8 K. Nonetheless, high precipitation rates can hamper this retreat.

305 Since our Antarctic sea-level contributions do not exceed the 10 mSLE, we cannot simulate a global sea-level contribution of more than 20 mSLE as suggested by some reconstructions (Dumitru et al., 2019; Hearty et al., 2020). Nonetheless, in a recent work of Richards et al. (2022) they perform geodynamic simulations during the mPWP and do a statistical comparison with Australian sea-level markers. Such analysis allows them to reassess the mPWP sea-level stands by comparing model results with proxy data. They obtain a lower mPWP sea-level stand, around 16 mSLE and argue that MICI mechanism is the studies of DeConto and Pollard (2016); DeConto et al. (2021) is overestimated. Assuming that Greenland was almost fully melted (~ 7.4
310 msle, Morlighem et al. (2017)), with such a revised sea-level reconstruction, our results are inside the geological constraints if Wilkes basin collapses via high oceanic thermal forcing or with low precipitation rates, as in MRI-CGCM2.3 (Table 1 in SM).

Although not focused on the mPWP, the study of Garbe et al. (2020) shows a threshold of the Wilkes basin between 4 to 6 degrees of warming relative to pre-industrial levels for the atmosphere (equivalent to 1.5-2.5 K in the ocean in their study). The Totten basin retreats in their experiment with an atmospheric anomaly of 7 K (close to 3 K of oceanic warming). Nonetheless,
315 as pointed out by their study, this threshold is highly sensitive to structural dependence. In our study we find that some ice dynamics can facilitate an irreversible retreat more than others.

For simulations forced with CESM1.0.5, we find that lower enhancement factors lead to more retreated Wilkes and Totten basin (Fig. S5). This might seem counterintuitive, since a low enhancement factor leads the grounded ice to flow more slowly . We explain this behavior as a consequence of the fact that once the marine basin enters into a MISI, ice does not flow
320 sufficiently fast to readvance again and prevent its collapse. However, in the MIROC4m model we find that a WAIS collapse is more likely to occur for high enhancement factors. In this case it seems that the low enhancement factors do not allow the ice sheet to reach the critical location where MISI is triggered. In summary, although we observe some trends associated with the dynamic configuration for CESM1.0.5 and MIROC4m, no clear relationship can be found. Such an analysis of structural dependence allows us to assess the sea-level uncertainties that arise from dynamical configuration and climatologies. Contrary
325 to Dolan et al. (2018), we find that the climatologies yield a higher uncertainty (~7 msle) than the dynamical configuration, if parameters are constrained with PD observations. Dolan et al. (2018) obtain more than 10 msle between different ice-sheet models, whereas we obtain less than 2 msle differences for simulations which are not close to tip, and up to 5 msle differences for CESM1.0.5 due to its proximity to tip or not in the Wilkes basin (Error bars Fig. 5). Thus, a large ensemble parameter constraint like in our study, helps considerably to reduce uncertainty from ice-sheet models.

330 Some of the AOGCMs employed here (CCSM4, CESM, HadGEM, IPSLCM5A, MIROC, NorESM1) were also used in the sixth phase of the Ice Sheet Model Intercomparison Project (ISMIP6, Seroussi et al. (2020)). Consistent with our results, ISMIP6 simulations forced with these and other climate models predict that Antarctic tipping points could be reached within this century (e.g., Fig. 9 in Lipscomb et al. (2021)) or thereafter (Lowry et al., 2021). Nonetheless, the latest round of the Coupled Model Intercomparison Project, phase 6 (CMIP6) has shown that some models show a very high sensitivity to warm-
335 ing processes, the so-called 'hot-model' problem (Hausfather et al., 2022). Two of the models employed here (EC-Earth3.3, HadGEM3, see Table S1) belong to CMIP6 whereas the rest belong to CMIP5. Since we aimed to investigate Antarctic tipping

points from PlioMIP2 simulations, assessing the AOGCM realism was out of the current scope. Still, it would be interesting for future studies to restrict the study to those AOGCM that can simulate realistic historical observations (Nijse et al., 2020).

It is important to mention that exceeding a tipping point does not mean that the ice sheet will collapse immediately, but rather that it has reached the threshold temperature by which a retreat will be induced which will be further amplified by MISI. Plotting the one dimensional evolution of the WAIS (Fig. S2), we observe that the WAIS collapse usually occurs with a lag of 1000-5000 years from the application of the forcing. In some cases it can reach up to 25000 years. MISI is not only a matter of the oceanic temperature threshold, but also depends on the grounding-line position and the thermal forcing at this location, as well as precipitation. Other factors, such as ice dynamics, can delay (or accelerate) the grounding-line position reaching a pronounced retrograde bedrock that leads to a full collapse of the WAIS.

4.2 Forcing limitations

In our study, the transient character of the climate system was neglected for the sake of simplicity. Instead, we decided to force towards a steady mPWP state for an ensemble large enough to be statistically significant (more than 30 simulations) for 12 different mPWP conditions. This approach permits us to assess Antarctic tipping points starting from PD conditions. This experimental setup goes in line with other studies, allowing for a similar comparison (Yan et al., 2016; DeConto and Pollard, 2016; DeConto et al., 2021). To our knowledge, only one study has simulated the transient evolution of the AIS under the Pliocene. The transient evolution of Berends et al. (2019) allowed only for a WAIS collapse, avoiding other tipping points, and thus simulated a lower sea-level contribution (Fig. S4c).

Another limitation in our study are the initial topographic boundary conditions. In order to overcome this problem we also performed certain experiments starting from PRISM4 conditions (Fig. 9). Our sea-level estimates then shift towards the high-range estimates, between 15-25 meters. Such an experiment was performed in the study of Dolan et al. (2018) and de Boer et al. (2014). Their results also show that starting from PRISM4 conditions leads to higher sea-level contributions and a less extended AIS during the mPWP. This result is expected. On the one hand a smaller ice sheet has warmer temperatures due to the melt-elevation feedback, captured in our experiments through a lapse-rate factor. On the other hand, growing back on a retrograde marine basin needs a strong decrease in ocean temperature due to the hysteresis behavior of the ice sheet. If started from PRISM4 conditions, our Antarctic sea-level estimates increase up to 20 mSLE.

It is important to mention that before the mPWP, CO₂ concentrations were below the pre-Industrial period, with sea-level estimates also below PD, pointing to larger and more extensive ice sheets (Rohling et al., 2014; Stap et al., 2016; Berends et al., 2019). This suggests that cooler conditions prevailed before the mPWP. Therefore, starting from PD initial conditions can help to assess the realism of the simulated mPWP from the AOGCMs. For instance, if retreat of Wilkes basin is a necessary condition for an accurate mPWP representation, then only 3 out of 12 AOGCM models can be considered to realistically simulate warm Pliocene conditions, according to our simulations.

In this study we applied an anomaly method based on climatic snapshots calculated taken from simulated PD and mPWP states for each AOGCM. Applying an anomaly method with respect to PD is a common approach (Tabone et al., 2018; Moreno-

370 Parada et al., 2023). An alternative approach would have been to force our experiments only with the mPWP snapshot directly. The anomaly method, however, greatly reduces any potential bias intrinsic to the AOGCMs.

4.3 Model limitations

As shown by Pattyn et al. (2013), high resolution is needed at the grounding line to simulate accurate grounding-line migrations. In order to overcome this, ice-sheet models use different techniques at the grounding line to compensate for coarse resolution. In
375 our study friction is scaled at the grounding line by the grounded fraction, which is computed via subgrid at the grounding line (a thorough description is presented in Robinson et al. (2020)). Another common approach is to apply flux conditions via Schoof (2007) or Tsai et al. (2015). In Tsai's parameterisation, basal stresses vanish at the grounding line. Such a parameterisation for instance can lead to a collapse of the Wilkes basin in less than 100 years under removal of the ice shelves (Sun et al., 2020; Kazmierczak et al., 2022). Here, we do not impose the flux at the ground line. However, we do ensure that effective
380 pressure, which enters the basal friction equation, tends to zero as the ice thickness approaches flotation (Leguy et al., 2014). Nonetheless, grounding-line parameterisations remain as a source of uncertainty that can strongly influence the retreat of marine based glaciers prone to MISI.

Another source of uncertainty is the melting at the grounding line. Observations have established that the ocean-induced basal melting close to the grounding is the highest and vanishes towards the ice-shelf front (Adusumilli et al., 2020). However,
385 the particular melting implementation at the grounding line is somewhat arbitrary (Seroussi and Morlighem, 2018; Leguy et al., 2021). In many coarse resolution ice-sheet models (more than 2 km resolution at the grounding line), no melting is applied directly at the grounding line since it can lead to overestimations (Seroussi and Morlighem, 2018). Other models avoid melting at the grounding line, but allow for frontal melt. This frontal melt can directly affect the grounding line in the absence of an ice-shelf front (Sun et al., 2020). In our study, no melting was applied at the grounding line. We expect that by adding
390 melting at the grounding line, the collapse of the Wilkes basin would have been more likely for those AOGCM climates with higher oceanic thermal forcing. Given that we do not apply flux conditions or grounding-line melting, our results are more conservative than other studies, as observed in Fig. 5.

In addition, the interpolation scheme applied to climate forcing has also impacted the results of our work. The AOGCMs did not provide any oceanic information for grounded or floating points with a marine bedrock. Since we need that grid information
395 to force our ice-sheet model, we decided to interpolate with the same value as the nearest neighbor at the same depth. Of course, applying other interpolation schemes - and increasing the spatial resolution of the grid - would change the oceanic conditions and lead to potentially slightly different final states. Nonetheless, since our aim here was to assess tipping points of the AIS, we decided to stay with the nearest neighbor interpolation for simplicity.

5 Conclusions

400 Here we investigated the AIS response to mPWP conditions to assess its sea-level contribution during the mPWP and the potential tipping points that could be reached in the coming centuries. We have identified that the WAIS exhibits a tipping

point for an oceanic warming of 0.5 K, as long as regional precipitation remains below that of PD. When the oceanic warming reaches 1 K anomaly, even precipitation similar to today's or higher is unable to prevent a MISI. In the Wilkes basin, a retreat occurs when the oceanic warming reaches 3 K. However, we have observed that high precipitation, up to three times higher
405 than today, can potentially prevent such a retreat. Additionally, we have found that the Totten glacier can also retreat, but only under high oceanic warming conditions of 8 K oceanic anomaly. Regarding ice dynamics, our analysis revealed that the enhancement factor has the strongest influence on the extension of ice. However, we were unable to establish a clear relationship between irreversible retreat and this parameter. In addition, we explored the initialization of the model with an ice-sheet thickness derived from PRISM4. This initialization resulted in a lower AIS in terms of both ice volume and extension
410 due to starting from already retreated marine basins. Consequently, the model initialized with the PRISM4 ice-sheet thickness displayed persistent differences in simulated AIS characteristics compared to other initializations.

Our study focused on tipping points that our ice-sheet model exhibits under mPWP scenarios. A way to gain insight into tipping-point behaviors of ice sheets would be to perform an intercomparison between different ice-sheet models and analyze different sources of uncertainty, like grounding-line basal melt, basal friction at the grounding line or resolution, among others.
415 In this study we aimed to contribute to this discussion by testing dynamic sources of uncertainty in the Yelmo ice-sheet model under mPWP climatic forces in the framework of the PlioMIP2 project. Our ensemble analysis suggests that the WAIS tipping point is close to being crossed, and that even a lowering of PD precipitation could lead to such an irreversible retreat. Other basins, such as the Wilkes basin, show tipping behavior but for considerably larger oceanic anomalies.

Finally, our simulated sea-level contributions ranged from -1.8 mSLE to -9.6 mSLE considering the whole ensemble. These
420 contributions are in agreement with geological constraints which do not exceed global sea-level stands above 20 mSLE. However, the collapse of the Wilkes basin is a necessary condition in order to achieve Antarctic sea-level rises above 5 mSLE. Ultimately, MICI mechanism is not a necessary condition for a collapse of the Wilkes basin, since high oceanic temperatures can also lead to such a collapse. Our sea-level estimates as well as grounding-line migrations reinforce the hypothesis that crossing of several Antarctic tipping points is necessary for large sea-level standings at the mPWP.

425 **Code and data availability**

Yelmo is maintained as a git repository hosted at <https://github.com/palma-ice/yelmo> under the licence GPL-3.0. Model documentation can be found at <https://palma-ice.github.io/yelmo-docs/>. The results used in this paper will be made available on Zenodo once published.

λ_3	$^{\circ}\text{C m}^{-1}$	$7.59 \cdot 10^{-4}$	Liquidus pressure coefficient

Table 1. Table summarizing the model parameters.

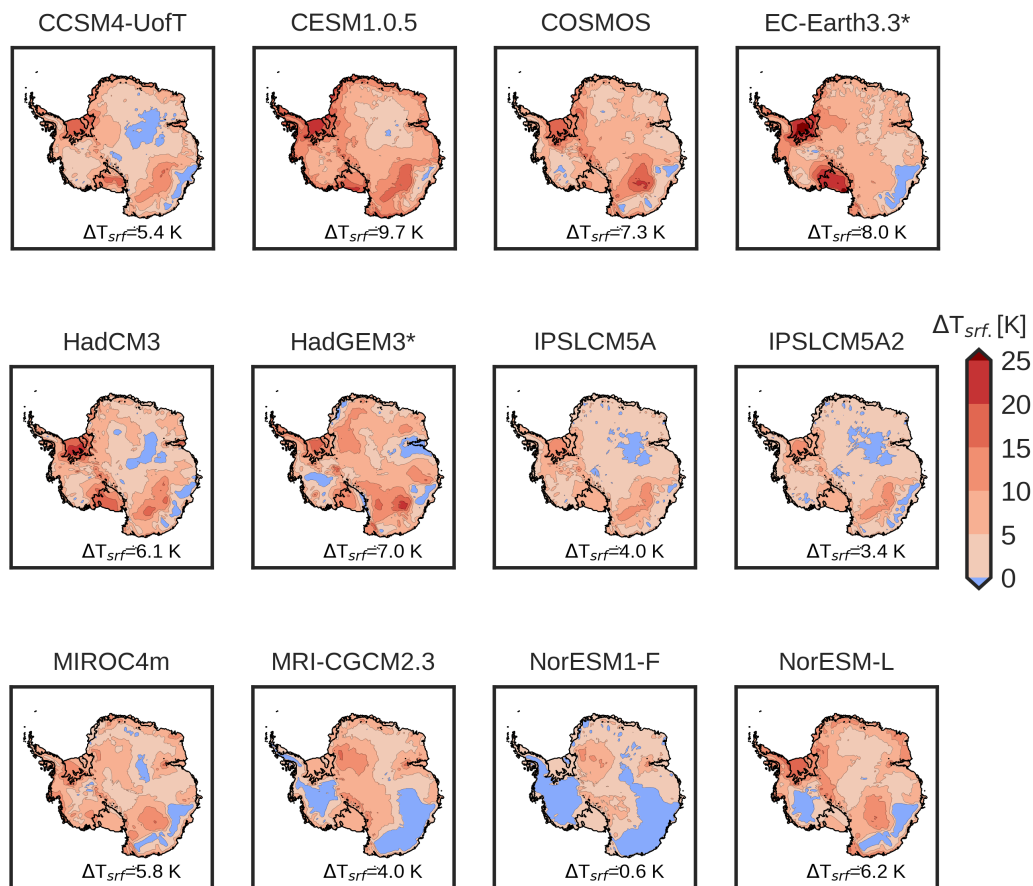

Figure 1. Surface temperature anomaly fields of the employed PlioMIP2 AOGCMs. Negative values (blue colors) represent a colder surface temperature than PD. Positive values (red colors) indicate a warmer surface temperature than PD. Numbers on the lower right corner shows the mean temperature anomaly inside the PD Antarctic domain (contour lines of the Antarctic grounding-line and ice shelves). CMIP6 models are marked with an asterisk.

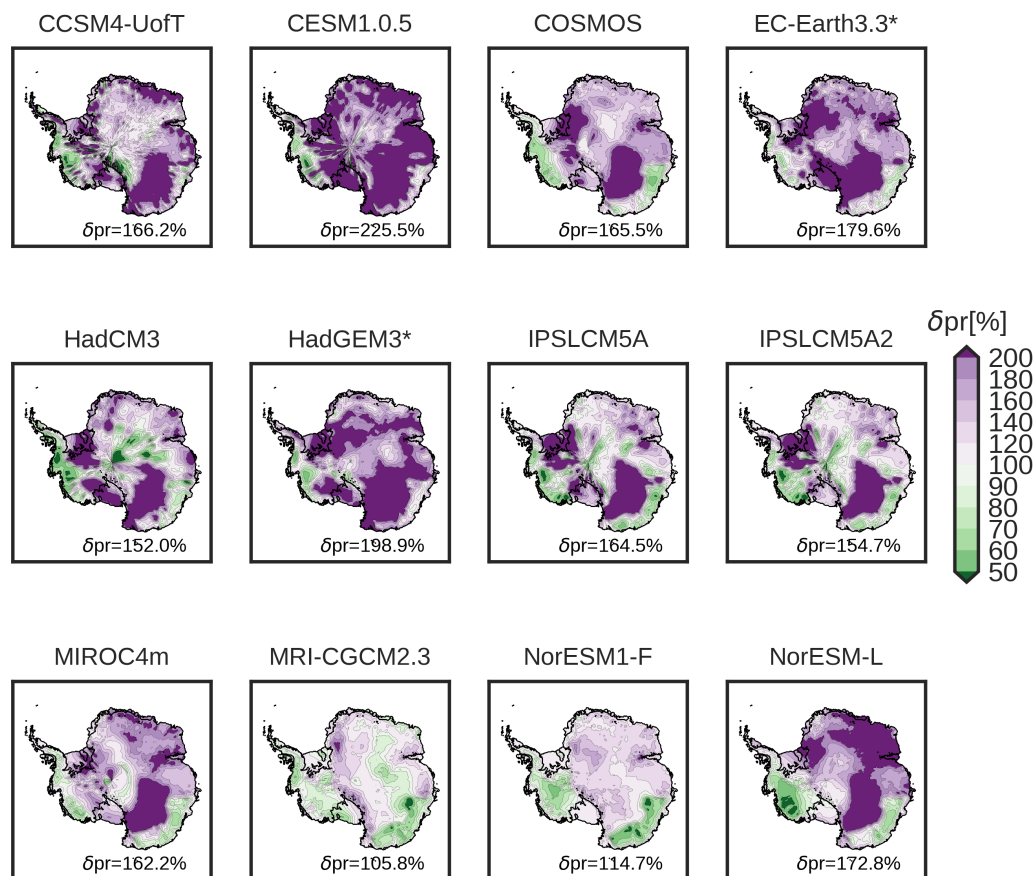

Figure 2. Relative precipitation anomaly fields of the employed PlioMIP2 AOGCMs. Values below 100% (green colors) represent a dryer climate (less precipitation than PD). Values above 100% (purple colors) indicate more precipitation than PD. Numbers on the lower right corner shows the mean relative precipitation anomaly inside the PD Antarctic domain (contour lines of the Antarctic grounding-line and ice shelves).

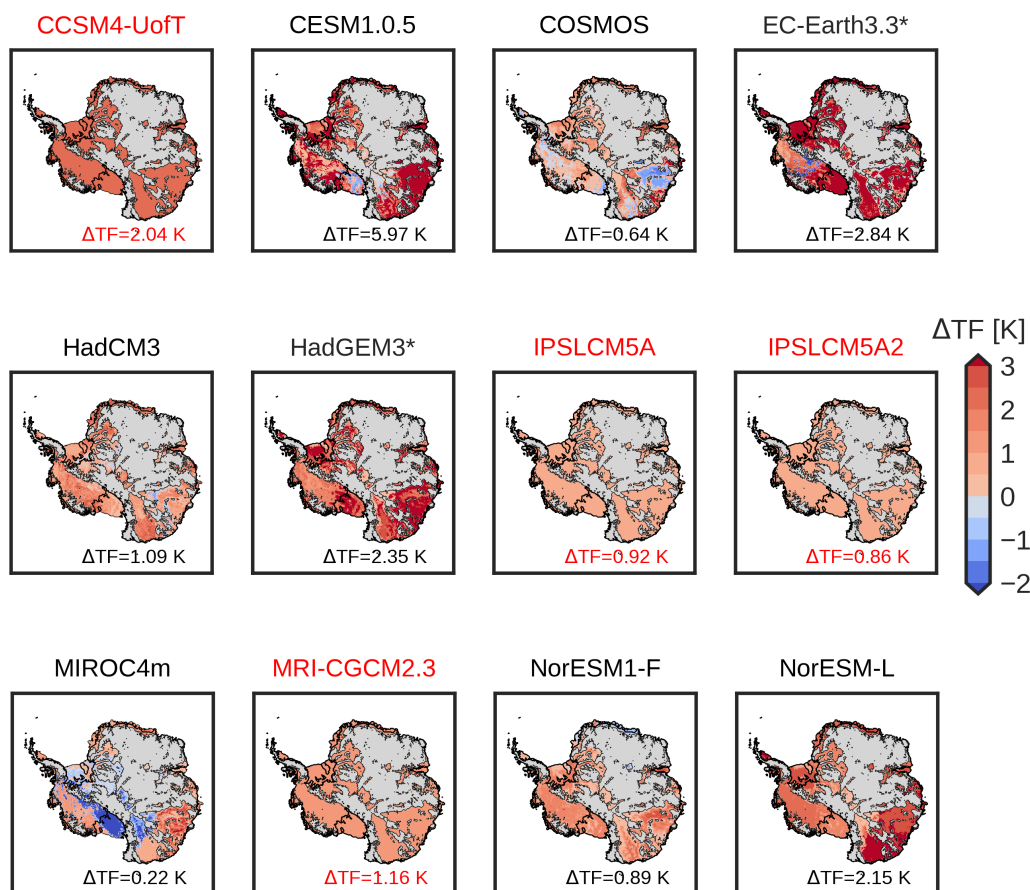

Figure 3. Ocean thermal forcing temperature anomaly fields at the ice-ocean interface of the employed PlioMIP2 AOGCMs. Positive values (red colors) indicate a warmer bed-ocean temperature than PD. Gray colors indicate a bedrock above sea level and thus, with no ice-ocean interaction. The number on the lower right corner shows the mean bed-temperature anomaly inside the PD Antarctic domain (contour lines of the Antarctic grounding-line and ice shelves). Models in red are AOGCMs that did not provide any ocean field. The inferred ocean field was obtained as a mean of the atmospheric temperatures scaled by a fraction of 1/4 (Taylor et al., 2012).

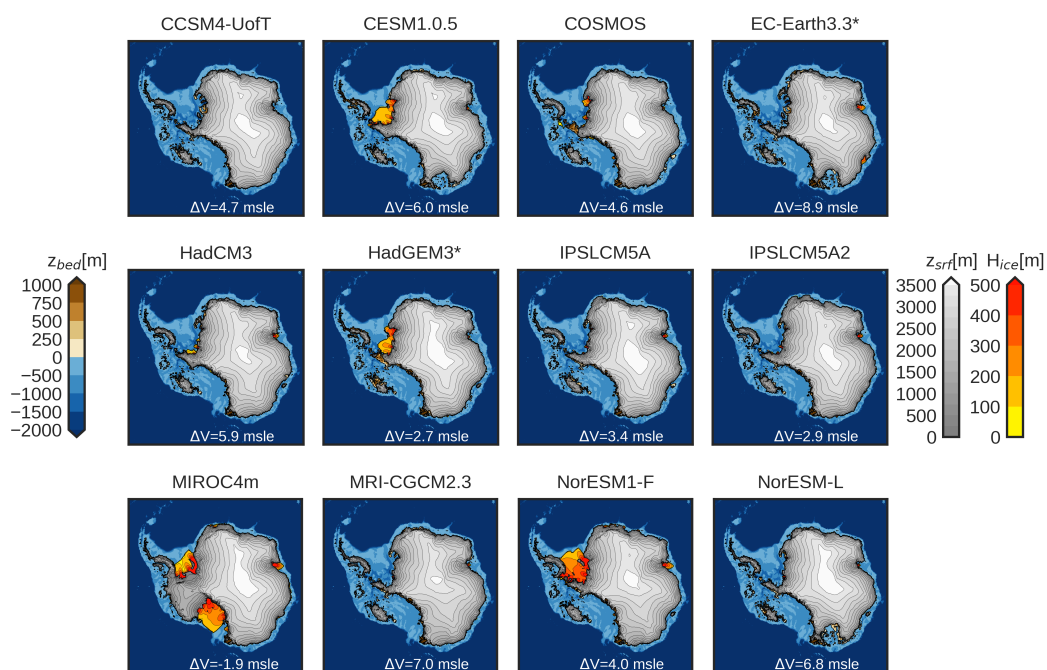

Figure 4. Surface elevation (gray), floating ice thickness (orange) and bedrock elevation (brown/blue) of the simulation closest to the mean ice volume and ice extension of the ensemble for every AOGCM starting from PD bedrock conditions. White number in the bottom corner represents the sea-level rise with respect to the PD state.

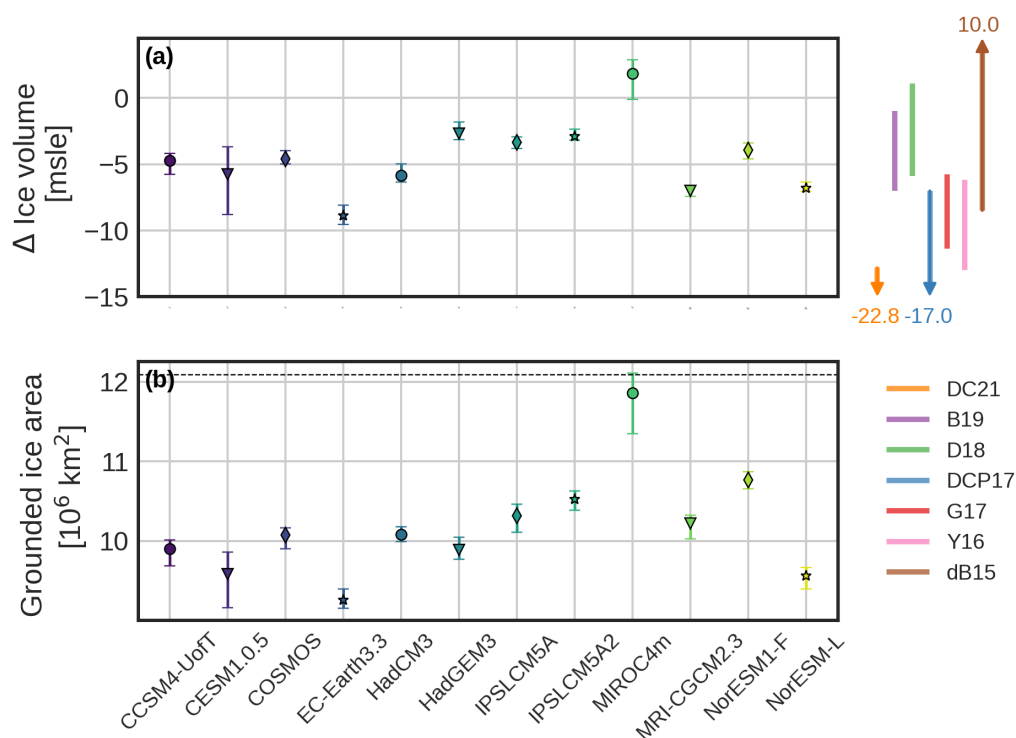

Figure 5. Scatter plot of the simulated (a) ice volume differences with respect to the simulated PD (negative/positive numbers indicate a lower/higher ice volume); (b) grounded ice extensions for every AOGCM. The scatter-point shows the mean values of the ensemble. The error bars represent the lowest/highest simulated AIS state starting from PD conditions. Light shaded colors at the right show the sea-level uncertainty ranges from the studies of deBoer et al., (2015, brown); Yan et al., (2016, pink); Golledge et al., (2017, red); DeConto and Pollard (2017, blue); Dolan et al., (2018, green); Berends et al., (2019; purple); DeConto et al., (2021, orange). The dashed black line in (b) represents the PD grounded ice extension.

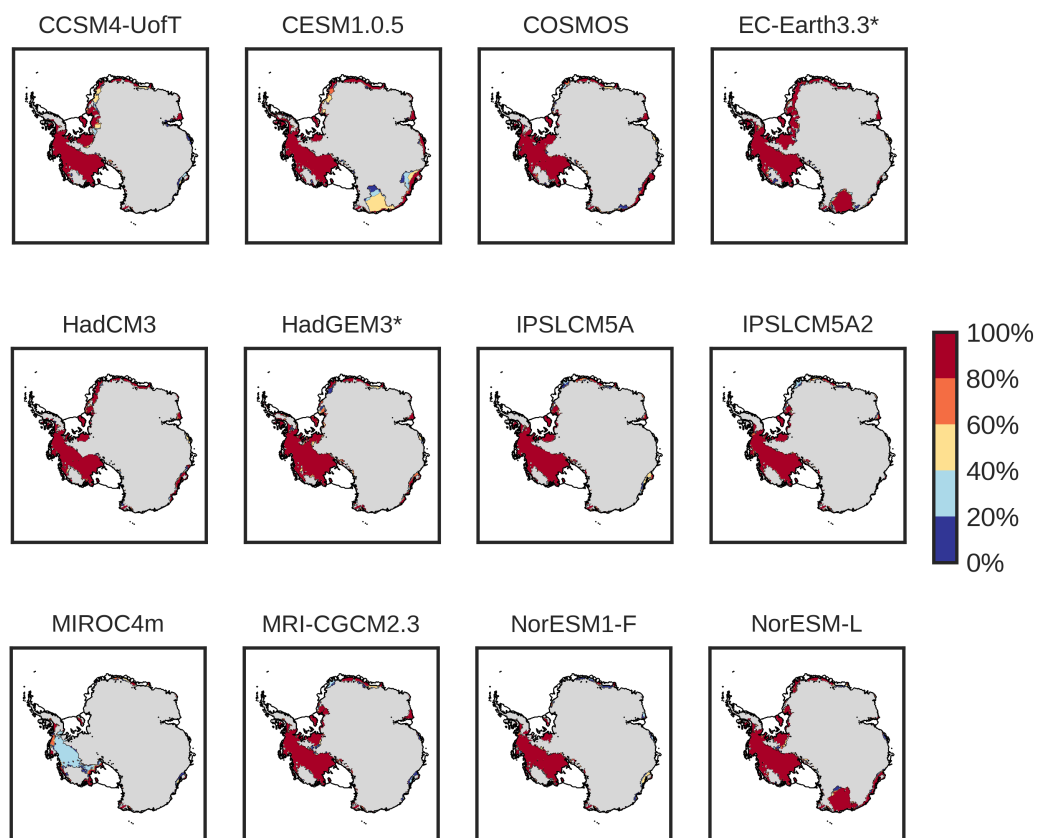

Figure 6. Ice-collapsed probability of the ensemble for every AOGCM. Red colors indicate a high probability of collapsed regions. Blue colors indicate a low probability of collapsed regions. Gray colors show grounded ice for all the ensemble simulations.

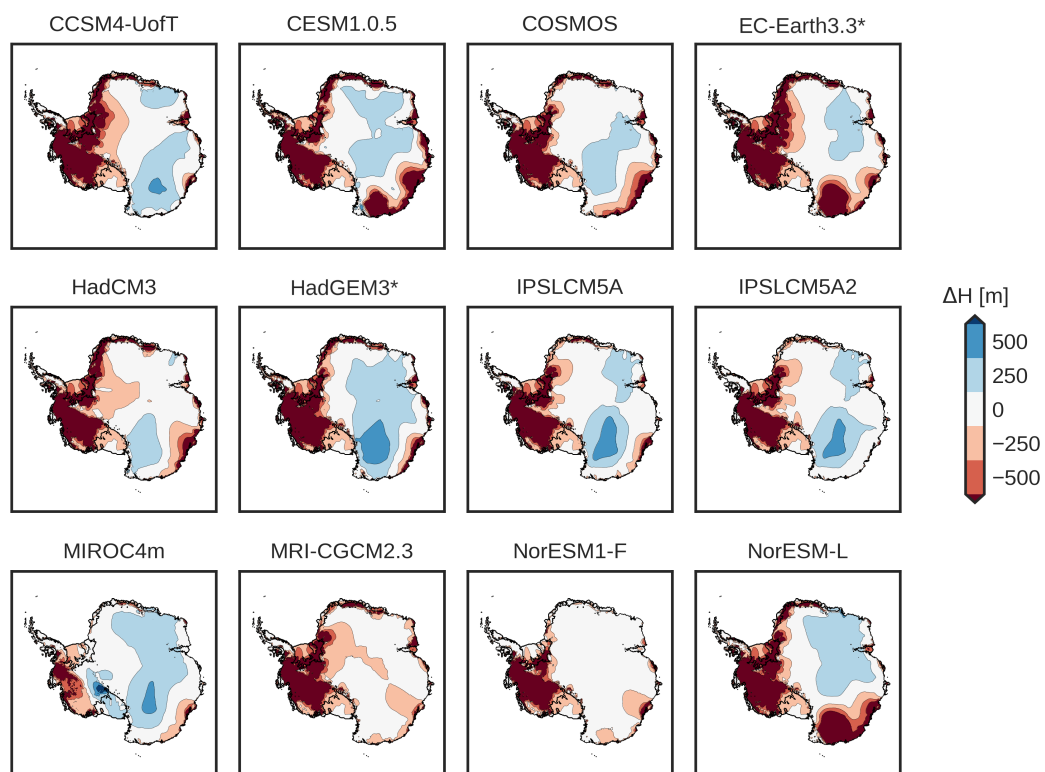

Figure 7. Mean ice-thickness anomaly between the mPWP state and the PD state. Positive/negative numbers (blue/red) represent a thicker/thinner ice column than the simulated PD.

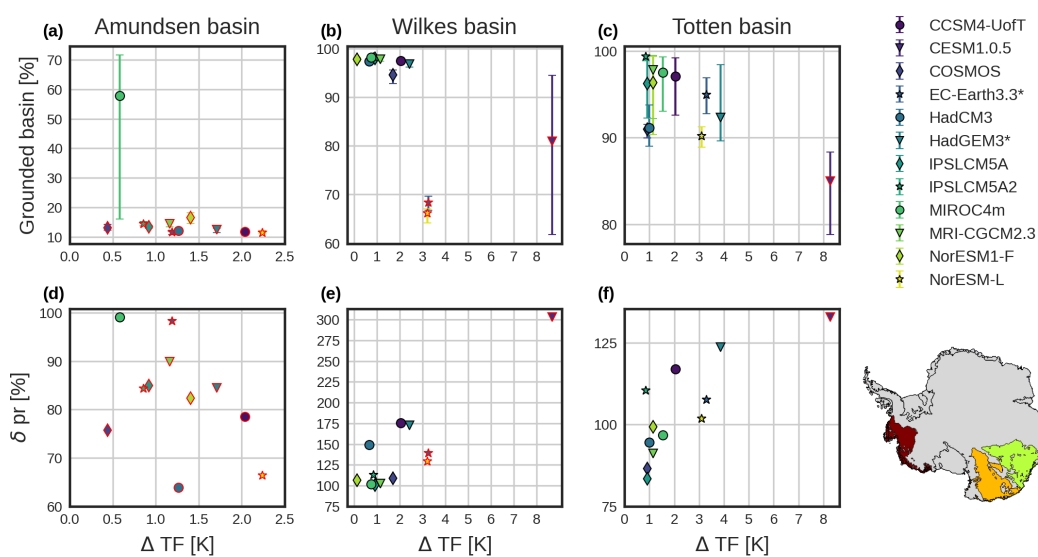

Figure 8. Scatter plot of grounded simulated AIS ice area at the mPWP (in percentage of the marine basin as in Fig. S3) with respect to the thermal forcing anomaly for (a) Amundsen basin; (b) Wilkes basin; (c) Totten basin in the retreated regions (Basins in Fig. S3). The error bars represent the lowest/highest simulated AIS state. (d- f) Same as a-c but for the relative precipitation anomaly relative to PD. Red borders represent either collapsed marine basins or more retreated than the rest of AOGCMs. In the bottom right corner the regions of interest are highlighted: Dark-Red: Amundsen. Orange: Wilkes. Green: Totten.

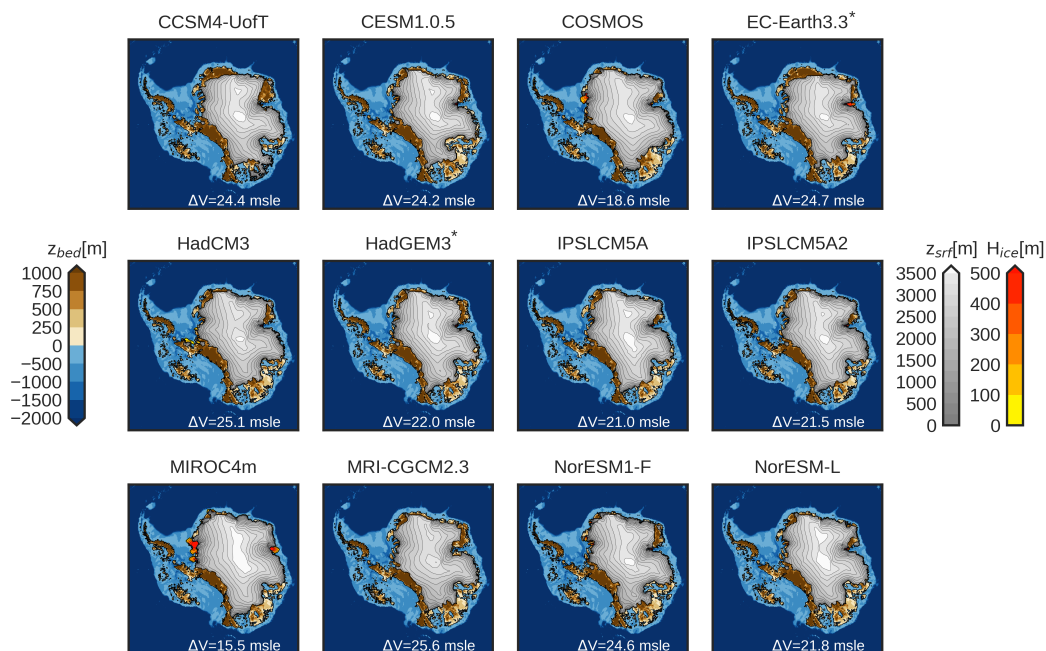

Figure 9. Surface elevation (gray), floating ice thickness (orange) and bedrock elevation (brown/blue) of the simulation closest to the mean volume and extension of the ensemble for every AOGCM forcing, starting from PRISM4 boundary conditions. White numbers in the bottom represent the sea-level rise with respect to the PD state.
