11 Abstract

12

13 Variations of the Atlantic Meridional Overturning Circulation (AMOC) are associated with
14 Northern Hemispheric and global climate shifts. Thermal thresholds of the AMOC have been
15 found in a hierarchy of numerical circulation models, and there is an increasing body of
16 evidence for the existence of highly sensitive AMOC modes where small perturbations can
17 cause disproportionately large circulation and hence climatic changes. We discovered such
18 thresholds in simulations with the intermediate complexity Earth system model Bern3D,
19 which is highly computationally efficient allowing for studying this non-linear behaviour
20 systematically over entire glacial cycles. By simulating the AMOC under different magnitudes
21 of orbitally-paced changes in radiative forcing over the last 788,000 years, we show that up
22 to three thermal thresholds are crossed during glacial cycles in Bern3D, and that thermal
23 forcing could have destabilised the AMOC repeatedly. We present the circulation and sea
24 ice patterns that characterise the stable circulation modes between which this model
25 oscillates during a glacial cycle, and assess how often and when thermal forcing could have
26 preconditioned the Bern3D AMOC for abrupt shifts over the last 788 kyr.

27

28 1 Introduction

29

30 The Atlantic Meridional Overturning Circulation (AMOC) transports warm waters from the
31 Southern Hemisphere and the Mexican Gulf towards the Nordic Seas, until the gradually
32 cooled salty water lost enough buoyancy and sinks, forming North Atlantic Deep Water
33 (NADW). This water mass moves southwards along the western boundary of the Atlantic
34 until it encounters the denser Antarctic Bottom Water (AABW) and slowly rises and upwells
35 in the Southern Ocean, being ultimately incorporated either into AABW or the lighter
36 Antarctic Intermediate Water (AAIW). The northward heat transport of the AMOC shapes
37 regional climate by pushing the polar front north by several degrees of latitude, effectively

38 producing a climate in Europe and Greenland that is milder than predicted from
39 latitude/insolation alone (Ruddiman and McIntyre 1981, Bard et al. 1987). It also affects
40 global climate by shifting the Intertropical Convergence Zone (ITCZ) and monsoon systems
41 (Wang et al., 2001, Bozbiyik et al., 2011), and interacting with the regional climate and deep
42 water formation in the North Pacific (Okazaki et al., 2010, Menviel et al., 2012, Praetorius
43 and Mix, 2014). The AMOC furthermore shapes biological surface productivity by regulating
44 nutrient supply to the surface ocean in the Atlantic and Pacific (Tetard et al., 2017, Joos et
45 al., 2017). On its southward path in the Atlantic, it influences deep ocean nutrient, carbon,
46 and oxygen concentrations (Broecker, 1991). By affecting primary production and deep
47 ocean carbon storage, AMOC changes also modulate atmospheric greenhouse gas
48 concentrations (e.g. Menviel et al., 2008). Rapid changes in AMOC and hence Atlantic heat
49 and carbon redistribution occurred repeatedly during the last glacial, termed Heinrich
50 (Heinrich, 1988, Broecker, 1994) and Dansgaard-Oeschger events (Oeschger et al., 1984,
51 Dansgaard et al., 1993), which had regional and global impacts on ecosystems and humans
52 (e.g. Severinghaus et al., 2009, Timmermann and Friedrich, 2016). Yet, the factors
53 determining AMOC stability are not fully understood.

54

55 As part of the thermohaline circulation, the AMOC is sensitive to both salinity and thermal
56 forcing. Depending on the location of deep water formation in both hemispheres, the AMOC
57 can switch between stable circulation states - either gradually or abruptly - as local vertical
58 density profiles, sea ice extent, and meridional heat and salinity gradients change. Numerical
59 experiments showed that large freshwater inputs into the North Atlantic can theoretically
60 cause abrupt shifts from a vigorous circulation state to a temporarily subdued or collapsed
61 circulation (e.g. Stocker and Wright, 1991, reviews by Weijer et al., 2019, Jackson et al.,
62 2023). Such possible shifts of circulation state were first identified in box models (Stommel
63 1961) and confirmed in intermediate complexity models and global circulation models
64 (Jackson and Wood, 2018, review in Jackson et al., 2023). Systematic testing of AMOC
65 stability is done more easily in lower complexity models than General Circulation Models
66 (GCMs), but the existence of multiple AMOC equilibria seems to be determined by the
67 model-dependent existence and strength of feedbacks, with more complex models including
68 more, possibly counteracting, feedbacks (Weijer et al., 2019). AMOC bistability could explain
69 reconstructed sudden AMOC state shifts in the Pleistocene, possibly caused by large
70 freshwater fluxes from melting continental ice shields and increased iceberg transport into
71 the North Atlantic at the onset of Heinrich Events (Broecker, 1994, Grousset et al., 2000).
72 Lags between the appearance of ice-rafted debris and the reconstructed cooling, however,
73 suggest that freshwater fluxes could have instead acted as a positive feedback to AMOC
74 weakening rather than triggering it (Barker et al., 2015).

75

76 Besides Heinrich event-like AMOC shifts to a less vigorous circulation in response to strong
77 freshwater forcing, there is increasing evidence for metastable AMOC states in-between the
78 glacial and interglacial circulation end-members. In some numerical models, and for narrow
79 parameter ranges (e.g. atmospheric CO₂ concentrations, ice sheet configurations), the
80 AMOC in such intermediate climate states is sensitive to small internal or external variability
81 and can sustain spontaneous oscillations (e.g. Aeberhardt et al., 2000, Knutti et al., 2002,
82 Zhang et al., 2014, Zhang et al., 2017, Brown and Galbraith, 2016, Vettoretti et al., 2022,
83 review of CMIP6 models in Malmierca-Vallet et al., 2023). Some of these oscillations could
84 be analogues to Dansgaard-Oeschger events that have been identified during intermediate
85 glacial climate conditions, specifically during Marine Isotope Stage (MIS) 3, and are thought
86 to be caused by internal feedbacks that amplified small changes of the North Atlantic salinity
87 balance (Zhang et al., 2014, Zhang et al., 2017, Vettoretti et al., 2022, Armstrong et al.,
88 2022). Meteoric and terrestrial freshwater input to the surface ocean are climate-dependent,
89 as is ice rafting and the salt rejection associated with sea ice formation. These processes
90 are thus impacted by, and impact themselves, the AMOC (Barker et al., 2015). Feedbacks
91 similarly exist for the salinity transport from the tropics to the North Atlantic, global circulation
92 patterns, and the salinity gradients which determine salt transport into the Atlantic basin
93 through the Bering Strait, Drake Passage, and from the Indian Ocean (e.g. Rahmstorf 1996).
94 Besides salinity changes, numerical experiments with GCMs also showed that the vertical
95 temperature profile affects AMOC stability (Haskins et al., 2020). Short-term AMOC
96 weakening in response to warming has been simulated by a wide range of GCMs (e.g.
97 Mikolajewicz et al., 1990, Gregory et al., 2005, Weijer et al., 2020). Thermal forcing of the
98 North Atlantic has also been found to cause longer term gradual changes in AMOC strength
99 in intermediate and higher resolution models (Manabe and Stouffer, 1993, Stocker and
100 Schmittner, 1997, Knorr and Lohmann, 2007, Zhang et al., 2017, Galbraith and Lavergne,
101 2019). In addition, bistability of AMOC under thermal forcing has been found in uncoupled
102 and coupled GCMs (Oka et al., 2012, Klockmann et al., 2018), and thermal forcing,
103 especially of the Southern Ocean, can cause abrupt AMOC state transitions similar to hosing
104 in the North Atlantic (Oka et al., 2021, Sherriff-Tadano et al., 2023). An important process in
105 the cooling-driven weakening of AMOC is the covering of former deep convection sites with
106 sea ice, which then causes a southward shift of deep convection (Oka et al., 2012). Such a
107 southward shift is only possible if the water column south of existing convection sites is
108 sufficiently destabilised by climate-driven density changes (Ganopolski and Rahmstorf,
109 2001).

110

111 So far, simulations of thermal AMOC thresholds have mostly been conducted with
112 computationally expensive numerical models, and the implications of the existence of AMOC
113 instability and thermal thresholds have not been tested across entire glacial cycles. While
114 providing crucial process understanding, direct comparisons of these simulations to proxy
115 records are therefore challenging.

116

117 Here, we demonstrate the existence of hysteresis and mode shifts in the AMOC in the
118 intermediate complexity model Bern3D, in the absence of freshwater hosing. Instead, we
119 only apply changes in the radiative forcing to the atmosphere-ocean system. We provide a
120 comprehensive description of the underlying processes and elucidate the influence of
121 radiative changes on the AMOC dynamics in the Bern3D model during orbitally-forced
122 glacial-interglacial cycles.

123

124 **2 Methods**

125

126 We employed the Bern3D intermediate complexity model version 2.0 (Müller et al., 2006,
127 Roth et al., 2014) to investigate the AMOC behaviour under a wide range of radiative forcing.
128 The Bern3D model comprises a 3D ocean component with a 40x41 horizontal grid and 32
129 depth layers, along with a 2D atmosphere (spatially-explicit energy-moisture balance with
130 prescribed wind fields) and dynamic sea-ice. The model explicitly calculates the thermo-
131 haline circulation with a frictional-geostrophic flow (Edwards et al., 1998) and contains
132 parameterizations to account for isopycnal diffusion and eddy-turbulence via the Gent-
133 McWilliams parameterization (Griffies, 1998). Temperature and salinity are dynamically
134 transported by the physical ocean model and respond to static seasonal wind fields and
135 changing atmospheric 2D energy and moisture balance, sea ice formation and external
136 forcings. Bern3D explicitly calculates Pacific-Atlantic transport through the Bering Strait, and
137 freshwater flux corrections are only imposed in the Weddell Sea, and compensated for in the
138 Southern Ocean to induce stronger deep water formation (Ritz et al., 2011, Roth et al.,
139 2014).

140

141 Table 1: Overview of the model experiments in this study. In set A, radiative forcing from
142 dust is scaled linearly with $\delta^{18}\text{O}$ and assuming different magnitudes at LGM as given in
143 parentheses.

144

Simulation Set	Simulation ID	Starting point and length	Forcing	Purpose

145

146

147 We conducted two sets of simulations with the Bern3D model (Table 1). In set A, comprising
148 nine simulations, we fully transiently simulated the last 788 kyr by imposing changes in
149 orbital configuration, ice sheet albedo, and globally-averaged radiative forcing from the well-
150 mixed greenhouse gases (GHG) CO₂ and CH₄ (combined here labelled as the ‘standard
151 forcing’). The runs started from an interglacial steady state (50 kyr with pre-industrial (PI)
152 conditions and 2 kyr of re-adjustment to the radiative balance of MIS 19c). Orbital (Berger,
153 1978, Berger and Loutre, 1991), GHG (Bereiter et al., 2015, Loulergue et al., 2008, Joos and
154 Spahni, 2008), and ice sheet albedo forcing (i.e. the standard forcing) is identical in each run
155 (Fig. 1). Ice sheet albedo changes are calculated based on the benthic δ¹⁸O LR04 stack
156 (Lisiecki & Raymo, 2005) smoothed by averaging over a 10000-year moving window for the
157 past 788 kyr.

158

159 The LR04 stack was chosen because it is the only complete record with constant temporal
160 resolution over the simulated period. In our experiments, we applied spatially-uniform
161 radiative forcings, to account for uncertainties in the glacial radiative balance, e.g. uncertain
162 atmospheric optical depth changes due to changes in aerosols and dust, in addition to the
163 better constrained temperature changes due to orbital changes and greenhouse gases,
164 hence termed dust forcing. The scale of this forcing varies between the simulations and
165 transiently within each simulation. The maximum radiative dust forcing, defined via the peak

166 LGM value in the smoothed $\delta^{18}\text{O}$ stack, is a free parameter, ranging from 0 to -8 W/m^2
167 relative to PI (Simulations A.0 to A.8). To construct the forcing, we scaled the maximum
168 forcing linearly with the smoothed LR04 stack, given the close correlation of reconstructed
169 dust fluxes and ice volume likely due to the dominant role of wind fields, sea level, and
170 hydrological cycle on dust fluxes (Winckler et al., 2008). The range of the resulting combined
171 radiative forcing is between -3 and -10 W/m^2 . This range brackets estimates of maximum
172 reductions in global mean radiative forcing at the LGM of $7 - 8 \text{ W/m}^2$ due to albedo,
173 greenhouse gas, and aerosol effects (Albani et al., 2018). The imposed forcings resulted in
174 global mean surface temperature (GMST) differences between the LGM and PI of -3 to -9.6
175 $^\circ\text{C}$. This temperature range encompasses most of the LGM-PI range reported in studies
176 investigating the Paleo Model Intercomparison Project (PMIP) 2, PMIP3, and PMIP4, which
177 range from -3.1 to $-7.2 \text{ }^\circ\text{C}$ (Masson-Delmotte et al., 2013, Kageyama et al., 2021).

178

179 Furthermore, these simulations are also consistent with proxy-based reconstructions that
180 indicate GMST differences between -2 and $-8 \text{ }^\circ\text{C}$ (Tierney et al., 2020), as well as covering
181 the $-6.1 \text{ }^\circ\text{C}$ GMST difference as constrained by a recent data assimilation study with the
182 CESM model (Tierney et al., 2020). It is important to note that we only considered the
183 radiative effect of an assumed uniform distribution of aerosols in our simulations. In reality,
184 this distribution would be non-uniform and aerosols would have additional effects on
185 atmospheric freshwater fluxes, two factors which are both relevant for AMOC stability
186 (Menary et al., 2013) but are poorly constrained for the last 788 kyr. Furthermore, freshwater
187 fluxes associated with the build-up and disintegration of continental ice sheets and glaciers
188 were not taken into account in any of the simulations presented here. We also kept the
189 topography constant and do not close the Bering Strait during glacial states.

190

191 Simulation set B (Tab. 1) was designed to investigate the mechanisms behind radiation-
192 driven AMOC changes under more idealised boundary conditions. This simulation set
193 includes one long run with “slowly” changing radiative forcing (105 kyr, B.slow), five short
194 simulations with “fast” changing forcing (25 kyr, B.fast), and four simulations branched off
195 from B.slow at different points in time. B.slow started from a pre-industrial state, followed by
196 a linearly decreasing negative radiative forcing over 50 kyr, followed by a linear increase of
197 forcing back to the initial state also over 50 kyr (Figure 4). We continued the simulation for
198 an additional 5 kyr under constant, pre-industrial conditions to let the model re-equilibrate.
199 The setup of B.fast.PI is analogous to B.slow with the radiation decrease and consecutive
200 increase spanning 20 kyrs. The simulations started from a steady state with pre-industrial
201 orbital and GHG configuration, and were run with orbital configurations of PI, 21, 30, 50 and

202 80 kyrBP (simulations B.fast.PI, B.fast.21ka, B.fast.30ka, B.fast.50ka, B.fast.80ka,
203 respectively).

204

205 At four specific time points in B.slow, we branched off simulations to test the AMOC stability
206 by keeping all forcings constant, but at the same time applying a small freshwater hosing to
207 the North Atlantic (45°N-70°N) with a magnitude of 0.1 Sv over 100 years. If the AMOC is in
208 a stable mode i.e. far from a bifurcation point, it should recover from these freshwater
209 perturbations returning to its initial strength, while an unstable AMOC close to a bifurcation
210 point should transition into a new circulation mode.

211

212 We incorporated three passive circulation tracers ('dyes') in set B. Each of these dye tracers
213 is restored to 1 at the surface of a chosen region (Fig. SI.1), and to zero elsewhere in the
214 surface ocean, and has no sources or sinks below the surface. In the deep ocean, the dye
215 tracer concentration is hence diluted only by mixing with other water masses sourced from
216 other regions. These artificial dye tracers allow us to track the dispersal of North Atlantic
217 Deep Water (NADW), Antarctic Intermediate Water (AAIW) and Antarctic Bottom Water
218 (AABW) in the ocean interior.

219

220

221 **3 Results and Discussion**

222

223 We first investigate the response of the AMOC to changes in orbital configuration and
224 radiative forcing as transiently simulated in our 788 kyr-long simulations of set A. We aim to
225 provide a comprehensive understanding of radiation-driven AMOC dynamics on glacial-
226 interglacial timescales. Subsequently, we utilise the more idealised setup of simulation set B
227 to further examine the underlying mechanisms driving these changes in more detail.

228

229

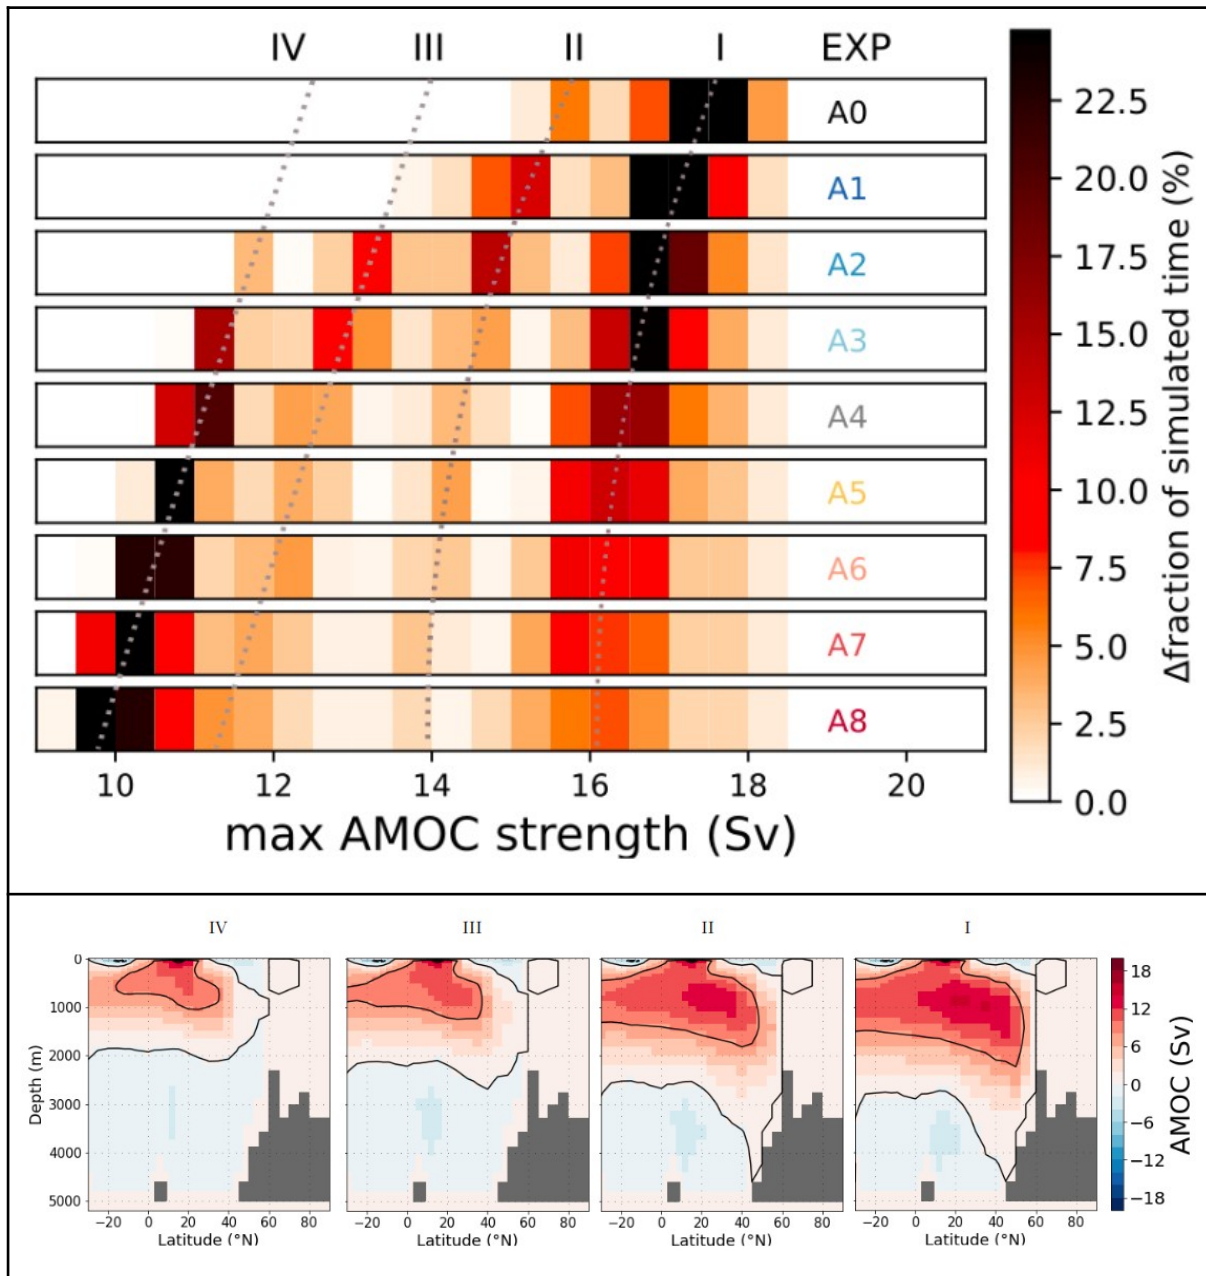

230 **3.1. AMOC changes over the past eight glacial cycles**

231
 232 Figure 1: Forcings, AMOC and temperature response over the last 125 kyr of simulation
 233 ensemble A. The upper three panels show July Insolation at 65°N, benthic $\delta^{18}\text{O}$ (10 kyr
 234 spline of LR04, Lisiecki and Raymo, 2005) used to scale the dust forcing and the combined
 235 effect of our dust forcing for each simulation and reconstructed atmospheric CO_2 changes
 236 (Bereiter et al., 2015), smoothed with a second-order lowpass filter (cutoff frequency:
 237 1/2000). The lower two panels show the 500 yr running mean of simulated AMOC strength
 238 and GMST deviations from the PI in every simulation of simulation set A. Colours in the
 239 lower two panels differentiate between simulations with different amplitudes of the radiative
 240 forcing (see Methods).

241
 242 In our simulations, radiative forcing- and orbitally-driven temperature changes resulted in
 243 both gradual and abrupt AMOC shifts during each of the last eight glacial cycles (Fig. SI.2).
 244 Fig. 1 illustrates the simulated AMOC threshold behaviour during these changes over the
 245 entire last glacial cycle (past 125 kyr) with the different dust forcing scalings. Abrupt changes
 246 in AMOC strength occurred in every simulation, with larger changes occurring under
 247 stronger forcing. The magnitude of the dust forcing also determined the phase of the glacial
 248 cycle during which the AMOC is most sensitive to radiative forcing: pronounced reductions in
 249 radiative forcing under strong scaling resulted in a shift to the weakest AMOC mode early in
 250 the last glacial cycle, which is from then on insensitive to further changes induced by
 251 additional reductions in radiative forcing later on. Conversely, under weaker scaling, the

252 initial decrease in forcing was insufficient to shift the AMOC out of its interglacial circulation
 253 mode.
 254
 255

256 Figure 2: Top: Fraction of each simulation in simulation set A (each over 788 kyr) during
 257 which a given maximum AMOC strength was simulated. Each row shows the results of one
 258 simulation, with the simulation ID on the right end of the column in colours that correspond to
 259 the lines in Fig 1. The bins are 0.5 Sv wide and four relative maxima in occurrence,
 260 exhibiting distinct AMOC modes, I – IV, are indicated by dotted lines. Bottom: AMOC stream
 261 function for the four circulation modes adopted across the last glacial cycle in simulation A3.
 262

263 All simulations revealed multiple intermediate circulation modes between the glacial and
264 interglacial end-members. These modes manifested as distinct bands of increased
265 occurrence in Fig 2, which displays the fraction of the entire simulated period of 788 kyr
266 during which the AMOC exhibited a given maximum strength (binned into 0.5 Sv intervals).
267 The two intermediate modes II and III are distinguishable by AMOC strength, but not by their
268 meridional temperature or salinity gradients (Fig. SI.4), which questions whether these are
269 indeed separate circulation modes or expressions of one single mode that can have different
270 AMOC strengths (Lohmann et al. 2023). Yet, these circulation modes differ in global mean
271 and Greenland temperatures and North Atlantic Sea ice cover, suggesting that they are still
272 separate climate states (Fig. SI.5). Thus, we identified four frequently occurring circulation
273 modes in simulation set A that can be distinguished by AMOC strength, sea ice and
274 temperature, and three which can be distinguished by meridional temperature and salinity
275 gradients.

276

277 AMOC transitioned between these modes across the simulated glacial cycles due to
278 radiative forcing (Fig 2). The glacial and interglacial 'end-member' circulation modes I and IV
279 occurred most commonly: The AMOC was in either of these two modes for 62-85% of the
280 simulated 788 kyr, depending on the dust forcing scaling. The AMOC was found in the
281 intermediate circulation modes II and III most commonly under weak dust forcing. For
282 stronger forcings, AMOC transitioned quickly through these modes, which were therefore
283 less frequently occupied. Thus, it appears that there is a tendency towards bi-modal AMOC
284 stability under strong forcing scaling, where the AMOC was almost exclusively either in the
285 glacial or interglacial circulation mode. Once AMOC had adopted the weakest mode,
286 additional reductions in radiative forcing only caused minor additional and gradual AMOC
287 weakening and did not cause another abrupt transition.

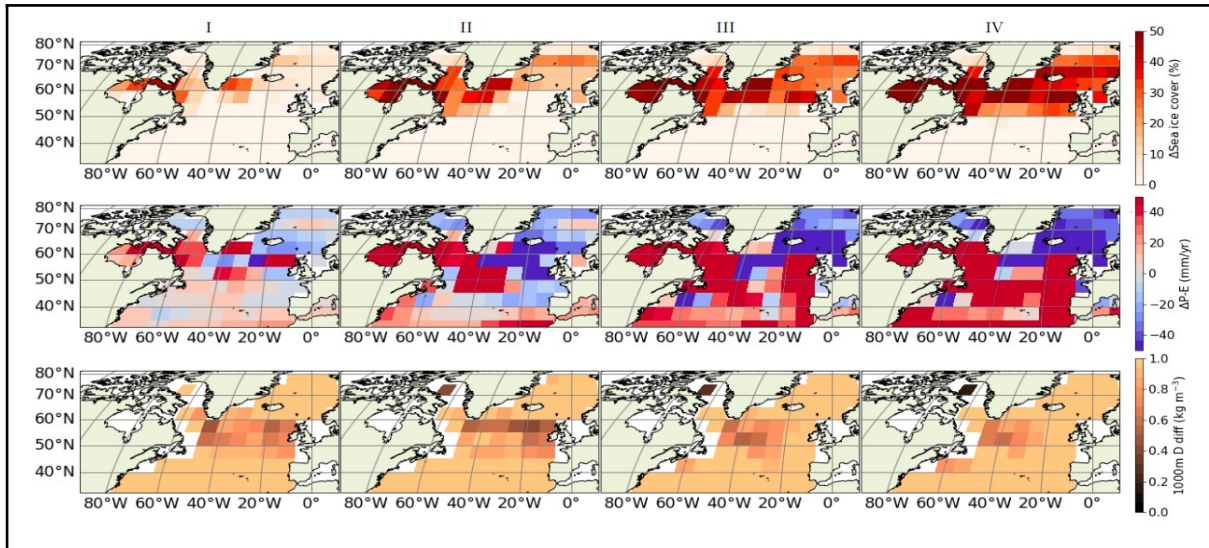

288

289 The simulations A3 and A4 with intermediate glacial-interglacial temperature changes (LGM-
290 PI Δ GMST -5 to -6 °C, similar to the -6.1 °C constrained by Tierney et al., 2020)
291 predominantly exhibited AMOC transitions between the interglacial (mode I, ~16-17 Sv) and
292 glacial mode (mode IV, ~11 Sv), with two rarer intermediate circulation modes in-between.

293

294

295 Figure 3: Initial annually averaged sea ice cover, meteoric freshwater balance, and the
 296 density difference over the uppermost 1000 m of the water column in the North Atlantic
 297 (upper panel). Changes of the annually averaged sea ice cover, meteoric freshwater
 298 balance, and the density difference over the uppermost 1000 m of the water column over the
 299 first 30 kyr of simulation B.slow in the lower panel.

300

301 The interglacial circulation mode (mode I in Figs. 2 and 3) is characterised by NADW
 302 formation in the subpolar North Atlantic, specifically south of Greenland and close to the
 303 British Isles, as indicated by the small density difference over the upper 1000 m of the water
 304 column. In the first intermediate AMOC mode (II), deep water formation is enhanced in the
 305 Eastern Atlantic while it weakens in the West as sea ice expands further South (Fig. 3). The
 306 next intermediate circulation mode (III) is marked by a reduction in deep water formation in
 307 the eastern North Atlantic, as the local water column increasingly stratifies. Deep water
 308 formation continues south of the sea ice edge in the western North Atlantic, albeit
 309 substantially weakened. As the northwards transport of subtropical water diminished under
 310 further cooling, the AMOC transitioned into the glacial stable mode (IV). In this mode,
 311 convection in the North Atlantic is strongly reduced and cold, fresh surface waters stratify the
 312 water column off the European coast. At this point, additional negative radiative forcing
 313 enhanced the amplitude of the temperature and salinity anomalies but without triggering
 314 additional changes in the North Atlantic circulation pattern.

315

316 Our simulations cover four glacial cycles before the Mid-Brunhes transition (MBT, MIS 12
 317 and MIS 11 (~430 ka)) and four thereafter. This transition was marked by a shift to warmer
 318 interglacials with higher atmospheric CO_2 concentrations. There are only small differences
 319 between the distributions of AMOC modes before and after the transition (fig SI.2), and none

320 are statistically significant in the two-sided Smirnov test, which determines the likelihood that
321 two distributions are the same (Berger and Zhou, 2014), even at the 50% confidence level.

 351 AMOC strength and the applied radiative forcing. At four points in time throughout B.slow,
 352 simulations were branched off to test the stability of the respective circulation mode (shown
 353 in dark grey). In these simulations, we kept the radiative forcing constant but applied a small
 354 freshwater perturbation after 500 yrs, before allowing the model to re-equilibrate (see
 355 Methods). b) AMOC variance calculated in a 50 yr moving window. c) Sea ice cover in the
 356 North Atlantic between 50-60°N ('North Atl', light blue) and the Atlantic sector of the
 357 Southern Ocean 50-68°S ('South Atl', teal). d) Volume fraction of AABW at three different

358 depth intervals in the subpolar North Atlantic (50-60°N). e) SST and SSS in the Caribbean
359 and Irminger seas. f) Change in the northward salinity transport by ocean currents in
360 freshwater flux (FWF) equivalents at different latitudes (following Liu et al., 2017). g)
361 Column-integrated heat flux convergence due to ocean circulation and heat loss to the
362 atmosphere (negative = heat loss by ocean) for the North Atlantic (40°N-70°N). Dotted
363 vertical grey lines indicate time points in the simulation at which we branched off stability
364 tests, and at which we analysed water mass distributions in Fig. 6.

365

366 In our simulations, the primary processes controlling the AMOC strength under changing
367 radiative forcing are density changes due to heat and salinity redistributions. We investigated
368 these in more detail in experiment B.slow (Fig. 4 and 5). This experiment is characterised by
369 a slow linear decrease in radiative forcing over 50 kyr, before it is increased again to the pre-
370 industrial value with the same rate of change (Fig. 4). Fig. 5 shows that AMOC weakened
371 gradually over the first 24 kyr, then weakened abruptly by 1 Sv at 24 kyr into the simulation
372 and by ~3 Sv at 27 kyr, and then continued to weaken gradually until the forcing is reversed
373 (Fig. 5a). In addition to the abrupt transition in AMOC strength, we found several additional
374 rapid changes in AMOC variability, heat, and salt fluxes (Fig. 5) and regional density profiles
375 (Fig. SI.7-9) which were not associated with persistent changes in AMOC strength, e.g. at 6
376 kyr into the simulation. In fact, experiment B.slow shows that a cascade of changes with little
377 effect on the mean AMOC strength occurred before the first abrupt AMOC weakening after
378 24 kyr. Since these changes might partially be artifacts of our coarse model resolution, we
379 here only focus on the larger scale changes instead. Initially, the whole Atlantic surface
380 ocean cooled and freshened, leaving the temperature and salinity differences between the
381 Irminger and Caribbean Seas almost unchanged (Fig 5e). However, NADW became less
382 salty and colder as a consequence of the changes in the surface ocean (not shown) and the
383 vertical density profiles in the subpolar North Atlantic steepened due to the temperature and
384 salinity changes (Fig. SI.7-8).

385

386 After about 6 kyr, the changes in the North Atlantic density profile shifted the location of
387 NADW formation: NADW formation moved south as vertical density profiles in the subpolar
388 east North Atlantic stabilised under a freshening of the surface and density profiles further
389 south steepened due to surface cooling combined with subsurface warming (Fig. SI.7-9).
390 These changes did not cause a step-change in AMOC strength, but freshwater and heat
391 advection into the North Atlantic was reduced, sea ice expansion increased in the eastern
392 North Atlantic, and AMOC variance (calculated over a moving 50-year window) was
393 increased (Fig. 5). Transport of heat and salinity into the North Atlantic decreased (Fig. 5f,
394 g), which reduced North Atlantic SST and SSS (Fig. 5e). The reduced influx of subtropical

395 surface waters also caused abrupt cooling and freshening in the Irminger Sea (Fig. SI.8). At
 396 24 kyr, the AMOC had weakened to ~ 14.5 Sv and sea ice cover extended south of the
 397 Irminger Sea (Fig SI.11). At this point, the AMOC strength dropped abruptly by 1 Sv, and
 398 then by an additional 3 Sv ~ 3 kyr later, as the reduced salinity advection into the North
 399 Atlantic and precipitation and evaporation changes led to a strong surface freshening. As a
 400 result of the North Atlantic density changes, the main North Atlantic convection site shifted
 401 southwards (determined by changes in the vertical density profiles, Fig SI.10). Sea ice also
 402 increasingly covered former areas of deep water formation in the North Atlantic. In the
 403 weakest circulation mode, the location of the maximum AMOC stream function shifted
 404 southwards by approximately 10 degrees and up in the water column by 400 m initially (28.5
 405 kyr) and eventually almost 800 m (47 kyr) This shift allowed cold, less dense water masses
 406 to extend further south into the North Atlantic.

407

408 In the Southern Ocean, the cooling enhanced Southern Ocean deep water formation early
 409 on in the experiment and led to a continuous expansion of sea ice in the Southern
 410 Hemisphere. The biggest AMOC weakening at ~ 27 kyr was also accompanied by a weak
 411 bipolar seesaw effect (Stocker and Johnsen, 2003), which caused a temporary decline in
 412 sea ice coverage in the Atlantic sector of the Southern Ocean (Fig. 5). It was, however, too
 413 small to reduce the radiation-driven sea ice increase in the longer term. Both shifts in AMOC
 414 strength were accompanied by an increased spread of AABW into the North Atlantic (Fig.
 415 5d).

416

417

418 Figure 6: Atlantic water mass distributions at the five time slices of our simulation B.slow
419 indicated in Fig. 5. Each row shows the zonally-averaged contribution of water sourced in
420 one of three regions: the North Atlantic (upper row), the Southern Ocean (middle row), and
421 the Southern Atlantic (bottom row), diagnosed with three passive dye tracers. Fig. SI.1
422 shows the spatial pattern of our dye forcing.

423

424 The changes in the AMOC stream function associated with the decreasing radiative forcing
425 in experiment B.slow bear close resemblance to the changes we observed in the transient
426 experiment set A during AMOC transitions from the interglacial to the glacial circulation
427 mode (Fig. 6 and Fig. SI.12 - SI.14).

428

429 We tracked the effects of these circulation changes on the Atlantic distribution of
430 intermediate and deep water masses as diagnosed from artificial dye tracers (see Fig SI.1
431 for their source regions). Figure 6 shows that, during the first 23 kyr of our simulation, AABW
432 slowly spread further North and occupied increasingly shallower depths while the northward
433 reach of AAIW was reduced. Accordingly, NADW shoaled as it was unable to sink further
434 when encountering AABW in the deep North Atlantic. The reduced export of NADW also led
435 to a decrease in its southward extent, contracting to 40°S. The first abrupt shift in AMOC
436 strength occurred at 24.5 kyr in B.slow and had only small effects on the water mass
437 distribution. It mainly led to a reduced fraction of NADW at intermediate depths of the North
438 Atlantic >45°N and a small increase of AABW in the abyssal North Atlantic (Fig. 5d). The
439 following AMOC shift at 27 kyr reduced AMOC strength by more than 3 Sv, and was hence
440 also more strongly expressed in changes in the water mass distribution. It was accompanied
441 by a further reduction of NADW export into the deep Atlantic, before NADW was entirely
442 replaced by AABW at depths below ~3.5 km in the weakest circulation mode. AAIW was
443 increasingly curtailed in its northward reach, until it effectively no longer extended toward the
444 equator (<10%).

445

446 In summary, in our simulation deep convection diminished first in the Irminger Sea while
447 deep water formation continued in the subpolar Northeast Atlantic and south of Greenland.
448 As sea ice extended into the Eastern North Atlantic south of Greenland and vertical density
449 profiles steepened further south, the northward reach of the AMOC was restricted and a new
450 circulation mode was established with increased sea ice cover >55°N. The weakened
451 northwestward transport of heat and salt due to the reduced AMOC strength led to a
452 relatively fresh and cold eastern North Atlantic, stabilising the water column in the region and
453 producing another persistent AMOC mode. The simulated step changes in AMOC strength
454 in our simulations were thus the response to gradual surface cooling and freshening, and

455 occurred when NADW formation shifted southwards. The resulting redistributions of heat
456 and salinity caused sudden shifts in the vertical density profiles and sea ice expansion which
457 consolidated the new circulation mode (Ando and Oka, 2021). In particular, reduced
458 advection of heat and salinity into former locations of deep water formation resulted in a
459 more stable local water column (Fig. SI.7-9). The deep water formation regions are sensitive
460 to heat and salt flux changes, because any reduction in sea surface temperatures (SST)
461 increases surface density but simultaneously reduces evaporation in ice-free areas, thus
462 effectively creating a small freshwater forcing and a negative feedback to the buoyancy
463 changes caused by the initial SST decrease. Sea ice covering the downwelling areas
464 stabilises the water column by preventing surface ocean cooling and evaporation. The
465 progressive influx of AABW into the North Atlantic is a further process stabilising new
466 circulation modes by stratifying the water column from below (Buizert and Schmittner, 2015).
467 The difference between freshwater transport into the South Atlantic at 32°S and into the
468 Arctic at 62.5°N in Fig. 5f can be used as a measure for the basin-wide salinity feedback
469 (Rahmstorf, 1996, de Vries and Weber, 2005). In our simulation, changes in this metric were
470 predominantly caused by changes in the transport across the northern edge, since transport
471 into the South Atlantic remained almost unchanged throughout the cooling phase of B.slow.
472 North Atlantic salinity is instead governed by changing transport from the subtropics into the
473 North Atlantic and between the North Atlantic and Arctic. As such, the processes involved in
474 the sudden AMOC strength changes, namely density changes in the upper water column,
475 and those that stabilised new circulation modes (salinity and heat redistributions, sea ice
476 expansion) mostly operated in the North Atlantic region.

477

478 Our stability experiments demonstrated that the circulation modes before and after the
479 abrupt shifts recovered from small freshwater perturbations, and can thus be considered
480 stable, i.e. sufficiently far from bifurcation points to recover from the small perturbation (Fig.
481 5a, Fig. SI.6). In these branched off sensitivity tests, the circulation mode adopted before the
482 first AMOC threshold (at ~24 kyr), showed increased variability in the order of 0.5 Sv. The
483 next circulation mode (~25 kyr) responded most strongly to small freshwater perturbations
484 and was also the only circulation mode in our simulation which showed gradually increasing
485 AMOC variability (as determined by an increase in its variance) while approaching the next
486 threshold (Fig. 5a, Fig. SI.6). When the forcing was reversed, the radiation increase
487 gradually strengthened the AMOC until it rapidly transitioned back into the stronger
488 circulation mode when North Atlantic sea ice had receded sufficiently for a northward shift of
489 the convection sites and evaporation and salinity transport resumed. The radiative forcing at
490 which the AMOC transitioned from one circulation mode to the other was not equal for
491 decreasing and increasing radiative forcing: a stronger negative radiative forcing was

492 required to push the AMOC into its weak circulation mode than for the transition out of it (Fig.
493 4b).

494

495 Our sensitivity tests with different orbital configurations indicated that the existence of AMOC
496 thresholds under radiative forcing was not dependent on the initial orbital configuration.
497 However, the AMOC was slightly more sensitive to perturbations when initiated with the
498 orbital configuration equivalent to 30 ka before present. In this case, the threshold for the
499 AMOC to transition to its weaker mode was reached ~1 kyr earlier than under PI or 50 ka
500 orbital configurations (simulations B.short.30ka, B.short.PI, Fig. SI.15). The processes that
501 affected AMOC behaviour in simulation set B also caused AMOC changes over the
502 transiently simulated 788 kyr in simulation set A, but the circulation modes adopted varied
503 slightly in sea ice extent, hydrological cycle and salinity distribution under varying orbital
504 configurations.

505

506

507 **3.3. Comparison with other modelling studies and proxy data**

508

509 In our transient simulations covering the past 788 kyr, the AMOC strength decreased during
510 glacial phases solely due to changes in the hydrological cycle and sea ice that were induced
511 by orbital, greenhouse gas, and the additional radiative cooling. The existence of multiple
512 stable AMOC modes under varying thermal or radiative forcings has been found in various
513 GCMs (e.g. Knorr and Lohmann, 2007, Oka et al., 2012, Banderas et al., 2012, Brown and
514 Galbraith, 2016, Zhang et al., 2017, Klockmann et al., 2018). In agreement with previous
515 studies, we found multiple persistent AMOC circulation modes with distinct AMOC strengths
516 for radiative forcing levels between full glacial and interglacial climate states. Moreover, we
517 found that the transitions between these modes occur abruptly, some within as little as 100
518 years. In accordance with Lohmann et al. (2023), we found that these shifts in AMOC
519 strengths are preceded by cascades of density and circulation field changes, the number
520 and sequence of which depend on the strength of the forcing. Similar to the findings from
521 Oka et al. (2021), AMOC transitions arise primarily from salt redistribution in the ocean and
522 sea ice expansion into deep convection zones.

523

524 In our simulations, each transition in AMOC strength was associated with a shift in the
525 convergence of heat and salt fluxes and a southward expansion of sea ice into the North
526 Atlantic. Sea ice cover decouples the surface ocean buoyancy from the atmosphere. In the
527 intermediate modes, locations with steep density gradients are close to a critical annually-
528 averaged sea ice cover. In these modes, small changes in sea ice cover can cause large

529 changes in surface buoyancy and the extent and location of deep convection, which makes
530 the AMOC sensitive to small perturbations. The AMOC was only pushed into its weakest
531 mode when all former convection sites in the subpolar North Atlantic were sea ice-covered
532 and heat convergence in the North Atlantic was strongly reduced.

533

534 In their examination of thermal forcing of both hemispheres, Oka et al. (2021) found that
535 thermal AMOC thresholds only exist in COCO, the ocean component of MIROC, if the
536 Southern Hemisphere is cooled more than the Northern Hemisphere. In contrast, Zhang et
537 al. (2017) found sudden AMOC changes due to greenhouse gas changes without a special
538 focus on the Southern Hemisphere. In our simulations with Bern3D, we also found thermal
539 thresholds with similar cooling rates in both hemispheres, but only after salinity
540 redistributions and changing meteoric freshwater fluxes in response to about six thousand
541 years of global cooling.

542

543 It is possible that changing meteoric freshwater fluxes are essential for the existence of such
544 a thermal threshold, which does not therefore appear in an ocean model without a thermally
545 responsive atmosphere with a climate-driven freshwater balance. In a model with a dynamic
546 energy moisture balance component, atmospheric cooling reduces evaporation and the
547 water-holding capacity of the atmosphere. With this feedback enabled, cooling can then
548 affect seawater density directly via changing temperatures, and indirectly via changing the
549 meteoric freshwater balance and surface salinities. These changes would induce additional
550 kinematic changes (i.e., in the wind fields) in fully dynamic atmosphere models but are kept
551 constant in our simulations, i.e. the moisture content of air changes with climate but not the
552 direction or strength of winds which disperse it. In our model, a decrease in the water-
553 holding capacity of air therefore directly leads to a reduction of the large-scale atmospheric
554 moisture transport from low to high latitudes. Accordingly, wind stress fields are also kept
555 constant here. Changes in wind stress have been documented to exert important controls on
556 AMOC stability (e.g. Arzel et al., 2008, Yang et al., 2016) and thermal thresholds (Oka et al.,
557 2012). These effects have been investigated in detail with the Bern3D model by Pöppelmeier
558 et al. (2021) focusing on LGM boundary conditions.

559

560 The primary importance of salinity and heat redistributions as well as sea ice extent in the
561 North Atlantic for the simulated AMOC shifts resembles the findings from Ando and Oka
562 (2021)'s hosing experiments under LGM conditions and Zhang et al. (2017)'s simulations of
563 AMOC shifts in response to CO₂ changes under intermediate-glacial conditions. While our
564 experiments were run with pre-industrial topography, sea level and wind fields, the initial
565 location of convection sites between Greenland and the British Isles (areas with lowest

566 density differences over upper 1000 m in Fig. SI.11) resembles the LGM and intermediate-
567 glacial circulation modes in Ando and Oka (2021) and Zhang et al. (2017).

568

569 Ganopolski and Rahmstorf (2001) found that the possibility of a southward shift of deep
570 convection depends on the latitude of prior deep convection and the density field further
571 south, and Oka et al. (2012) showed that the location of deep convection and its distance
572 from the winter sea ice edge define thermal thresholds in AMOC strength. Several controls
573 on the location and strength of deep convection in the North Atlantic, that would have
574 affected AMOC stability over glacial cycles, have been established. The location of deep
575 convection is dependent on wind fields, climate and sea level/bathymetry (Ganopolski and
576 Rahmstorf, 2001, Oka et al., 2012, Zhang et al., 2017), and thus the thermal AMOC
577 thresholds are model and forcing dependent (Oka et al., 2012). Our simulations capture the
578 albedo effect of varying terrestrial ice sheet extent, but we did not consider their orography
579 or sea level effects, including impacts on the atmospheric circulation, which were shown to
580 affect AMOC (Li and Born, 2019; Pöppelmeier et al., 2021). Previous studies suggested that
581 pre-industrial or intermediate glacial ice sheet configurations are required to even produce a
582 thermal AMOC threshold in the range of glacial-interglacial CO₂ concentrations in a full GCM
583 and that the presence of a full glacial Laurentide ice sheet prevents such a threshold (e.g.
584 Klockmann et al., 2018). In addition, changes in the interconnection of marine basins,
585 specifically the Bering Strait, also affect AMOC stability (Hu et al. 2012). The values of the
586 thermal thresholds in our experiments are thus likely sensitive to the model design and
587 initiation. Pöppelmeier et al. (2021) showed that the sensitivity of Bern3D to freshwater
588 hosing increases when additional LGM boundary conditions are prescribed (changed wind
589 fields, closed Bering Strait, tidal mixing differences due to sea level changes). The different
590 wind fields and tidal mixing strengthened AMOC and increased the salt and heat transport
591 into the subpolar North Atlantic. This could mean that stronger cooling is required to stabilise
592 the water column in the Irminger Sea and reach the first thermal threshold, when the full
593 range of glacial boundary conditions are applied. Closure of the Bering Strait increased the
594 salt advection feedback, which stabilises the weak circulation state without deep water
595 formation in the subpolar North Atlantic.

596

597 Further investigations are needed to determine how changes in strength and location of the
598 wind stress due to the ice sheet's orography, sea level and Bering Strait closure would affect
599 sea ice formation in the northern North Atlantic and the AMOC thresholds in our simulations
600 quantitatively. Since we chose to focus on radiation driven AMOC changes in our
601 experiments, we would not expect a close model-data match with reconstructed AMOC
602 changes from paleo-records. Our simulations show that the reconstructed temperature

603 changes had the potential to alter the density field in the North Atlantic by redistributing heat
 604 and salt, and that some of these changes might have resulted in abrupt changes of AMOC
 605 strength. By testing a wide range of glacial-interglacial temperature changes, our
 606 experiments demonstrate that the cooling during glacial periods likely contributed to a
 607 weakened AMOC. The strength and timing of the weakening depends on the actual
 608 temperature change in the North Atlantic which would have been modulated by changes in
 609 winds and ice shields.

610

611

612

613

614

615

616

617 Figure 7: Simulated and reconstructed SST differences from PI over the last glacial cycle in
 618 the North Atlantic (a, reconstruction by Candy and Alonso-Garcia, 2018) and on the Iberian
 619 Margin (b, reconstruction by Davtian and Bard, 2023). The model data was interpolated to
 620 the time points for which proxy reconstructions exist.

621

622 Unlike in our simulations, most GCMs participating in PMIP4 do not show a shoaling or
 623 weakening of the overturning cell under LGM boundary conditions (Sherriff-Tadano and
 624 Klockmann, 2021). The difference could arise from the static wind fields that we prescribed,
 625 since an ice-sheet related increase in wind speeds over the North Atlantic leads to a
 626 strengthened AMOC (Klockmann et al., 2018), or different representations of processes
 627 affecting AABW density changes (e.g. brine rejection, Bouttes et al., 2011). A shallower and
 628 likely weaker AMOC during peak glacials is however consistent with observational data
 629 (Lynch-Stieglitz et al., 2017, Pöppelmeier et al., 2023). In Fig. 7, simulated SST changes
 630 from the Rockall Trough and the Iberian Margin are compared to proxy-based
 631 reconstructions. Circulation changes alter the distribution of heat in the North Atlantic, and
 632 simulated SST patterns are strongly affected by AMOC changes. In response to the
 633 stepwise AMOC weakening, simulated Atlantic SST also transitioned stepwise from
 634 interglacials to glacial maxima. Step changes are also an established feature of Atlantic SST

635 reconstructions over the last glacial cycle (Fig. 7), with the biggest steps at 120-110 ka and
 636 80-60 ka also captured in our simulations. During glacial inception between 120 ka and 70
 637 ka, the amplitudes of reconstructed SST changes in both locations resemble those simulated
 638 with strong radiative forcing (simulations A6, A7, A8). Afterwards, SSTs in those simulations
 639 decreased more than in the reconstructions, and the latter align more closely with weaker
 640 radiative forcing (simulations A3, A4). After ~70 ka, shorter millennial-scale events (Heinrich
 641 and Dansgaard-Oeschger), that were not included in our simulations, were more frequent
 642 than before and could affect the comparability between reconstructed and simulated SST.
 643 Additionally, the further into the glacial cycle, the more the topography and wind fields would
 644 have deviated from their pre-industrial states that we kept constant throughout the
 645 simulations. These factors could have caused a shift in AMOC and SST changes that are
 646 not captured by our simulations.
 647

648
 649 Figure 8: Simulated AMOC changes due to thermal forcing over the last 140 kyr. Gray dots
 650 indicate AMOC strength estimated from $^{231}\text{Pa}/^{230}\text{Th}$ (Böhm et al., 2015, Lippold et al., 2009)
 651 by assuming a sensitivity of -0.0024 Sv^{-1} (Rempfer et al., 2017).
 652

653 Fig. 8 compares the simulated changes in AMOC strength over the last 120 kyr in simulation
 654 set A to indications of AMOC weakening based on $^{231}\text{Pa}/^{230}\text{Th}$ from the Bermuda Rise (Böhm
 655 et al., 2015). The simulations A2-A4 have PI-LGM GMST differences of 4.7-6.2°C (within the
 656 proxy-constrained and PMIP range and close to the most recent estimate of 6.1°C by
 657 Tierney et al., 2020) and show a shift to a weaker AMOC at the beginning of MIS 4 around
 658 70 ka ago, when a negative $^{231}\text{Pa}/^{230}\text{Th}$ shift occurred. While the simulated radiation-driven
 659 AMOC changes cannot explain weaker or collapsed circulation modes (<11 Sv) during
 660 Heinrich stadials, this comparison shows that the long term AMOC weakening during glacial

661 phases could have been driven by temperature changes. It is important to note that AMOC
662 strength estimates based on this $^{231}\text{Pa}/^{230}\text{Th}$ record need to be treated with caution.
663 Pöppelmeier et al. (2021; 2023) showed a strong local influence on sedimentary proxies at
664 this site, and we did not correct the $^{231}\text{Pa}/^{230}\text{Th}$ signal for potential productivity changes.

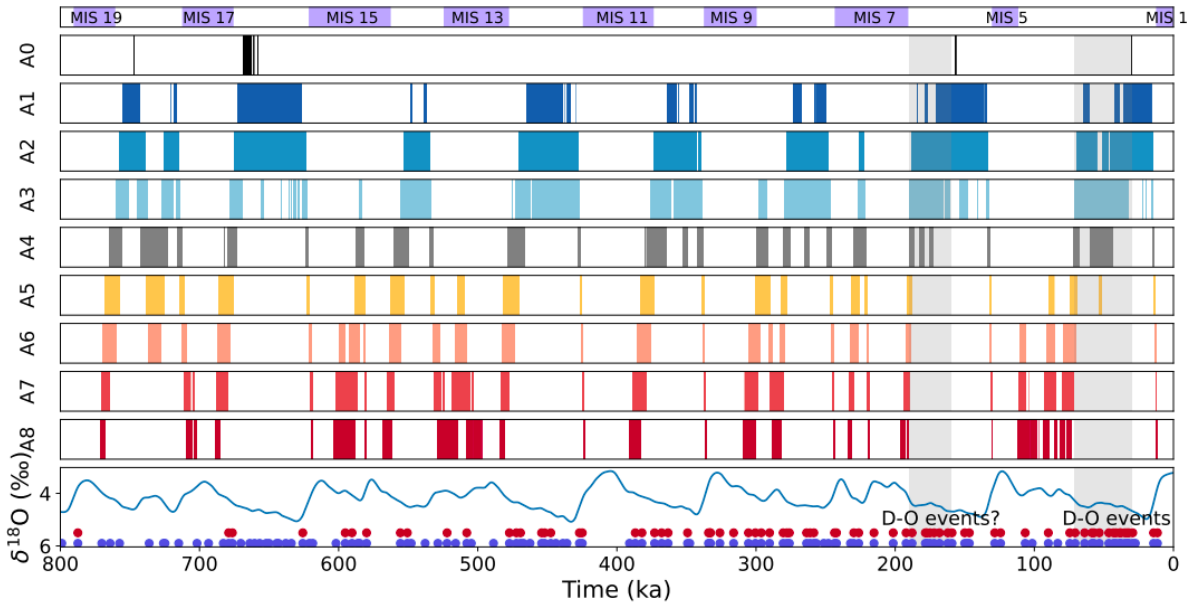

665

666 **3.4. Meta-stable AMOC modes over the last 788 kyr**

667

668 Finally, we can test whether our simulations capture the periods with increased frequency of
669 AMOC transitions that are indicated by proxies over the last eight glacial cycles. Using our
670 788 kyr long simulations in simulation set A, we determined how often and when the
671 radiative forcing pushed the AMOC into ‘excitable’ circulation modes, i.e. modes II and III,
672 which showed more frequent AMOC strength shifts than the interglacial and glacial modes I
673 and IV (Fig. 1 and SI.2), and how this varied with the applied forcing strength (Fig. 9). In all
674 simulations, the AMOC transitioned into such excitable modes in all of the past eight glacial
675 cycles, but the timing of these shifts varied. For example, during the last glacial cycle, the
676 simulations A2-A4 exhibited an intermediate circulation mode during MIS 3 (57-29 ka), when
677 frequent AMOC mode shifts occurred (see Fig. 1). Similar rapid mode switches occurred
678 earlier in the glacial cycle, i.e. during MIS 5d-e in simulations A6-A8. In these simulations,
679 the AMOC already transitioned into the persistent glacial circulation mode IV at the
680 beginning of MIS 4 (71-57 ka), in which North Atlantic density profiles are more stable. In
681 simulations A1-A3, the AMOC persisted in these modes for several tens of thousands of
682 years at a time, during most glacials. Under stronger radiative forcing, the periods in which
683 AMOC adopted these modes were shorter and mostly occurred at the start of glacial cycles.

684

685
 686 Figure 9: Occurrence of intermediate AMOC modes II and III due to radiative forcing over the
 687 last 788 kyr in simulation set A. The time periods with intermediate AMOC modes are
 688 marked as vertical bars, each row showing the results for a different forcing magnitude from
 689 simulation set A. At the bottom, $\delta^{18}\text{O}$ from Lisiecki and Raymo (2005) is shown for reference,
 690 alongside the time period with confirmed and suspected Dansgaard-Oeschger events (light
 691 gray bars based on Rousseau et al., 2020, blue and red circles are based on reconstructions
 692 Barker et al., 2011, who used two different detection thresholds).

693
 694 We can assess the skill of our simulations at predicting 'excitable' AMOC modes from the
 695 radiative forcing by comparing the output with records of high AMOC variability in the past.
 696 Simulations A3 and A4 shift into a meta-stable circulation mode during MIS 3, and similarly
 697 between 190 and 160 ka during the penultimate glacial cycle, and prior to each previous
 698 glacial maximum but not during the glacial maxima themselves. An 'excitable' AMOC mode
 699 during these intervals seems realistic given the high frequency of Dansgaard-Oeschger
 700 events in MIS 3 and the suspected occurrence of Dansgaard-Oeschger events during MIS 6
 701 (191-123 ka, Rousseau et al. 2020). Similarly, Barker et al. (2011), who predicted the
 702 occurrence of Dansgaard-Oeschger events during previous glacial cycles based on the
 703 Antarctic methane and temperature records (with two different identification thresholds, red
 704 and blue circles in Fig. 9) following the approach of Siddall et al. (2006), found a high
 705 frequency of occurrence of Dansgaard-Oeschger events during MIS 3 and 6, but also
 706 throughout most other glacial phases. None of our simulations predicts such a ubiquity of
 707 'excitable' AMOC modes, possibly due to the prescribed boundary conditions although the
 708 detection method of Barker et al. (2011) is also more uncertain for glacial cycles further back
 709 in time. The consistency of the simulated radiation-induced AMOC instability with

710 observational indication of millennial-scale AMOC variability at least during MIS 3 and 6 in
711 simulations A3 and A4 suggests that these could present a more realistic temporal AMOC
712 evolution than the others. Simulations A3 and A4 also exhibit PI-LGM temperature
713 differences of 5.4 and 6.2°C, respectively, close to the proxy-constrained reconstruction
714 (Tierney et al., 2020), and roughly reproduce the reconstructed regional SST changes and
715 reduced circulation strength in MIS 3 and 2 (Fig. 7 and 8).

716

717 Thermal conditioning of AMOC excitability is in line with studies that found the existence of a
718 ‘sweet spot’ in atmospheric CO₂ radiative forcing which is particularly conducive to short,
719 abrupt AMOC perturbations and/or self-sustained AMOC oscillations (e.g. Li and Born, 2019,
720 Vettoretti et al., 2022). Yet, our simulations do not produce such perturbations, partly due to
721 the smoothed forcing and static wind fields (see discussion of model limitations above). The
722 transient circulation mode switches in response to orbitally-paced radiation changes in our
723 simulations are much weaker than those found in other studies (Vettoretti et al., 2022,
724 Klockmann et al., 2018, Kuniyoshi et al., 2022), and our simulations do not contain
725 oscillations that could directly be compared to Dansgaard-Oeschger events.

726

727

728 **4 Conclusions**

729

730 Our study demonstrates the existence of thermal AMOC thresholds and multiple stable
731 circulation modes in the Bern3D model. This adds to previous studies showing that thermal
732 AMOC thresholds emerge in a range of Earth system models varying in complexity and
733 number of components coupled (Zhang et al., 1993), in particular, they also arise in an
734 energetically and hydrologically coupled ocean-sea ice-atmosphere model of intermediate
735 complexity like Bern3D. These thresholds shape the response in the simulated AMOC to
736 radiative orbital and atmospheric composition-driven temperature changes over the last 788
737 kyr. During this period the AMOC transitions between up to four persistent circulation modes.
738 The full glacial and interglacial circulation modes are most frequently simulated, as relatively
739 strong forcing is required to push the AMOC out of them. In contrast, the intermediate AMOC
740 modes are more sensitive to perturbations as small variations in orbital and radiative forcing
741 are able to push the circulation out of these modes. This behaviour resembles the one found
742 in more complex General Circulation Models that exhibit self-sustained oscillations at
743 ‘sweetspot’ CO₂ levels, which lie between glacial and interglacial values. Our simulations
744 suggest that radiative forcing could have created time periods during which highly sensitive
745 intermediate AMOC modes occurred repeatedly over the last 788 kyr.

746

747 **Data availability**

748

749 All simulation output necessary to produce the figures in this manuscript are available at
750 <https://doi.org/10.5281/zenodo.8424878>

751 Proxy data plotted against the simulation output for comparison was taken from public
752 repositories and are available via the citations provided.

753

754 **Author contributions**

755

756 AJT ran the simulations. MA analysed the output and drafted the manuscript. All authors
757 contributed to the interpretation of the results and the final manuscript text.

758

759 **Conflicts of interest**

760

761 The authors declare that they have no conflict of interest.
