**Version: February 14, 2024**

**Abstract.** Laboratory experiments showed that the isotopic fractionation of  $\delta^{13}\text{C}$  and of  $\delta^{18}\text{O}$  during calcite formation of planktic foraminifera are species-specific functions of ~~oceanic~~oceanic ambient  $\text{CO}_3^{2-}$ -concentration. This effect became known as the carbonate ion effect (CIE), whose role ~~during~~during for the interpretation of marine sediment data will be investigated here in an in-depth analysis of the  $^{13}\text{C}$  cycle. For that effort we ~~compiled~~compiled-constructed new 160 kyr-long mono-specific stacks of changes  
5 in both  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  from either the planktic foraminifera ~~G.~~G. *Globigerinoides ruber* (rub) or ~~T.~~T. *Trilobatus sacculifer* (sac) from 112 and 40 ~~non-polar marine records~~marine records from the wider tropics (latitudes below 38°), respectively. Both mono-specific time series  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  are very similar to each other and a linear regression through a scatter plot of both data sets has a slope of  $\sim 0.99$  — although the laboratory-based CIE for both species differ by nearly a factor of two, implying that they should record distinctly different changes in  $\delta^{13}\text{C}$ , if we accept that the carbonate ion concentration  
10 changes on glacial/interglacial timescales. For a deeper understanding of the  $^{13}\text{C}$  cycle we use the global carbon cycle model BICYCLE-SE to calculate how surface ocean  $\text{CO}_3^{2-}$  should have varied over time in order to be able to calculate the potential ~~corrections which would follow the laboratory-based CIE offsets which would be caused by the CIE quantified in culture experiments~~corrections which would follow the laboratory-based CIE offsets which would be caused by the CIE quantified in culture experiments. Our simulations are forced with atmospheric reconstructions of  $\text{CO}_2$  and  $\delta^{13}\text{CO}_2$  derived from ice cores to obtain a carbon cycle which should at least at the surface ocean be as close as possible to expected conditions and which ~~agrees~~agrees-in the  
15 deep ocean ~~in~~in-largely agrees with the carbon isotope ratio of dissolved inorganic carbon (DIC),  $\delta^{13}\text{C}_{\text{DIC}}$ , ~~with reconstruction as reconstructed~~with reconstruction as reconstructed from benthic foraminifera. ~~We find~~We find that both  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  agree better with changes in simulated  $\delta^{13}\text{C}_{\text{DIC}}$  when ignoring the CIE than those time series which were corrected for the CIE. The combination of data- and model-based evidence for the lack of a role for the CIE in  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  suggests ~~to us~~to us that the CIE as measured in laboratory experiments is not directly transferable to the interpretation of marine sediments records. ~~We~~We  
20 ~~hypothesise that both foraminifera species can optimise their light environments via vertical motion and therefore calcify under nearly stable  $\text{CO}_3^{2-}$  concentration.~~hypothesise that both foraminifera species can optimise their light environments via vertical motion and therefore calcify under nearly stable  $\text{CO}_3^{2-}$  concentration. The much smaller CIE-to-glacial/interglacial-signal-ratio in foraminifera  $\delta^{18}\text{O}$ , when compared to  $\delta^{13}\text{C}$ , prevents us to draw robust conclusions on the role of the CIE on  $\delta^{18}\text{O}$  as recorded in the hard shells of both species. However, theory proposes that the CIE in  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  depends both on the  $\text{pH}$  in the surrounding water, suggesting

that the CIE should be detectable in neither or both of the isotopes. Whether this lack of role of the CIE in the interpretation of planktic paleo data is a general feature, or restricted to the two species investigated here, needs to be checked with further data from other planktic foraminiferal species.

## 1 Introduction

For a reconstruction of past changes in the ocean and the carbon cycle various variables are measured on microfossils obtained from marine sediment cores. Among the most widely used are the stable carbon and oxygen isotope ratios,  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ , from hard shells of planktic and benthic foraminifera. Since the publication of the first stable isotope time series (Emiliani, 1955) a vast number of of stable isotope records has been published and to a large part compiled in the World Atlas of late Quaternary Foraminiferal Oxygen and Carbon Isotope Ratios (Mulitza et al., 2022). One of the fundamental problems with the interpretation of foraminiferal isotope ratios is how and why was a stable isotope signal altered on its way from the sea water to the shell of living foraminifera. Are there vital and other effects necessary to be considered when interpreting the paleo records (e.g. Bijma et al., 1999; Zeebe et al., 2008; Kimoto, 2015)?

The carbonate ion effect (CIE) ~~describes that is one of these potentially important effects that might alter the isotopic signal. The CIE implies that~~ both  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  measured in hard shells of marine organisms undergo isotopic fractionation during calcite formation with the amplitude of the fractionation, among other factors, being a function of the carbonate ion concentration ( $[\text{CO}_3^{2-}]$ ) of the surrounding seawater (Spero et al., 1997). The CIE has been found to be species-specific (Spero et al., 1999), ranging from  $-4.7$  to  $-13.0 \times 10^{-3} \text{‰}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  for  $\delta^{13}\text{C}$  and between  $-1.4$  and  $-4.5 \times 10^{-3} \text{‰}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  for  $\delta^{18}\text{O}$  in four planktic foraminifera. The CIE for  $\delta^{13}\text{C}$  has been explained for ~~*O. Orbulina universa*~~, a spinose, symbiont bearing species, by the  $\text{pH}$ -related distribution of dissolved inorganic carbon (DIC) into its three species  $\text{CO}_2$ ,  $\text{CO}_3^{2-}$ , and  $\text{HCO}_3^-$  (Wolf-Gladrow et al., 1999; Zeebe et al., 1999). The CIE on  $\delta^{18}\text{O}$  is also explained by the  $\text{CO}_3^{2-}$ -related varying  $\text{pH}$  (Zeebe, 1999). These theories, however, were unable to base the full amplitudes found in experiments solely on this effect. The CIE is maybe the most prominent isotopic fractionation effect which ~~asks for consideration has to be considered~~ when interpreting the paleo records, but others, e.g vital effects and dependency on light, temperature, pressure and shell size, have been put forward (e.g. Spero and Williams, 1988, 1989; Spero et al., 1991; Spero, 1992; Spero and Lea, 1993; Oppo and Fairbanks, 1989). The CIE is found to play a minor role when comparing late Holocene deep ocean  $\delta^{13}\text{C}$  in benthic foraminifera with  $\delta^{13}\text{C}$  of DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) (Schmittner et al., 2017) being responsible for  ~~$-2.4 \times 10^{-3}$~~   $-2.6 \times 10^{-3} \text{‰}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  disturbance in the recorded signal. In a recent study focusing on the benthic species ~~*C. Cibicidoides wuellerstorfi*~~  $-3.0 \times 10^{-3} \text{‰}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  have been obtained for the late Holocene (Nederbragt, 2023). Both studies also found in addition to the CIE that  $\delta^{13}\text{C}_{\text{benthic}}$  was also partly controlled by other variables, mainly pressure (water depth) and temperature.

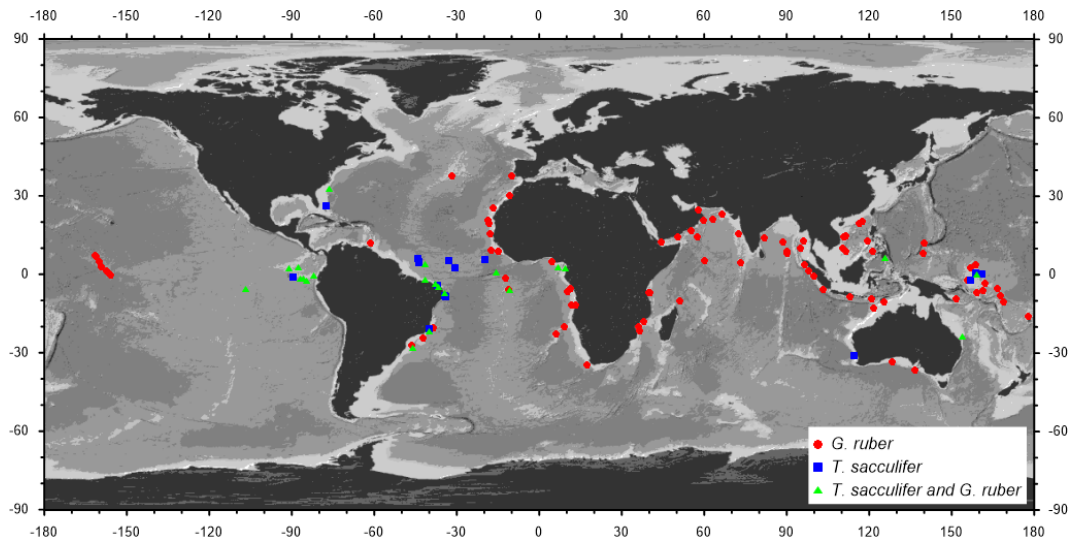

The CIE in planktic foraminifera is one of the reasons why the interpretation of the whole  $\delta^{13}\text{C}$  cycle over glacial/interglacial timescales is still challenging. The data compilation of Oliver et al. (2010) covering the last 150 kyr of  $\delta^{13}\text{C}$  in planktic and benthic foraminifera ~~contained large uncertainties and did not consider potentially necessary corrections such as the CIE in~~

~~the final interpretation.~~ was a step in the direction of basin-wide splines finding large uncertainty attributed to the estimate of  $\delta^{13}\text{C}_{\text{DIC}}$  from planktic species. Since benthic compilations are less affected by the CIE, they should, however, robustly constrain deep ocean changes in  $\delta^{13}\text{C}$ . A more recent compilation of benthic  $\delta^{13}\text{C}$  was given in Lisiecki (2014). Furthermore,  $\delta^{13}\text{C}$  of atmospheric  $\text{CO}_2$  ( $\delta^{13}\text{C}_{\text{CO}_2}$ ) is now available over the last 155 kyr (Eggleston et al., 2016a) from ice cores. Missing in our understanding are so far ~~tight~~ constraints on change in surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$ , but in principle ~~these~~ this information should be recorded in the hard shells of planktic foraminifera, even if hidden under the CIE.

We therefore here aim to construct ~~the first a~~ robust time series of orbital changes in surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  based on planktic foraminifera data. We ~~compile compiled~~  $\delta^{13}\text{C}$  data from the World Atlas of late Quaternary Foraminiferal Oxygen and Carbon Isotope Ratios (Mulitza et al., 2022) covering largely based on Mulitza et al. (2022) covering up to the last 160 kyr, in which data went through a rigorous quality control before entry and all applied age models have been revised to a most recent standard. In order to be able to apply any species-specific CIE corrections we compile mono-specific ~~stacks using isotope records on~~ the widely abundant shallow-dwelling planktic foraminifera species *Globigerinoides ruber* (*G. ruber* (or rub) and *Trilobatus sacculifer* (*T. sacculifer* (sac) or sac) into stacks. Due to their spatial distribution (Fraile et al., 2008) this species selection leads effectively to the construction of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  stacks ~~fed by based on~~ sediment core data from the latitudes smaller than  $40^\circ$ , potentially informing us about mean changes of  $\delta^{13}\text{C}_{\text{DIC}}$  in the non-polar ocean on orbital timescales in the surface of the wider tropical ocean. Accompanied stacks of  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  and  $\Delta(\delta^{18}\text{O}_{\text{sac}})$  from the same cores will add further information on the CIE in  $\delta^{18}\text{O}$ .

A first surface ocean  $\delta^{13}\text{C}$  stack based on data from *T. sacculifer* obtained from five equatorial Atlantic records has been constructed by Curry and Crowley (1987) without any knowledge on the CIE. Furthermore, Spero et al. (1999) used data from *G. ruber* and *T. sacculifer* from a single core in the Indian Ocean and the lab-based size of their species-specific CIE to deconvolve surface ocean  $[\text{CO}_2^-]$ . We here will use our new mono-specific  $\delta^{13}\text{C}$  stacks, which have due to the underlying number of records a much higher signal-to-noise-ratio to test the robustness of their findings.

In the following we will investigate the connection of  $\delta^{13}\text{C}$  in atmosphere and ocean in closer detail in order to improve our understanding of the  $^{13}\text{C}$  cycle. ~~For this effort, we will first~~ The remainder of the article is structured as follows. We first (section 2.1) describe the construction of our mono-specific  $\delta^{13}\text{C}$  anomaly stacks  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  (and of the accompanied  $\delta^{18}\text{O}$  anomalies) and what we know about atmospheric and deep ocean. Some published benthic  $\delta^{13}\text{C}$  (section 2.1). Having two mono-specific stacks of surface ocean enables us to address the CIE initially solely based on data. data are also needed for our understanding (section 2.2). For a deeper interpretation the global isotope enabled carbon cycle model BICYCLE-SE (Köhler and Munhoven, 2020), which has been proven to simulate glacial/interglacial (G/IG) changes in the carbon cycle reasonably well, is used. The model is briefly described in section 2.1 including a completely revised parametrisation of the  $^{13}\text{C}$  cycle in BICYCLE-SE is completely revised for this study. We then first discuss (section 2.1) 3.1) what we already know from data on the  $\delta^{13}\text{C}$  cycle and the role the CIE might play. We then analyse in section 3.1 the simulated  $\delta^{13}\text{C}$  cycle in our model simulations (section 3.1). results. This enables us to evaluate (section 3.2) if our stacks  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  are good representations of changes in  $\delta^{13}\text{C}_{\text{DIC}}$  in the non-polar wider tropical surface ocean

**Figure 1.** Location of the 127 sediment cores from which data have been compiled for this study. In 87 cores data from the planktic species *G. ruber* and in 18 cores data from *T. sacculifer* have been included, while 22 cores provided mono-specific data from both species.

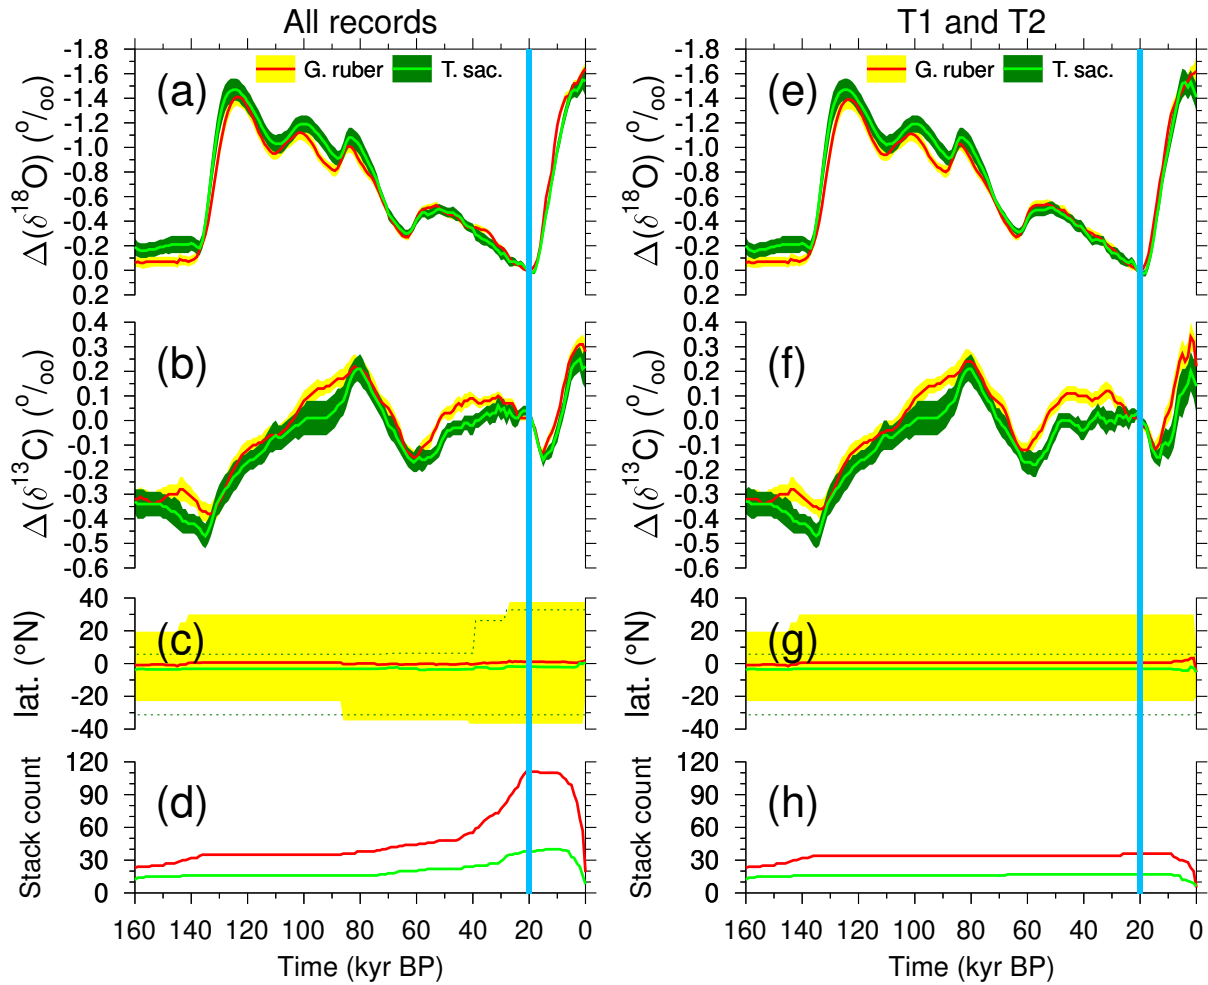

or if corrections such as the CIE need to be applied (section 3.2). Finally, we briefly discuss the CIE in  $\delta^{18}\text{O}_{\text{rub}}$  and  $\delta^{18}\text{O}_{\text{sac}}$  (section 3.3), before we come to our conclusions (section 4).

## 2 Methods

### 3 **Data on changes**

#### 95 2.1 Constructing new mono-specific stacks from planktic foraminifera

**Data source and age modelling:** To construct time series of low-latitude  $\delta^{13}\text{C}$  variations through the past 160 kyr, we selected 112 and 40  $\delta^{13}\text{C}$  records of the shallow-dwelling planktic foraminifera *G. ruber* and *T. sacculifer*, respectively, predominantly from the World Atlas of late Quaternary Foraminiferal Oxygen and Carbon Isotope Ratios (Mulitza et al., 2022). ~~Since the publication of the 2022 version of the World Atlas various other records have been added to this repository. From these newly~~  
100 ~~added records six are actually contained in our data selection here.~~ A list of the ~~sediment cores from which data are~~ isotope records contributing to our stacks with relevant meta data, references to the original publications and data sources is compiled provided in Table S1. In three sediment cores time series from both *G. ruber white* and *G. ruber pink* contribute to our *G. ruber* stacks, while data from 22 cores contain mono-specific data from both *G. ruber* and *T. sacculifer*. All combined our data selection is based on material from 127 sediment cores. The core sites cover a latitudinal range from 37.6°N to 36.7°S for *G.*  
105 *ruber* and of 32.8°N to 31.3°S for *T. sacculifer* in all major ocean basins (Figure 1), although the contributions from individual cores (and therefore the latitudinal range) changed over time (Figure 2c). Our age models are based on either radiocarbon ages

**Figure 2.** Stacks of anomalies in (a,e)  $\delta^{18}\text{O}$  and (b,f)  $\delta^{13}\text{C}$  from the planktic species *G. ruber* and *T. sacculifer* across the last 160 kyr. Mean anomalies ( $\pm 1$  SE) are calculated with respect to the mean of 21–19 kyr BP (blue vertical band). Data are largely based on Mulitza et al. (2022). (c,g) Latitudinal distribution of cores contributing to the stack (mean and full range) and (d,h) stack count. Either data from all cores for each species are compiled (left-d) or (right-h) from a reduced core selection, in which contributing cores cover both Termination 1 and 2 (T1+T2).

or oxygen isotope stratigraphy or a combination of both methods. To calibrate radiocarbon ages, we first subtracted a simulated local reservoir age from the nearest grid-box of the modelling experiments conducted for Marine20 (Butzin et al., 2020; Heaton et al., 2020) and then calibrated the corrected radiocarbon age with the IntCal20 calibration curve (Reimer et al., 2020).

110 For core sections with insufficient radiocarbon coverage or outside the radiocarbon dating range ages were added through the visual alignment with the software [PaleoDataView \(Langner and Mulitza, 2019\)](#) using the isotope stacks by Lisiecki and Raymo (2005) and Lisiecki and Stern (2016). ~~In an using the software [PaleoDataView \(Langner and Mulitza, 2019\)](#). In a few~~

cases age models were derived by visual alignment with the oxygen isotope records of well-dated nearby cores. The details of the age model construction are available in the netCDF files of the age models in the corresponding PaleoDataView collection (Köhler and Mulitza, 2023). A continuous age model was then constructed with the age modelling software BACON (Blaauw and Christen, 2011). For each record we produced an ensemble of 1000 time series by combing 1000 BACON-generated age models with 1000 down-core  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  series by adding a random value within the typical analytical  $1\sigma$ -uncertainty of 0.05‰ and 0.07‰ to each down-core  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  value, respectively. The resulting 1000  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  time series were then interpolated to a time step of 1 kyr to calculate the mean and the standard deviation of the time series ensembles. The averaging of the individual ensemble members then led to a considerable smoothing of the final time series.

**Stacking of down-core isotope records:** ~~Sediment cores covering the Anthropocene clearly show that the  $\delta^{13}\text{C}_{\text{rub}}$  of *G. ruber* and *T. sacculifer* shells ( $\delta^{13}\text{C}_{\text{rub}}$ ,  $\delta^{13}\text{C}_{\text{sac}}$ ) faithfully reflects changes in  $\delta^{13}\text{C}_{\text{DIC}}$  (Al-Rousan et al., 2004; Black et al., 2011), albeit with a notable offset. This offset is influenced by the CIE (e.g. Spero et al., 1997), light intensity (e.g. Spero et al., 1991) and the size of the foraminiferal shells (e.g. Oppo and Fairbanks, 1989).~~ Although the size class used for stable isotope measurements can vary considerably among records, it is common practice to use a fairly constant size down-core to minimise size-related effects on both oxygen and carbon isotope ratios (e.g. Oppo and Fairbanks, 1989). To provide a common baseline, we corrected all single isotope records by their individual mean values for the period from 21 to 19 kyr BP marked as Last Glacial Maximum (LGM) in various plots. To produce final isotope stacks, we averaged all corrected time series and calculated the standard error (SE) of the means at 1 kyr intervals. The final mono-specific stacks of both  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  anomalies based on either *G. ruber* or *T. sacculifer* are plotted in Figure 2a,b. The oxygen isotope stacks are here also shown to give a clear reference for G/IG changes,  $\delta^{18}\text{O}$  has its maxima during peak glacial times and its minima during peak interglacials. In section 3.3 we will come back to these data to discuss the CIE in  $\delta^{18}\text{O}_{\text{rub}}$  and  $\delta^{18}\text{O}_{\text{sac}}$ . ~~We compiled two sets of data compilations, one to which all records contributed. To test to what extent the data distribution affects the stacks, we generated two versions of stacks, one based on all records (Figure 2a–d), and another, in which only those records have compiled which covered both Terminations 1 and 2—an alternative based only on records which contain both Terminations (T1+T2, Figure 2e–h).~~ The stack counts (Figure 2d,h) ~~shows that the different compilations show that the two versions~~ differ mainly in the younger half, they are identical beyond 85 kyr BP. The latitudinal ranges in the young half are slightly smaller for the compilations T1+T2 than when all cores are compiled, but the mean latitudes of all cores are throughout the covered time window of the last 160 kyr in all cases (for both species and for both compilations) close to the equator (Figure 2d,g). This stationarity consistency in the mean latitude suggests that the incoming light which varied in its annual mean values between  $\sim 420 \text{ W m}^{-2}$  at the equator and  $\sim 330 \text{ W m}^{-2}$  around latitudes of  $40^\circ$  (Laskar et al., 2004) should only marginally affect the isotopic fractionation (e.g. Spero et al., 1991).

## 2.2 Benthic $\delta^{13}\text{C}$

Focus of this study is the  $\delta^{13}\text{C}$  of the surface ocean. However, for a rough comparison of  $\delta^{13}\text{C}$  changes in the deep ocean we rely on the published  $\delta^{13}\text{C}$  stack compiled-constructed from six deep Pacific core as contained in Lisiecki (2014). The six cores are all ODP cores (677, 846, 849, 1123, 1143, 1208) from between 2700 and 3500 m water depth, located between  $42^\circ\text{S}$

**Figure 3.** Carbon cycle time series of the last 160 kyr, including the Penultimate and Last Glacial Maximum (PGM, LGM) and Terminations 1 and 2 (T1, T2). Spline of atmospheric CO<sub>2</sub> (a) and δ<sup>13</sup>CO<sub>2</sub> (b) based on data from various ice cores (grey, ±1σ around the mean, (Köhler et al., 2017a; Eggleston et al., 2016a)) and highly resolved recent data from the “horizontal ice core” approach in Taylor Glacier (yellow, (Menking et al., 2022b)(Bauska et al., 2016, 2018; Menking et al., 2022b)). (c) Δ(δ<sup>13</sup>C<sub>rub</sub>) and Δ(δ<sup>13</sup>C<sub>sac</sub>) based on the planktic foraminifera *G. ruber* or *T. sac.*, respectively, averaging signals in the non-polar wider tropical surface ocean (this study, based on Mulitza et al., 2022)(this study, largely based on Mulitza et al., 2022). (d) Deep ocean δ<sup>13</sup>C from benthic foraminifera stacked from 6 six Pacific cores (Lisiecki, 2014).

and 36°N. The deep Pacific δ<sup>13</sup>C stack should cover the most depleted end member of the marine δ<sup>13</sup>C cycle (Figure 3d) and should give us some indication how δ<sup>13</sup>C in deep ocean is performing in our simulations. More details on the stack are found in Lisiecki (2014).

### 150 2.3 Overview on cycle changes over the last 160 kyr

Reconstructed changes in the late Quaternary carbon cycle are still not completely understood. The ice cores give us a precise picture of atmospheric (Bereiter et al., 2015; Köhler et al., 2017a) (Fig. 3a), which in the meantime has also been met reasonably well with various different carbon cycle models (e.g. Menviel et al., 2012; Ganopolski and Brovkin, 2017; Köhler and Munhovc, 2017). These findings suggest, that the main processes responsible for the observed changes on orbital timescales might indeed have been identified, although improvements in details are certainly necessary.

The corresponding atmospheric  $\delta^{13}C_{atm}$ , now available over the last 155 kyr (Eggleston et al., 2016a), however, is in all its features still waiting for a process-based interpretation (Figure 3b). Since  $\delta^{13}C_{atm}$  helps to pinpoint on processes responsible for changes, any simulation that is able to explain one without the other might need to be interpreted with caution. Models suggest that especially physical and biological processes in the Southern Ocean processes robustly influence  $\delta^{13}C_{atm}$ , while the impact of the Atlantic meridional overturning circulation (AMOC) on  $\delta^{13}C_{atm}$  seems to be model-dependent (Menviel et al., 2015). Consequently, the abrupt drop in  $\delta^{13}C_{atm}$  at the onset of Termination 1 (T1) (Smith et al., 1999; Schmitt et al., 2012) is nowadays understood to be caused by marine processes, while subsequent changes during T1 and its recovery during the Holocene to LGM-like values were potentially related to a mixture of oceanic and terrestrial processes (Köhler et al., 2005; Bauska et al., 2016).

Two surprising and largely unexplained features stand out in the 155 kyr record. First, there exist a long-term trend by  $+0.45$  from the Penultimate and the Last Glacial Maximum (PGM and LGM). When first discovered (Schneider et al., 2013) it has been hypothesised that changes in the isotopic composition of solid Earth fluxes or of their intensities or long-term peat build-up might be responsible for them. Second, a  $0.5$  deep and nearly 20 kyr long minima centred around 58 kyr BP happened, rather uncorrelated with changes. Eggleston et al. (2016a) hypothesise that the minima might have been partially caused by a change in ocean stratification between Marine Isotope Stage (MIS) 4 and MIS 3, allowing for a different amount of isotopically light carbon being stored in the deep ocean. Recently, high resolution data of  $\delta^{13}C_{carb}$  from Taylor Glacier covering 74 to 59.5 kyr BP including MIS 4 and the drop into the minimum have been published (Menking et al., 2022b) showing more variability and between 66 and 60 kyr BP with  $-1$  a twice as large change as previously contained in the smoothed record of Eggleston et al. (2016a). Menking et al. (2022b) also performed first model simulations in order to understand which processes might be responsible for the reconstructed changes in the carbon cycle. However, to our knowledge none of the ideas put forward in Schneider et al. (2013) for the long-term trend in  $\delta^{13}C_{carb}$  have so far been convincingly and successfully verified with carbon cycle model simulation. Furthermore, 400–500 kyr variability related to slow eccentricity changes found in marine Plio-Pleistocene (Russon et al., 2010; Wang et al., 2014; Paillard, 2017) might be superimposed on faster variations, making a process-based understanding of observed changes in  $\delta^{13}C_{carb}$  even more challenging.

Our new mono-specific stacks from the non-polar surface ocean of  $\Delta(\delta^{13}C_{carb})$  and  $\Delta(\delta^{13}C_{sac})$  without any corrections (Figure 3c) contain a G/IG rise of 0.25 across T1, but of only 0.15 across T2, while atmospheric  $\delta^{13}C_{atm}$  at the same time rose by 0.1 (T2), or stayed constant (T1) (Figure 3b), showing local minima during terminations in both records. Deep ocean benthic  $\delta^{13}C_{carb}$  (Figure 3d) is here approximated by a stack from six deep Pacific cores (Lisiecki, 2014), that contains a G/IG rise of 0.45 across both T1 and T2. This value is on the upper end of the 95% confidence interval of compilations of marine  $\delta^{13}C_{carb}$  changes across T1

(Peterson et al., 2014; Peterson and Lisiecki, 2018) which suggest to represent global ocean-wide changes. The marine time series, both from surface and deep ocean, also contain wide and deep minima around 60 kyr BP, similarly to the smoothed atmospheric data of Eggleston et al. (2016a), but different to the higher resolved Taylor Glacier of Menking et al. (2022b). Furthermore, all marine data, similarly as the atmospheric, contain a long-term rise from PGM to LGM (about +0.33 in the non-polar surface ocean, +0.18 in the deep Pacific, Figure 3) potentially connected with eccentricity-related long-term variability of 400 to 500 kyr (Pälike et al., 2006; Ma et al., 2011; Wang et al., 2014), that have been found in various parts of the Cenozoic.

Scatter plot of our new stacks (a)  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  versus  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  and (b)  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  versus  $\Delta(\delta^{18}\text{O}_{\text{sac}})$ . Data stacks without corrections for the CIE are plotted. The time series are restricted to data of last 150 kyr to allow comparison later on with simulation results which were based on the only 155 kyr long atmospheric record. Linear regressions using only the mean values and when using also uncertainties in both x and y are performed.

Before we start with deeper model-based interpretation of the cycle, we have a closer look on our new isotope stacks. If the CIE plays a role for how the isotopes of the surface ocean are recorded in the foraminifera shells on orbital timescales then the two mono-specific time series in both and should differ, since the size of the CIE as detected from laboratory experiments in both species differs by nearly a factor of two,  $-0.0089$  and  $-0.0047$  change in per of  $\text{CO}_3^{2-}$  for *G. ruber* and *T. sacculifer*, respectively, and of  $-0.0022$  and  $-0.0014$  change in per of  $\text{CO}_3^{2-}$  for *G. ruber* and *T. sacculifer*, respectively (Spero et al., 1999). At first glance (Figure 2a,b) the time series are remarkable similar. A more quantitative evaluation is obtained by calculating the linear regression from scatter plots, when results based on one species are plotted against those of the other. Doing so (Figure 6) reveals for that on average changes are identically recorded in both species. In other words, the linear slope of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  against  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  is  $0.98$  ( $r^2 = 0.95$ ) or  $0.99 \pm 0.03$  ( $r^2 = 0.95$ ) when considering the uncertainties of our stack during regression. For the agreement is only slightly worse, the regression slope of  $\delta^{18}\text{O}_{\text{rub}}$  against  $\delta^{18}\text{O}_{\text{sac}}$  is  $0.96$  ( $r^2 = 0.96$ ) or  $0.98 \pm 0.01$  ( $r^2 = 0.96$ ) with uncertainties. Since  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  are on average recording virtually the same changes it is difficult to image how the species-specific CIE can play a role here. Due to the small amplitudes of the CIE in it is yet inconclusive if the CIE plays a role for  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  versus  $\Delta(\delta^{18}\text{O}_{\text{sac}})$ .

### 3 The carbon cycle model BICYCLE-SE

#### 2.1 The carbon cycle model BICYCLE-SE

#### 2.2 Brief model description

##### 2.1.1 Brief model description

At the core of BICYCLE — the Box model of the Isotopic Carbon cYCLE — sits a ten-boxes large an ocean (O) with 10 boxes and a terrestrial biosphere consisting of seven boxes (B) together with a one box atmosphere (A), in which the concentration of carbon (as DIC in the ocean, as  $p\text{CO}_2$  in the atmosphere, as organic carbon in the biosphere) and both of the isotopes  $\delta^{13}\text{C}$

215 and  $\Delta^{14}\text{C}$  are traced (Köhler et al., 2005). Furthermore, in the ocean alkalinity,  $\text{PO}_4^{3-}$  as macro-nutrient and  $\text{O}_2$  is represented. From the two variables of the marine carbonate system (DIC and alkalinity) all other variables ( $\text{CO}_2$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$  and  $\text{pH}$ ) are calculated according to Zeebe and Wolf-Gladrow (2001) with updates of the dissociation constants  $\text{pK}_1$  and  $\text{pK}_2$  (Mojica Prieto and Millero, 2002). The ten ocean boxes distinguish 100 m deep equatorial (or ~~non-polar~~wider tropical) surface waters in Atlantic and Indo-Pacific from 1000 m deep surface ocean boxes in the high latitudes (North Atlantic, Southern Ocean, 220 North Pacific). ~~Here, non-polar~~In the model, wider tropical boxes range from  $40^\circ\text{S}$  to  $40^\circ\text{N}$  in the Indo-Pacific and to  $50^\circ\text{N}$  in the Atlantic, rather similar to the latitudinal coverage of the sediment cores from which  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  have been ~~compiled~~constructed. Deep ocean boxes ~~contain~~represent all waters below 1 km in the three basin Atlantic, Southern Ocean, Indo-Pacific. In the equatorial regions the waters between 100 and 1000 m water depth are described by intermediate boxes. The terrestrial biosphere (Köhler and Fischer, 2004) distinguishes  $\text{C}_3$  and  $\text{C}_4$  photosynthesis of grasses and trees, and 225 soil carbon with different turnover times of up to 1000 years.

The model extension towards the version BICYCLE-SE used here, that can take care of solid Earth processes, is sketched in Figure 4. The main improvement documented in detail in Köhler and Munhoven (2020) is the implementation of a sediment module, that captures early diagenesis in a 8 cm deep sedimentary mixed layer (M), under which numerous historical layers are implemented. In effect, we now simulate the ~~AOBM~~-subsystem of the global carbon cycle consisting of atmosphere, 230 ocean, terrestrial biosphere and sedimentary mixed layer (AOBM) within BICYCLE-SE. In each of the three ocean basins (Atlantic; Southern Ocean, Indo-Pacific) the pressure-dependent carbonate system is calculated for every 100 m water depth and depending on the over- or undersaturation of the carbonate-ion concentration  $\text{CaCO}_3$  is either accumulated or dissolved. Parametrisation and realisation of the sedimentary processes directly follows Munhoven and François (1996) and Munhoven (1997). The carbon isotopes in the sedimentary mixed layer are only followed in aggregated boxes (one for each of the three 235 ocean basin).

Equipping BICYCLE with a process-based sediment module enables the revised model version BICYCLE-SE to address questions related to changes in solid Earth carbon fluxes in detail and on long-term. Roughly speaking the following processes are considered: 1)  $\text{CO}_2$  outgassing from volcanoes on land, hot spot island volcanoes and mid ocean ridge (MOR) hydrothermal activity is realised as partly being dependent on changing sea level. 2) Coral reef growth is a known shallow water carbonate 240 sink, that is to some extent also following sea level rise. 3) Weathering of silicate or carbonate rocks on land, consuming different amounts of atmospheric  $\text{CO}_2$ , and both leading to bicarbonate fluxes into the ocean. These solid Earth processes are not directly coupled to each other. Their implementation into the model might therefore lead to temporal offsets in various variables, to which the sediment module might react in a carbonate compensation feedback. Further details on the model and the time-dependent forcing are found in Köhler and Munhoven (2020). Part of this brief model description has been taken from 245 Köhler (2020).

**Figure 4.** Sketch of the Box model of the isotopic carbon cycle, version solid Earth (BICYCLE-SE), modified from Köhler and Munhoven (2020). V: outgassing of CO<sub>2</sub> from volcanoes on land potentially and temporally overlain by land ice and from hot spot island volcanoes (and mid ocean ridges, not shown) influenced by changing sea level; C: shallow water carbonate deposition due to coral reef growth; Si-W: silicate weathering and Ca-W: carbonate weathering with different sources of C, but both delivering HCO<sub>3</sub><sup>-</sup> -ions into the ocean; P: PO<sub>4</sub><sup>3-</sup> riverine input and sedimentary burial; S: CaCO<sub>3</sub> sedimentation and dissolution. A2BA-B: atmosphere-biosphere exchange of CO<sub>2</sub>; A2OA-O: atmosphere-ocean exchange of CO<sub>2</sub>. The cyan-coloured broken circles mimic the two overturning cell in the Atlantic and Indo-Pacific Ocean. The isotopic fractionation  $\epsilon$  during exchange processes, or the prescribed  $\delta^{13}\text{C}$  of external fluxes are given, summarising the parametrisation of the <sup>13</sup>C cycle within the model.

## 2.2 Complete formulation of the cycle in BICYCLE-SE

### 2.1.1 Complete formulation of the <sup>13</sup>C cycle in BICYCLE-SE

The following isotopic fractionations are now considered in the BICYCLE-SE model. For this study the whole  $\delta^{13}\text{C}$  cycle has been revised. While isotopic fractionations are given here in the  $\epsilon_{(A-B)}$ -notation (in ‰) they are implemented after Zeebe and Wolf-Gladrow (2001) in the model as factors-fractionation factors  $\alpha_{(A-B)}$ . Both are related after

$$\underline{\alpha}_{\epsilon_{(A-B)}} = \frac{\epsilon_{(A-B)}}{1000} + 11000 \cdot (\alpha_{(A-B)} - 1). \quad (1)$$

defined as Furthermore,  $\alpha_{(A-B)}$  is related to  $\delta^{13}\text{C}$  in reservoirs A and B after

$$\alpha_{(A-B)} = \frac{\delta^{13}\text{C}_A + 1000}{\delta^{13}\text{C}_B + 1000}. \quad (2)$$

There is no convention if the initial or final reservoir is given as A or B here, however here A is always the final and B the initial reservoir of the fractionation process. In some cases a specific process instead of two reservoirs is mentioned in the

subscript, e.g.  $\epsilon_{(a2o)}$  and  $\epsilon_{(o2a)}$  and  $\epsilon_{(a\rightarrow o)}$  and  $\epsilon_{(o\rightarrow a)}$  for the atmosphere-ocean gas exchange, for which not only the two different reservoirs, but also the direction of the flux plays a role for the size of the isotopic fractionation. In that case the quantified fractionation implies an isotopic depletion connected with the related process for  $\epsilon < 0\text{‰}$ .

**Air-sea gas exchange:** Using the measurements from Zhang et al. (1995) we formulate, following in most parts Marchal et al. (1998), for the isotopic fractionation during gas exchange to be consisting of contributions from equilibrium ( $\alpha^{\text{eq}}$ ) and kinetic ( $\alpha^{\text{k}}$ ) fractionation ( $\alpha^{\text{total}} = \alpha^{\text{eq}} \cdot \alpha^{\text{k}}$ ). For the atmosphere-to-ocean  $\text{CO}_2$  flux a temperature-dependent equilibrium fractionation of  $\epsilon_{a2o}^{\text{eq}} = \epsilon_{(\text{aq-g})}^{\text{eq}} = -1.31 + 0.0049 \cdot T_C$  and  $\epsilon_{a2o}^{\text{k}} = -1.08\text{‰}$  is used. Note,  $\epsilon_{a2o}^{\text{k}}$  differs by  $-0.2\text{‰}$  from  $\epsilon_{o2a}^{\text{k}} = -0.88\text{‰}$  for the ocean-to-atmosphere flux, a necessary correction already given in Zhang et al. (1995), but to our knowledge only rarely applied. For the reverse ocean-to-atmosphere flux we use the equilibrium fractionation  $\alpha_{o2a}^{\text{eq}} = \alpha_{(\text{aq-DIC})}^{\text{eq}} = \sum_i f_i \alpha_{(\text{aq-i})}$  with  $f_i$  being the relative shares of  $\text{CO}_2$ ,  $\text{HCO}_3^-$  and  $\text{CO}_3^{2-}$  on DIC in the representative ocean box. Furthermore, from the available measurements in Zhang et al. (1995) we derive:  $\alpha_{(\text{aq-HCO}_3^-)} = \frac{\alpha_{(\text{aq-g})}}{\alpha_{(\text{HCO}_3^- \text{-g})}}$ ,  $\alpha_{(\text{aq-CO}_3^{2-})} = \frac{\alpha_{(\text{aq-g})}}{\alpha_{(\text{CO}_3^{2-} \text{-g})}}$  and  $\alpha_{(\text{aq-CO}_2)} = 1$  using  $\epsilon_{(\text{CO}_3^{2-} \text{-g})} = 7.22 - 0.052 \cdot T_C$  and  $\epsilon_{(\text{HCO}_3^- \text{-g})} = 10.78 - 0.114 \cdot T_C$  with  $T_C$  being the sea surface temperature in  $^\circ\text{C}$ .

**Marine biology:** ~~The pre-industrial~~ The preindustrial marine export production of organic carbon at 100 m water depth is set to 10 PgC/yr (which in the model can increase in glacial periods due to iron fertilisation in the Southern Ocean up to 13 PgC/yr, Figure S1d) with a fixed molar rain ratio of organic C:CaCO<sub>3</sub> of 10:1. Existing data on fractionation during marine organic matter production (marine photosynthesis) are rather weak in determining if and how it depends on CO<sub>2</sub> (Young et al., 2013; Brandenburg et al., 2022; Liu et al., 2022). Furthermore, as discussed in Brandenburg et al. (2022) some species might contain so-called carbon concentrating mechanisms and use not CO<sub>2</sub>, but HCO<sub>3</sub><sup>-</sup> as source of their carbon, in which case a completely different isotopic fractionation during marine photosynthesis ( $\epsilon_{(\text{C}_{\text{org}} \text{-DIC})}$ ) would follow. We base our initial formulation of  $\epsilon_{(\text{C}_{\text{org}} \text{-DIC})}$  ~~in scenario SEi0~~ on the data compilation of  $\delta^{13}\text{C}_{\text{PPOC}}$  in Verwega et al. (2021) who found a dependency on latitude. Using average preindustrial  $\delta^{13}\text{C}_{\text{DIC}}$  of  $+2.5\text{‰}$  (Schmittner et al., 2013) as starting values and the  $\delta^{13}\text{C}_{\text{PPOC}}$  in Verwega et al. (2021) of  $-22$ ,  $-24$ ,  $-28\text{‰}$  for low, high northern, and high southern latitudes, respectively, and approximating  $\epsilon_{(\text{C}_{\text{org}} \text{-DIC})} \approx \delta^{13}\text{C}_{\text{PPOC}} - \delta^{13}\text{C}_{\text{DIC}}$ , we come up with the following isotopic fractionation  $\epsilon_{(\text{C}_{\text{org}} \text{-DIC})}$  of  $-24.5$ ,  $-26.5$ , and  $-30.5\text{‰}$  accordingly (~~scenario SEi0~~). This approximation is motivated by the high uncertainties in  $\delta^{13}\text{C}_{\text{PPOC}}$  as documented in Verwega et al. (2021).

The breadth spread in  $\delta^{13}\text{C}_{\text{PPOC}}$  in the data of Verwega et al. (2021) is huge, ranging from  $-15$  to  $-35\text{‰}$ . Furthermore, they confirmed the finding of earlier studies (Young et al., 2013; Lorrain et al., 2020) that  $\delta^{13}\text{C}_{\text{PPOC}}$  becomes much more depleted over time than what is explainable by the  $^{13}\text{C}$  Suess effect (Keeling, 1979). In details, between 1960 and 2010  $\delta^{13}\text{C}_{\text{PPOC}}$  decreased by about  $3 \pm 4\text{‰}$ . The Suess Effect shows a decrease in atmospheric  $\delta^{13}\text{CO}_2$  of about  $1.5\text{‰}$  during that time (Rubino et al., 2013) and it is known that in the ocean the Suess Effect is decreasing with depth (Eide et al., 2017). In-At the same time, global mean temperature rose by about 0.8 K (Rohde and Hausfather, 2020). This shift in  $\delta^{13}\text{C}_{\text{PPOC}}$  is probably caused by a shift in the composition of the phytoplankton communities. We therefore use

290 the ~~numbers above~~ values derived in the previous paragraph from Verwega et al. (2021) as our preindustrial parameter values of  $\varepsilon_{(C_{org}-DIC)}$  to which we add a temperature-dependent part of  $-1.5\%$  for any K the sea surface temperature in the relevant surface ocean box disagrees from its preindustrial value (~~standard scenario SEi~~). The assumed value fits in the range of recent temperature-dependent  $\delta^{13}C_{POC}$  found in Verwega et al. (2021) and has been obtained by tuning to simulate  $\delta^{13}CO_2$  at preindustrial times to be similar to its values at LGM, as seen in the ice core data (Figure 3b). This  
295 leads to  $\varepsilon_{(C_{org}-DIC)}$  at LGM of  $-19.3, -20.4, -24.4\%$  for low, high northern, or high southern latitudes, respectively.

Data are also rather uncertain for the isotopic fractionation during the formation of  $CaCO_3$ . We assume, in agreement with Buitenhuis et al. (2019), that 65% of the  $CaCO_3$  exported in the abyss consists of aragonite and 35% of calcite. Calcite is either produced by coccolithophores or planktic foraminifera. Some coccolithophore species suggest an enrichment, others a depletion in  $\delta^{13}C$  in their shells with respect to  $\delta^{13}C_{DIC}$  in the surrounding water (Ziveri et al., 2003). For planktic foraminifera the CIE is ~~the dominant one of various possible processes of~~ isotopic fractionation hypothesised to occur during hard shell formation (~~e.g. Spero et al., 1997, 1999; Russell and Spero, 2000~~). ~~It is~~ (Bijma et al., 1999; Zeebe et al., 2008; Kimoto, 2015). Isotopic fractionation factors are in comparison to  $\varepsilon_{(C_{org}-DIC)}$  rather small and in the case of the CIE species-specific (Spero et al., 1999). We therefore choose in the model to set the fractionation during calcite production to be neutral with respect to  $^{13}C$ , thus  $\varepsilon_{(cal-DIC)} = 0\%$ , but we will consider  
300 the CIE in post-processing when comparing simulations with reconstructions. For simplicity and due to missing further evidence for fractionation during aragonite production  $\varepsilon_{(ara-DIC)}$  was also kept at  $0\%$ .  
305

More general, we keep  $\varepsilon_{(CaCO_3-DIC)} = 0\%$ .

The shallow water sink of carbonate in corals is assumed to have a  $\delta^{13}C$  that follows after an isotopic fraction of  $\varepsilon_{(corals-DIC)} = -2\%$  from the  $\delta^{13}C$  of the DIC in the surface waters. This value is based on a combination of recent  
310 data, paleo data from the Great Barrier reef and insights from simulations (Linsley et al., 2019; Felis et al., 2022).

**Terrestrial biosphere:** On land, isotopic fractionation is only assumed to occur during photosynthesis with  $\varepsilon_{(C_3-CO_2)} = -19\%$  and  $\varepsilon_{(C_4-CO_2)} = -5\%$  for  $C_3$  (all woody plants and some grasses) and  $C_4$  (some other grasses) photosynthesis, respectively (Vogel, 1993; Lloyd and Farquhar, 1994).

**External fluxes to the AOBM subsystem:** The volcanic  $CO_2$  outgassing flux is assumed to have a fixed  $\delta^{13}C$  signature  
315 ( $\delta^{13}C_V$ ) of  $-5.0\%$ , the typical mean value for volcanic outgassing (e.g. Deines, 2002; Roth and Joos, 2012), but note ~~its uncertainty of about~~ that the uncertainty is  $\pm 3\%$  around it.

From the two weathering fluxes based on either silicate or carbonate rocks, only the latter has a contribution which bring new carbon into the system. Here, 50% of the carbon that as bicarbonate — the weathering product — is entering the ocean with a  $\delta^{13}C$  signature ( $\delta^{13}C_{rock}$ ) of  $+2\%$  — identical to the most likely  $\delta^{13}C$  values in carbonate rocks build  
320 during the Phanerozoic (Bachan et al., 2017). The carbon for the other half of the carbonate weathering flux and for all of the silicate weathering flux is assumed to come from  $CO_2$  in the soil environment. We therefore assume that this  $CO_2$

might be dominated by soil respiration fluxes and therefore a  $\delta^{13}\text{C}$  signature that corresponds to the mean value of the two soil carbon boxes is assumed here.

325 To balance the inflow of  $^{13}\text{C}$  via volcanism and weathering the model has been tuned for long-term stable mean  $\delta^{13}\text{C}$  values in the AOBM subsystem by the following sink: About 6% of the organic carbon, that is exported from the surface boxes into the abyss is assumed to be lost in the sediment. Note, that this number has been tuned with the previous version of the  $^{13}\text{C}$  cycle in operation (Köhler and Munhoven, 2020), but has not been revised thereafter.

~~In summary, the new parametrisation of the cycle has been implemented as follows: (1) The overall philosophy here is to keep the main carbon cycle untouched, but consider only changes the stable isotope. For this reason, the previously tuned value of organic matter flux into the sediment of about 6% is kept as is, since the strength of this carbon sink also changes the overall C cycle including atmospheric. (2) Equations for isotopic fractionation during gas exchange are revised from the literature. (3) Fractionation during marine photosynthesis was completely revised and follows in its latitudinal dependency Verwega et al. (2021), is most uncertain and very likely has a temperature dependency due to species shifts. The size of this temperature dependency  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$  was tuned to dynamics in atmospheric  $\delta^{13}\text{C}$  during the last 20 ka. (4) Fractionation during calcite formation is species-specific and roughly neutral. The CIE is therefore only considered in post-processing. (5) All other parameter values, namely fractionation during terrestrial photosynthesis or during coral reef growth, of volcanic and of weathered carbonate rock are also rather uncertainties. However, their chosen parameter values correspond to the means of the reconstructions, and are kept fixed. One might also take alternative approaches by giving more room to uncertainties in other parameter values, or by also reconsidering changes in the main carbon cycle, and not only in the cycle.~~

340 ~~Overview of simulation scenarios. Name Description SEi standard run for BICYCLE-SE with updated cycle SEi0 as SEi, but no temperature-dependent contribution to  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$  C1 as SEi, but atmospheric are prescribed from data (Eggleston et al., 2016a) C1CO2 as SEi, but atmospheric records (-) are prescribed from data (Eggleston et al., 2016a; Köhler et al., 2017a)~~

## 2.2 ~~Simulation Setup and Scenarios~~

### 2.1.1 Simulation Setup and Scenarios

345 The BICYCLE-SE model simulates the global carbon cycle as function of changing time-dependent physical boundary conditions (forcing), which are nearly identical to the simulations published in Köhler and Munhoven (2020) and which are also in detail described in that study. Briefly, ocean circulation is prescribed from modern data of the WOCE experiment, while its main temporal changes are restricted to: (a) the ~~Atlantic Meridional Overturning Circulation (AMOC)~~AMOC, which is reduced from modern/interglacial 16 Sv to 10 Sv during glacial periods (Figure S1b); (b) Southern Ocean (SO) vertical deep mixing is a function of SO sea surface temperature (Figure S1c). Ocean and land temperature are prescribed from reconstructions (Figure S1e), ocean salinity is varied as function of prescribed sea level (Figure S1a). Additionally, aeolian iron input in the SO is assumed to follow dust fluxes measured in Antarctic ice cores, which might change marine biology in the SO from an iron-limited to an iron-unlimited regime, increasing glacial export production of organic matter to the deep ocean (Figure S1d). The standard scenario SEi used here is — apart from the revised  $\delta^{13}\text{C}$  cycle — nearly identical to the scenario SE in Köhler

**Table 1.** Overview of simulation scenarios.

<u>Name</u>	<u>Description</u>
<u>SEi</u>	<u>standard run for BICYCLE-SE with updated <math>^{13}\text{C}</math> cycle</u>
<u>SEi0</u>	<u>as SEi, but without temperature-dependent contribution to <math>\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}</math></u>
<u>C1</u>	<u>as SEi, but atmospheric <math>\delta^{13}\text{CO}_2</math> is prescribed from data (Eggleston et al., 2016a)</u>
<u>C1CO2</u>	<u>as SEi, but atmospheric records (<math>\delta^{13}\text{CO}_2</math>, <math>\text{CO}_2</math>) are prescribed from data (Eggleston et al., 2016a; Köhler et al., 2017a)</u>

355 and Munhoven (2020). The only difference is that in the application here we revised the applied equatorial SST sea surface temperature (SST). It has been based in previous applications on changes in planktic  $\delta^{18}\text{O}$  in only one ODP record. Now we use the SST stack from Barth et al. (2018), which is based on a compilation of SST from 15 non-polar sediment cores. ~~The new equatorial SST forcing is now based on more data, is temporally higher resolved and contains a smaller G/IG amplitude than before.~~ This leads to only minor changes in atmospheric  $\text{CO}_2$  of less than 5 ppm, but is important for the  $^{13}\text{C}$  cycle, and  
 360 its temperature-dependencies (isotopic fractionation during atmosphere-ocean gas exchange and during carbon uptake by the marine biology). Simulations are started from interglacial conditions around 210 kyr BP. Scenario SEi0 is only performed to illustrate how the implementation of the temperature-dependency in  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$  improve the simulated  $^{13}\text{C}$  cycle, illustrated by plotting atmospheric  $\delta^{13}\text{CO}_2$  against data in Figure 5b.

Simulated changes in the atmospheric record are already in scenario SEi not too far away from the reconstructions, especially  
 365 in  $\text{CO}_2$  (Figure 5a). However, to bring the carbon cycle in atmosphere and surface ocean as close as possible to the reconstructions we perform additional simulations in which the atmospheric  $\delta^{13}\text{CO}_2$  alone (scenario C1) or together with atmospheric  $\text{CO}_2$  (scenario C1CO2) is forced by the reconstructions. Here, we use the data splines as plotted in Figure 3a,b (Eggleston et al., 2016a; Köhler et al., 2017a) and ignore the higher resolved data from Taylor Glacier (~~Menking et al., 2022b~~), since these more abrupt changes in  $\delta^{13}\text{CO}_2$  are either during the last 50 kyr to a large extent covered in the dynamics of the spline  
 370 (Bauska et al., 2016, 2018) or around 70 kyr BP (Menking et al., 2022b) probably not recorded in our marine sediment records. This implies that internally calculated fluxes are overwritten by changes that are necessary to keep the simulated atmospheric carbon variables identical to the reconstructions. ~~This approach is typically applied in~~ This approach is typically applied in  $\text{CO}_2$  concentration  
An overview of the applied simulation scenarios is compiled in Table 1.

## 2.2 Data analysis

375 Linear regression was performed with the software MATLAB (The MathWorks Inc., 2023). The uncertainties of the fits are approximated by root-mean-square-errors calculated after  $s = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - f_i)^2}$ , with  $f_i$  being the calculated values according

**Figure 5.** Simulation results of atmospheric variables showing reasonable good agreement with and comparison to data splines for (a) atmospheric  $\text{CO}_2$ , and necessary improvements in (b) atmospheric  $\delta^{13}\text{CO}_2$  during parameter tuning of  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$ . See Table 1 Results for details of scenario SEi (standard) and SEi0 are shown. The latter differs from the different scenarios standard run by a lack of temperature dependency in  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$ .

to the linear regression equations. In cases in which the uncertainties in both variables should be considered we used the function “linfitxy”, version 1.2.0.0 (Browaeys, 2023). The frequency analysis was performed using R (R Core Team, 2023), including the function “coh” from the R-package seewave, version 2.2.3, calculating coherence.

### 380 3 Results and Discussion

#### 3.1 Overview on $^{13}\text{C}$ cycle changes over the last 160 kyr

Reconstructed changes in the late Quaternary carbon cycle are still not completely understood. The ice cores give us a precise picture of atmospheric  $\text{CO}_2$  concentration driven present day or future ocean carbon cycle simulations (e.g. Hauck et al., 2020). It has already been used in BICYCLE-SE for (Bereiter et al., 2015; Köhler et al., 2017a) (Figure 3a), which in the meantime has also been met reasonably well with various different carbon cycle models (e.g. Menviel et al., 2012; Ganopolski and Brovkin, 2017; Knorr et al., 2017). These findings suggest, that the main processes responsible for the observed changes on orbital timescales might indeed have been identified, although results are to some extent model-dependent and improvements in details are certainly necessary.

The corresponding atmospheric  $\delta^{13}\text{CO}_2$ , now available over the last 155 kyr (Eggleston et al., 2016a), however, is in all its features still waiting for a process-based interpretation (Figure 3b). Since  $\delta^{13}\text{CO}_2$  to obtain radiocarbon in the surface ocean as close to the data as possible during the construction of the most recent marine radiocarbon calibration curve Marine20

(Heaton et al., 2020) and subsequent studies (Köhler et al., 2022). However, since atmospheric  $\delta^{13}\text{C}$  helps to pinpoint on processes responsible for  $\text{CO}_2$  changes, any simulation that is able to explain one without the other might need to be interpreted with caution. Models suggest that especially physical and biological processes in the Southern Ocean processes robustly influence  $\delta^{13}\text{CO}_2$ , while the impact of the Atlantic meridional overturning circulation (AMOC) on  $\delta^{13}\text{CO}_2$  seems to be model-dependent (Menviel et al., 2015). Consequently, the abrupt drop in  $\delta^{13}\text{CO}_2$  at the onset of Termination 1 (T1) (Smith et al., 1999; Schmitt et al., 2012) is nowadays understood to be caused by marine processes, while subsequent  $\delta^{13}\text{CO}_2$  changes during T1 and its recovery during the Holocene to LGM-like values were potentially related to a mixture of oceanic and terrestrial processes (Köhler et al., 2005; Bauska et al., 2022).

Two largely unexplained features stand out in the 155 kyr  $\delta^{13}\text{CO}_2$  record. First, there exist a long-term trend by +0.45‰ from the Penultimate and the Last Glacial Maximum (PGM and LGM). When first discovered (Schneider et al., 2013) it has been hypothesised that changes in the isotopic composition of solid Earth fluxes or of their intensities or long-term peat build-up might be responsible for them. Second, a 0.5‰ deep and nearly 20 kyr long minima centred around 58 kyr BP happened, rather uncorrelated with  $\text{CO}_2$  changes. Eggleston et al. (2016a) hypothesise that the  $\delta^{13}\text{CO}_2$  minima might have been partially caused by a change in ocean stratification between Marine Isotope Stage (MIS) 4 and MIS 3, allowing for a different amount of isotopically light carbon being stored in the deep ocean. Recently, high resolution data of  $\delta^{13}\text{CO}_2$  from Taylor Glacier covering 74 to 59.5 kyr BP including MIS 4 and the drop into the  $\delta^{13}\text{CO}_2$  minimum have been published (Menking et al., 2022b) showing more variability and between 66 and 60 kyr BP with -1‰ a twice as large change as previously contained in the smoothed record of Eggleston et al. (2016a). Menking et al. (2022b) also performed first model simulations in order to understand which processes might be responsible for the reconstructed changes in the carbon cycle. However, to our knowledge none of the ideas put forward in Schneider et al. (2013) for the long-term trend in  $\delta^{13}\text{CO}_2$  are normally prognostic variables of the model have so far been convincingly and successfully verified with carbon cycle model simulation. Furthermore, 400–500 kyr variability in  $\delta^{13}\text{C}$  related to slow eccentricity changes found throughout the Cenozoic (e.g. Pälike et al., 2006; Russon et al., 2022) might be superimposed on faster variations, making a process-based understanding of observed changes in  $\delta^{13}\text{CO}_2$  even more challenging.

Sediment cores covering the Anthropocene clearly show that the  $\delta^{13}\text{C}$  of *G. ruber* and their calculated changes should be derived out of *T. sacculifer* shells ( $\delta^{13}\text{C}_{\text{rub}}$ ,  $\delta^{13}\text{C}_{\text{sac}}$ ) faithfully reflects changes in  $\delta^{13}\text{C}_{\text{DIC}}$  caused by the model's differential equations followed by a proper integration scheme, this approach slightly violates the mass conservation. It nevertheless guarantees that simulated surface ocean variables of the carbon cycle are within the model realm as consistent as possible with the atmospheric reconstructions.  $\delta^{13}\text{C}$  Suess Effect (Al-Rousan et al., 2004; Black et al., 2011), albeit with a notable offset. This offset might be influenced by the CIE (e.g. Spero et al., 1997), light intensity (e.g. Spero et al., 1991) and the size of the foraminiferal shells (e.g. Oppo and Fairbanks, 1989). Our new mono-specific stacks from the wider tropical surface ocean of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  (Figure 3c) contain a G/IG rise of 0.25‰ across T1, but of only 0.15‰ across T2, while atmospheric  $\delta^{13}\text{CO}_2$  at the same time rose by 0.1‰ (T2), or stayed constant (T1) (Figure 3b), showing local minima during terminations in both records. Deep ocean benthic  $\delta^{13}\text{C}$  (Figure 3d) is here approximated by a stack from six deep Pacific cores (Lisiecki, 2014), that contains a G/IG rise of 0.45‰ across both T1 and T2. This value is on the upper end of the 95%

**Figure 6.** Scatter plot of our new stacks (a)  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  versus  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  and (b)  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  versus  $\Delta(\delta^{18}\text{O}_{\text{sac}})$ . Data stacks without corrections for the CIE are plotted. The time series are restricted to data of last 150 kyr to allow comparison later-on with simulation results which were based on the only 155 kyr long atmospheric  $\delta^{13}\text{CO}_2$  record. Linear regressions using only the mean values and when using also uncertainties in both x and y are performed. The root-mean-square-error is depicted by  $s$ .

confidence interval of compilations of marine  $\delta^{13}\text{C}$  changes across T1 (Peterson et al., 2014; Peterson and Lisiecki, 2018) which suggest to represent global ocean wide changes. The marine time series, both from surface and deep ocean, also contain wide and deep minima around 60 kyr BP, similarly to the smoothed atmospheric  $\delta^{13}\text{CO}_2$  data of Eggleston et al. (2016a), but different to the higher resolved Taylor Glacier  $\delta^{13}\text{CO}_2$  of Menking et al. (2022b). Furthermore, all marine  $\delta^{13}\text{C}$  data, similarly as the atmospheric  $\delta^{13}\text{CO}_2$ , contain a long-term rise from PGM to LGM (about  $+0.33\text{‰}$  in the wider tropical surface ocean,  $+0.18\text{‰}$  in the deep Pacific, Figure 3), which might be potentially connected with the 400-to-500 kyr variability.

#### 4 Results and Discussion

Before we start with deeper model-based interpretation of the  $^{13}\text{C}$  cycle, we have a closer look on our new isotope stacks. The size of the CIE as detected from laboratory experiments in both species differs by nearly a factor of two,  $-0.0089$  and  $-0.0047\text{‰}$  change in  $\delta^{13}\text{C}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  for *G. ruber* and *T. sacculifer*, respectively, and of  $-0.0022$  and  $-0.0014\text{‰}$  change in  $\delta^{18}\text{O}$  per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  for *G. ruber* and *T. sacculifer*, respectively (Spero et al., 1999). Therefore, if the CIE plays a role for how the isotopes of the surface ocean are recorded in the foraminifera shells on orbital timescales then the two mono-specific time series in both  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  should differ. At first glance (Figure 2a,b) the time series are remarkable similar. A more quantitative evaluation is obtained by calculating the linear regression from scatter

440 plots, when results based on one species are plotted against those of the other. Doing so (Figure 6) reveals for  $\delta^{13}\text{C}$  that on  
average changes are identically recorded in both species. In other words, the linear slope of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  against  $\Delta(\delta^{13}\text{C}_{\text{sac}})$   
is 0.98 ( $r^2 = 0.95, s = 0.04\%$ ) or  $0.99 \pm 0.03$  ( $r^2 = 0.95$ ) when considering the uncertainties of our stack during regression.  
445 For  $\delta^{18}\text{O}$  the agreement is only slightly worse, the regression slope of  $\delta^{18}\text{O}_{\text{rub}}$  against  $\delta^{18}\text{O}_{\text{sac}}$  is 0.96 ( $r^2 = 0.96, s = 0.09\%$ )  
or  $0.98 \pm 0.01$  ( $r^2 = 0.96$ ) with uncertainties. Since  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  are on average recording virtually the same  
changes it is difficult to image how the species-specific CIE can play a role here. Due to the small amplitudes of the CIE in  
 $\delta^{18}\text{O}$  it is yet inconclusive if the CIE plays a role for  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  versus  $\Delta(\delta^{18}\text{O}_{\text{sac}})$ .

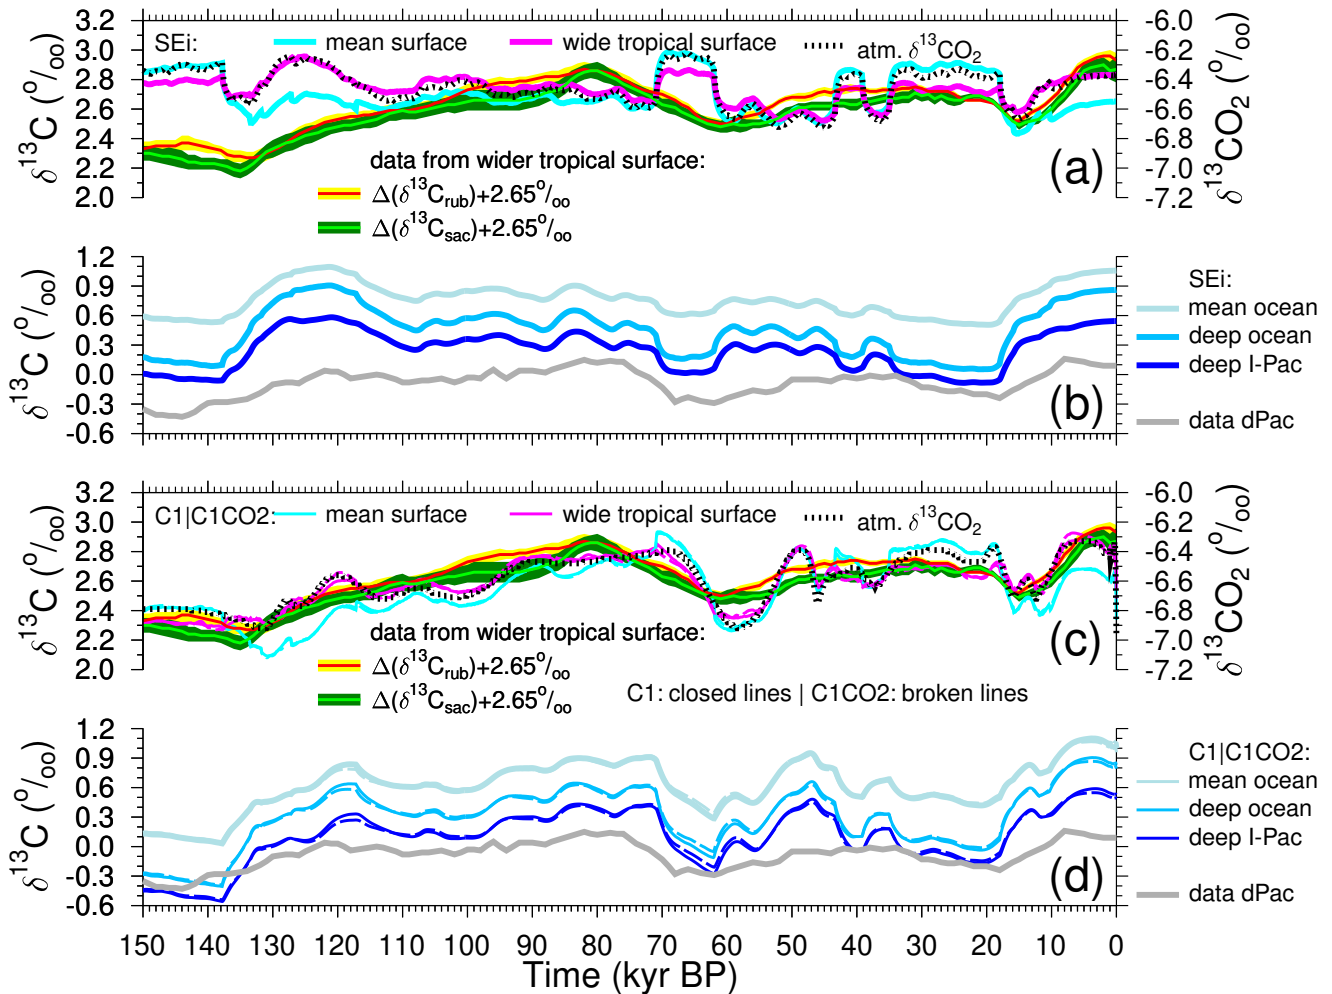

### 3.1 Simulated $\delta^{13}\text{C}$ cycle using the BICYCLE-SE model

General dynamics of the global carbon cycle in the BICYCLE-SE model have been analysed in detail in Köhler and Munhoven (2020). We here focus on the revised  $\delta^{13}\text{C}$  cycle, but see how atmospheric  $\text{CO}_2$  in scenario SEi meets the ice core data in  
450 Figure 5a. Note, that some analysis of  $\delta^{13}\text{C}$  in the precursor model BICYCLE without solid Earth contributions have been  
described in Köhler et al. (2010), who showed that the model misses variations in  $\delta^{13}\text{C}$  related to periodicities longer than  
100-kyr.

### 3.2 Simulated cycle using the BICYCLE-SE model

Atmospheric  $\delta^{13}\text{CO}_2$  (Eggleston et al., 2016a) is met by the results from scenario SEi only roughly, including some millennial-  
455 scale variations around 50–30 kyr BP and the transition from LGM to pre-industrial/preindustrial, shows some deficit the second  
half of T1 and in the Holocene (Figure 5b). The PGM-to-LGM trend of 0.45‰ and the minimum around 60 kyr BP are both  
largely unexplained in this simulation. The attribution of changes in  $\delta^{13}\text{CO}_2$  to individual processes in the ocean and land  
carbon cycle has been done before for the precursor model BICYCLE (Köhler et al., 2005, 2010), and is not repeated here,  
since the misfit to the data indicates some fundamental shortcomings.

460 More interesting is how How simulated changes in atmospheric  $\delta^{13}\text{CO}_2$  compares/compare to simulated changes in various  
marine  $\delta^{13}\text{C}_{\text{DIC}}$  time series (is shown for scenario SEi in Figure 7)a,b. Both global mean surface  $\delta^{13}\text{C}_{\text{DIC}}$  and non-polar/wider  
tropical surface  $\delta^{13}\text{C}_{\text{DIC}}$  show clear similarities with atmospheric  $\delta^{13}\text{CO}_2$ . Here, non-polar-surface values are area-weighted  
averages covering either the global ocean or the mean from the-two equatorial ocean boxes in case of the wider tropics,  
which spatially cover a similar area than as the sediment cores used for our new stacks  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$ . During  
465 glacial times and the onset of deglaciations the dynamics in global mean surface  $\delta^{13}\text{C}_{\text{DIC}}$  (cyan line in Figure 7a) are in  
close agreement with  $\delta^{13}\text{CO}_2$  in the atmosphere (black broken line in Figure 7a), while for the later part of the deglaciations  
and the interglacials the dynamics in non-polar/wider tropical surface  $\delta^{13}\text{C}_{\text{DIC}}$  (magenta line in Figure 7a) fits better to  
 $\delta^{13}\text{CO}_2$  in the atmosphere. This difference is probably explained by the dynamics in the polar oceans. During glacial times,  
the Southern Ocean is highly stratified with little vertical exchange between surface and deep ocean. This stratification breaks  
470 down during the terminations and in interglacials allowing faster exchange of tracers between surface and deep ocean leading  
in the polar oceans to smaller surface-to-deep gradients in  $\delta^{13}\text{C}_{\text{DIC}}$ . In other words, the lower deep ocean  $\delta^{13}\text{C}_{\text{DIC}}$  values have  
a larger impact on polar surface  $\delta^{13}\text{C}_{\text{DIC}}$  during interglacials than during glacials leading to a divergence between  $\delta^{13}\text{C}_{\text{DIC}}$

**Figure 7.** Simulated surface and deeper ocean  $\delta^{13}\text{C}$  time series from scenario SEi (a, b) and scenarios C1 and C1CO2 (c, d) compared with reconstructions. (a,c) Simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in the global mean surface and in the non-polar wider tropical surface ocean together with simulated atmospheric  $\delta^{13}\text{CO}_2$  (right y-axis) are plotted together with our new stacks from the non-polar wider tropical surface ocean,  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  shifted by  $+2.65\text{‰}$  to meet simulated surface  $\delta^{13}\text{C}_{\text{DIC}}$  at LGM. In (b,d) simulated  $\delta^{13}\text{C}_{\text{DIC}}$  for the deep Indo-Pacific (I-Pac), the mean deep ocean and the mean global ocean are plotted together with  $\delta^{13}\text{C}$  from benthic foraminifera stacked from six cores in the deep Pacific (dPac) (Lisiecki, 2014). In (c,d) the scenarios C1 (closed lines) and C1CO2 (broken lines) are plotted together. Most of the time the differences between both are so small that lines are indistinguishable.

in the global mean surface and the non-polar wider tropical surface ocean. The scatter plots between atmospheric  $\delta^{13}\text{CO}_2$  and either global mean surface or non-polar wider tropical surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  show that the latter has the higher correlation (Figure S1S2,  $r^2 = 0.82$  vs.  $r^2 = 0.59$ , ~~all regression results are compiled in Table ??~~). Furthermore, frequency analysis showed that the coherence between atmospheric  $\delta^{13}\text{CO}_2$  and wider tropical surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  is in periodicities slower

than 20 kyr higher than between atmospheric  $\delta^{13}\text{CO}_2$  and global mean surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  (Figure S3a). This implies, that simulations which agree in atmospheric  $\delta^{13}\text{CO}_2$  with reconstructions (which will be achieved later-on in scenarios C1 and C1CO2) should contain a very likely realisation of  $\delta^{13}\text{C}_{\text{DIC}}$  in the ~~non-polar surface ocean being a perfect target for~~  
 480 ~~comparison wider tropical surface ocean. A comparison of these simulated time series~~ with our new mono-specific  $\delta^{13}\text{C}$  stacks ~~should therefore enable us to address if and how  $\delta^{13}\text{C}$  has been modified during hard shell formation.~~ For scenario SEi the misfit in simulated ~~non-polar wider tropical~~ surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  and the new  $\delta^{13}\text{C}$  reconstructions (Figure 7a) is large, but it is yet unclear if this discrepancy can be explained by the CIE or by other processes.

~~Linear regression result between various variables. Analysed time series are 150 kyr long with time step between 100 yr and~~  
 485 ~~1 kyr. When needed lower resolved time series are interpolated before analysis. More details are given in the corresponding scatter plots. In column “source” either the simulation scenario or “data” is mentioned with the following data references: 1: this study; 2: Lisiecki and Stern (2016); 3: Lisiecki (2014). Column “Fig.” states the label of the figure with the corresponding scatter plot.~~

505 To understand how representative the reconstructed  $\delta^{13}\text{C}$  stack from benthic foraminifera in six deep Pacific cores (Lisiecki, 2014) might be we compare it with various different simulated time series:  $\delta^{13}\text{C}_{\text{DIC}}$  in the deep Indo-Pacific, in the mean deep ocean, or in the mean ocean (Figure 7b). Here, deep ocean results from the model refers to ocean boxes that contain waters deeper than 1 km. As expected the deep Indo-Pacific contains the end-member of the  $\delta^{13}\text{C}$  cycle with the most depleted values. The mean deep ocean  $\delta^{13}\text{C}_{\text{DIC}}$  is offset by 0.2–0.4‰ towards more positive values and shows larger G/IG amplitudes than  
 510  $\delta^{13}\text{C}_{\text{DIC}}$  in the deep Indo-Pacific. The mean ocean is again 0.2–0.4‰ more positive in  $\delta^{13}\text{C}_{\text{DIC}}$  than the mean deep ocean with again smaller G/IG amplitudes of 0.53‰ across T1. This number compares  $\delta^{13}\text{C}_{\text{DIC}}$  in the last 6 ka with the mean at the

LGM (23–19 ky BP) similarly as in Peterson et al. (2014) who proposed a mean ocean rise in  $\delta^{13}\text{C}$  by  $0.34 \pm 0.19\text{‰}$ . However, be aware that in Peterson et al. (2014) the CIE in benthic foraminifera as deduced in Schmittner et al. (2017) is ~~ignored~~not included. This suggests that the reconstructions are potentially recording a smaller G/IG change in  $\delta^{13}\text{C}$  than how  $\delta^{13}\text{C}_{\text{DIC}}$  in the deep ocean might have changed.

~~The simulated deep ocean is in our simulation results known to be linearly related to simulated atmospheric as analysed in Köhler et al. (2010). However, the model misses variations in related to periodicities longer than 100-kyr being one main reason for the model/data misfit. This shortcoming is also responsible why when using real world data not deep ocean, but the gradient between the two end members North Atlantic and Pacific needs to taken to match atmospheric (Lisiecki, 2010).~~

Above When discussing results of scenario SEi (Figure 7a) we have shown that once changes in the atmospheric  $\delta^{13}\text{CO}_2$  are met by the simulations the model then also should give a reasonable answer for how  $\delta^{13}\text{C}_{\text{DIC}}$  in the ~~non-polar wider tropical~~ surface ocean might have looked like. Furthermore, the close agreement of simulated and reconstructed atmospheric  $\text{CO}_2$  (Figure 5a) suggests that the assumed carbon cycle changes in our approach might be one possible realisation that is not too far away from the truth real world changes. However, the misfit between simulation results from scenario SEi and reconstruction in the  $\delta^{13}\text{C}$  cycle — linear regressions between simulations and reconstructions found no correlation at all (Figure S2a  $r^2 < 0.02$ , Figure S4a,b) — is not easily fixed. To improve our results we force in the following the model with the atmospheric records (scenario C1: only using  $\delta^{13}\text{CO}_2$ ; scenario C1CO2: using both  $\delta^{13}\text{CO}_2$  and  $\text{CO}_2$ ) to have conditions in the surface ocean as close to reconstructions as possible. Doing so leads to even tighter correlations between simulated atmospheric  $\delta^{13}\text{CO}_2$  and simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in the surface ocean than what we obtained for scenario SEi, the  $r^2$ -correlations between these variables are in scenarios C1 and C1CO2 with prescribed atmospheric  $\delta^{13}\text{CO}_2 \geq 0.76$ –0.77 and  $\geq 0.88$  for global mean surface  $\delta^{13}\text{C}_{\text{DIC}}$  and ~~non-polar wider tropical~~ surface  $\delta^{13}\text{C}_{\text{DIC}}$ , respectively (Figure S1)–S2). Again, the coherence is higher between atmospheric  $\delta^{13}\text{CO}_2$  and the wider tropical surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  than between atmospheric  $\delta^{13}\text{CO}_2$  and the global mean surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  (Figure S3b). Furthermore, in both scenarios the changes in simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in the ~~non-polar wider tropical~~ surface ocean agree remarkably well ( $r^2$  between 0.76 and 0.78, Figure S2e–S4c–f) with changes in our new stacks  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  without consideration of the CIE (Figure 7c), at least on the orbital timescales. This effect is also seen by the rise in coherence between simulated wider tropical surface  $\delta^{13}\text{C}_{\text{DIC}}$  and both our stacks from less than 0.1 (scenario SEi) to higher than 0.7 (scenario C1CO2) in the 41-kyr and 100-kyr bands (Figure S3c,d), while in the precession bands (19, 23-kyr) the coherence stayed below 0.6. Some more abrupt changes contained in the simulations are not recorded in the reconstructions, probably because bioturbation in the surface sediments together with the stacking procedure ~~prevents our marine record~~prevent our marine records from successfully resolving millennial-scale features. Thus, our forcing of atmospheric carbon records with data therefore seemed to be a promising approach to obtain simulated surface ocean in agreement with reconstructions for the slow frequency bands (41-kyr and beyond), while it seems to fail for precession and faster changes. When forcing atmospheric  $\delta^{13}\text{CO}_2$  by data the temperature-dependent isotopic fractionation during marine photosynthesis in  $\varepsilon_{(\text{C}_{\text{org}}-\text{DIC})}$  is only of minor importance for the simulated surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$ . If this effect is switched off the  $\delta^{13}\text{C}_{\text{DIC}}$  in the wider tropical surface ocean differs in general by less than 0.05‰ from the values in scenario C1.

Furthermore, deep ocean  $\delta^{13}\text{C}_{\text{DIC}}$  is on orbital time scale now also in better agreement with the data (Figure 7d), —the  $r^2$  of a linear regression between simulated deep Indo-Pacific  $\delta^{13}\text{C}_{\text{DIC}}$  and reconstructed deep Pacific rises from 0.59-0.49 for scenario SEi to 0.77 and above for the scenarios forced by atmospheric carbon records (Figure S3S5), although the rise in mean ocean  $\delta^{13}\text{C}_{\text{DIC}}$  during T1 has now been increased to 0.59‰. Considering a CIE of  $-2.6 \times 10^{-3}$  ‰ per  $\mu\text{mol kg}^{-1}$  of  $[\text{CO}_3^{2-}]$  disturbance for epi-benthic foraminifera (Schmittner et al., 2017) simulated variations in deep ocean  $[\text{CO}_3^{2-}]$  of  $+20 \mu\text{mol kg}^{-1}$  (Köhler and Munhoven, 2020) would translate to a comparably small reduction in deep Pacific benthic  $\delta^{13}\text{C}$  of up to 0.05‰. While the timing of changes in deep ocean  $[\text{CO}_3^{2-}]$  with highest values during the deglaciation is crucial to assess how such a benthic CIE would reduce the existing data/model mismatch a more thorough assessment of the benthic CIE would require the comprehensive compilation of benthic  $\delta^{13}\text{C}$  time series in different ocean basins, which is beyond the scope of this study. Note that the approximated amplitude of this benthic CIE is close to the measurement error of benthic  $\delta^{13}\text{C}$ .

### 3.2 The importance of the carbonate ion effect for non-polar wider tropical surface ocean $\delta^{13}\text{C}$

Although the initial analysis of our results when forced with atmospheric records already suggests only a minor, if any, role for the CIE in the interpretation of stacked mono-specific  $\delta^{13}\text{C}$  on orbital timescales, in the following we make a more quantitative assessment. The CIE has not yet been implemented in the  $^{13}\text{C}$  cycle of the model, but is only investigated here in post-processing. The carbonate ion concentration of either globally mean surface or non-polar wider tropical mean surface waters in our simulations are tightly anti-correlated to atmospheric  $\text{CO}_2$  ( $r^2 \geq 0.93$ , Figure S4–S6), which is a consequence of the marine carbonate system (Zeebe and Wolf-Gladrow, 2001). Interestingly, both Both scenarios C1 and C1CO2 lead to rather similar results here, which suggests that the  $\text{CO}_2$  forcing in scenario C1CO2 and its violation of mass conservation, is perturbing the carbon cycle only slightly. To be as close as possible to the reconstructions we nevertheless continue in the following by using results from scenario C1CO2, but results differ only slightly when based in scenario C1, thus our conclusions are independent from this choice.

Thus,  $\text{CO}_3^{2-}$  in non-polar wider tropical surface ocean in the simulation typically falls from maximum glacial values of  $\sim 320 \mu\text{mol kg}^{-1}$  to interglacial minimum of  $\sim 250 \mu\text{mol kg}^{-1}$  across both Terminations 1 and 2 (Figure 8a). This translates into a potential CIE of about 0.62‰ (Figure 8b) for *G. ruber* when we use the slope of  $m = -0.0089$  ‰ per  $\mu\text{mol kg}^{-1}$  change in  $[\text{CO}_3^{2-}]$ , and of 0.33‰ for *T. sacculifer* (slope of  $m = -0.0047$  ‰ per  $\mu\text{mol kg}^{-1}$  change in  $[\text{CO}_3^{2-}]$ ) (Spero et al., 1999). The y-axis intercepts of the complete regressions for the CIE is determined in order to have maximum agreement between reconstructions and simulations during the LGM. When comparing the potential CIE to the simulated LGM-to-preindustrial (PRE) amplitude of only 0.16‰ in wider tropical surface waters (Figure 8c) the CIE-to-G/IG ratios are between a factor of 2 and 4 and CIE signals should clearly stand out in the paleo records. If we add this CIE to our simulated mean equatorial surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  (Figure 8c) we end up with time series, which should compare well with the mono-species stacks of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  (Figure 8d). Unfortunately However, this is not the case. The  $r^2$  in the linear regressions between CIE-corrected  $\delta^{13}\text{C}_{\text{DIC}}$  in non-polar wider tropical surface waters and reconstructions is reduced to 0.55-0.54 (*G. ruber*) and 0.67-0.68 (*T. sacculifer*), while it had been  $\geq 0.76$  without CIE correction (Figures S2–5–S4, S7). When plotting results as hypothetically recorded in both species against each other we obtain a slope of 1.26 (Figure S8a). The slope between both time

580 ~~series without the CIE was  $\sim 0.99$  (Figure 6a). The consideration of the CIE did not lead to time series which agree better with each other.~~ Thus, we conclude that both species *G. ruber* and *T. sacculifer* are already good recorders of changes in  $\delta^{13}\text{C}_{\text{DIC}}$  in ~~non-polar wider tropical~~ surface ocean waters on orbital timescales, ~~albeit with notable offsets in individual records.~~

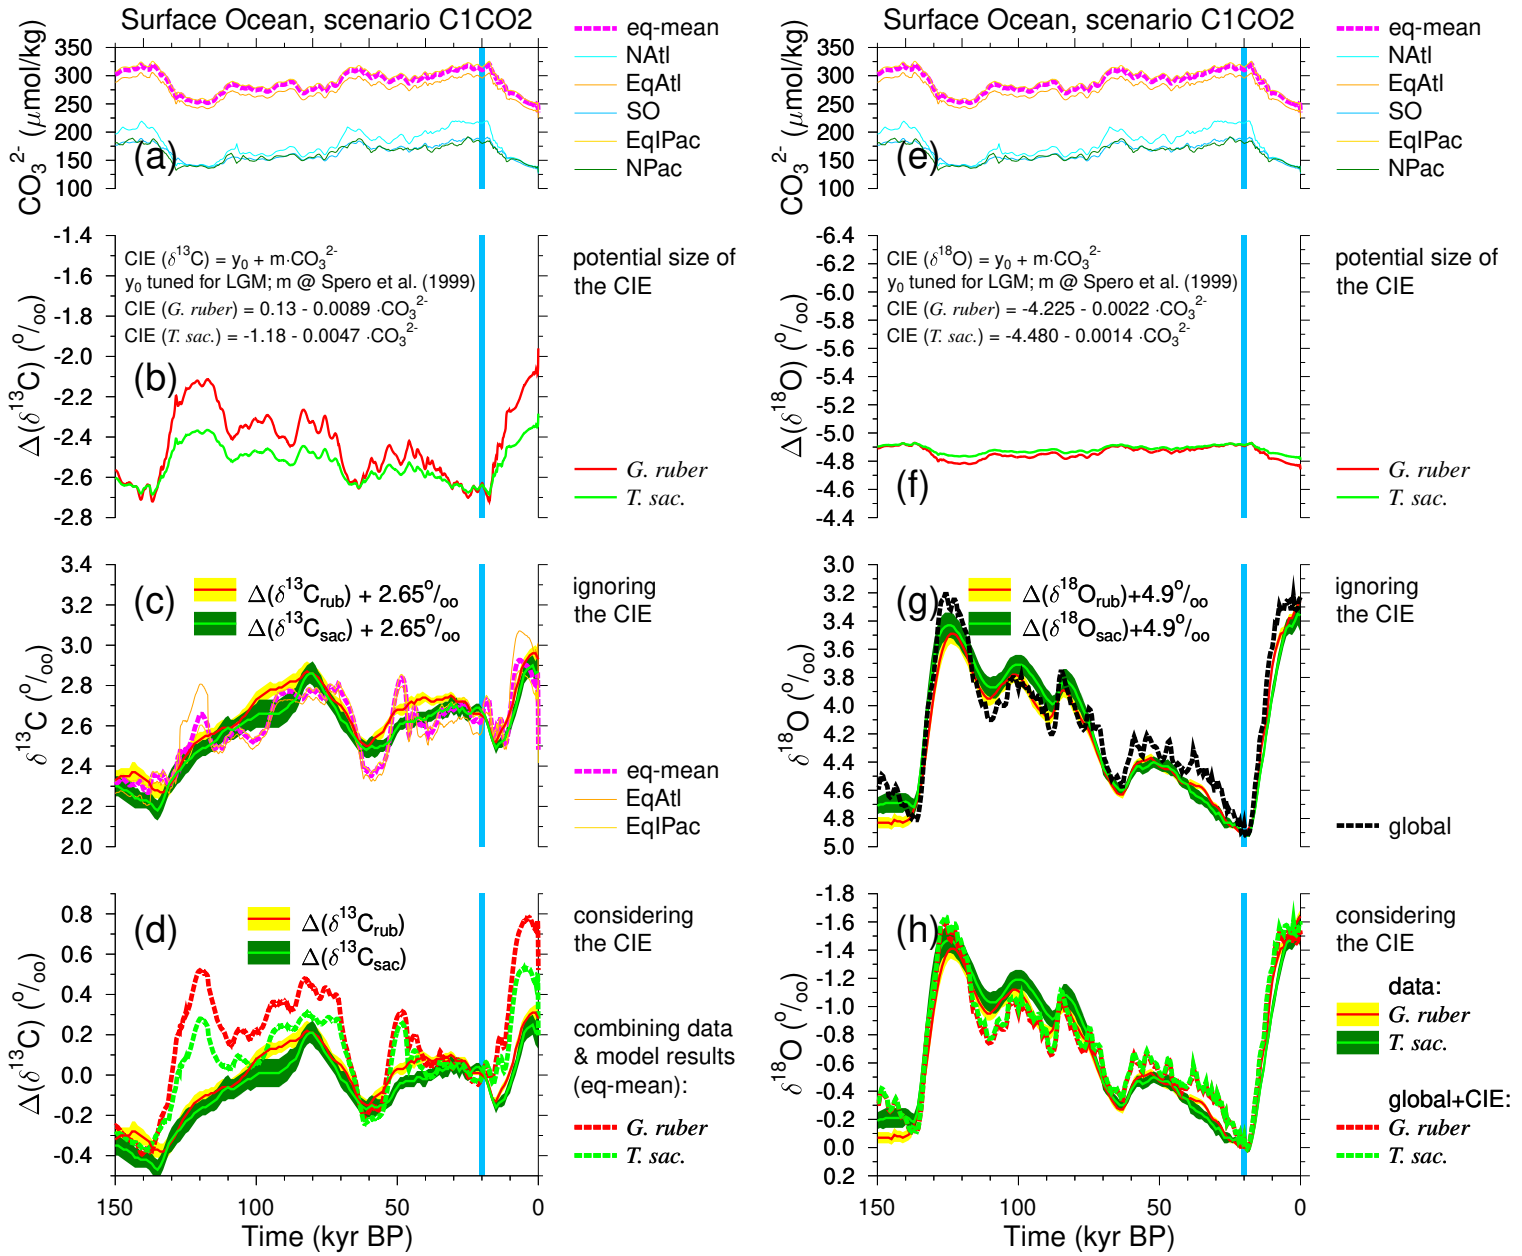

### 3.3 Carbonate ion effect in $\delta^{18}\text{O}$

The focus of this study is on stable carbon isotope  $\delta^{13}\text{C}$ . However, during the construction of our mono-specific ~~non-polar wider tropical~~ stacks of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  the corresponding stacks of  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  and  $\Delta(\delta^{18}\text{O}_{\text{sac}})$  are easily-  
585 ~~generated by-products initially used to cross-check the applied age models. However, these  $\delta^{18}\text{O}$  data give us the possibility to also have a closer look on the role of the CIE in the recording of oxygen isotopes in foraminiferal shells. For that effort we need a background time series of  $\delta^{18}\text{O}$  which represents the signals when not modified by the CIE. Such a mean  $\delta^{18}\text{O}$  in the non-polar wider tropical surface ocean should record the same sea-level related variations than the average global ocean,~~  
590 ~~but might differ in the recorded temperature effect, if the change in average non-polar wider tropical sea surface temperature differed from the mean ocean temperature (MOT) change. Pöppelmeier et al. (2023) showed that the LGM-to-preindustrial times (PRE)-LGM-to-PRE change in MOT derived from the model-based interpretation of noble gas reconstructions in ice cores is  $2.1 \pm 0.7$  K. The reconstructed rise in MOT is slightly higher when ignoring the effect of past saturation changes on noble gases (Shackleton et al., 2023). The data assimilation effort on LGM temperature changes by Tierney et al. (2020) is~~  
595 ~~broadly in agreement with the MOT change of Pöppelmeier et al. (2023) and proposes that the tropical ( $30^\circ\text{S}$  to  $30^\circ\text{N}$ ) sea surface was around 2.6 K colder at LGM than at PRE, agreeing within the uncertainties with the MOT change. To a first order we therefore assume that the planktic foraminifera should record the same temperature effect in  $\delta^{18}\text{O}$  as contained in the mean ocean. Thus, the global ocean  $\delta^{18}\text{O}$  calculated from stacking benthic time series (Lisiecki and Stern, 2016) represents the CIE-free background against which we compare our new  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  and  $\Delta(\delta^{18}\text{O}_{\text{sac}})$  stacks.~~

600 From the simulated LGM-to-PRE change in mean ~~non-polar wider tropical~~ surface ocean  $\text{CO}_3^{2-}$  of about  $-70 \mu\text{mol kg}^{-1}$  (Figure 8e) and the laboratory-based amplitudes of the CIE ( $-0.0022$  and  $-0.0014\%$  change in  $\delta^{18}\text{O}$  per  $\mu\text{mol kg}^{-1}$  for *G. ruber* and *T. sacculifer*, respectively (Spero et al., 1999)), we derived that  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  and  $\Delta(\delta^{18}\text{O}_{\text{sac}})$  should record the changes since the LGM by  $+0.15$  and  $+0.10 \%$  differently than how  $\delta^{18}\text{O}$  in the surface waters truly changed (Figure 8f). Compared to the G/IG amplitude in mean ocean  $\delta^{18}\text{O}$  of  $-1.65\%$  (Figure 8g) these potential CIEs represent corrections of  
605  $-9\%$  and  $-6\%$ , a difference by  $3\%$  which might be difficult to detect in the paleo records. A linear regression through a scatter plat of  $\delta^{18}\text{O} + \text{CIE}_{\text{rub}}$  versus  $\delta^{18}\text{O} + \text{CIE}_{\text{sac}}$  has a slope of  $0.97$  ( $r^2 = 1.00$ , Figure ~~S6b~~~~S8b~~), which is indistinguishable from the slope obtained from regression through the data stacks (Figure 6b), while the slope when considering the CIE should move to unity (indicating that both species were recording the same signal underneath the CIE) if the effect plays an important role during data interpretation. The evidences for or against the CIE in  $\delta^{18}\text{O}$  from both data and models are therefore inconclusive.

610 ~~The relative size of the potential CIE on  $\delta^{13}\text{C}$  is much larger. The same  $\Delta()$  would lead to  $0.62$  and  $0.33$  changes in  $\delta^{13}\text{C}_{\text{rub}}$  and  $\delta^{13}\text{C}_{\text{sac}}$ , respectively (Figure 8b). When compare to the simulated LGM-to-PRE amplitude of only  $0.16$  in non-polar surface waters (Figure 8g) the CIE-to-G/IG ratios are between a factor of  $2$  and  $4$  and CIE signals should clearly stand out in the paleo records.~~

**Figure 8.** Calculating the suggested carbonate ion effects (CIE) on *G. ruber* and *T. sacculifer*. Left: effects on  $\delta^{13}\text{C}$ ; Right: effects on  $\delta^{18}\text{O}$ . (a,e) surface ocean  $[\text{CO}_3^{2-}]$ ; (b,f) potential CIE using slopes from Spero et al. (1999) (c,g) surface ocean conditions when ignoring the CIE or (d,h) when considering the CIE. Mean anomalies ( $\pm 1$  SE) of the isotope stacks are calculated with respect to the mean of 21–19 kyr BP (blue vertical band). Simulations use the results from scenario C1CO2. Different surface ocean areas are distinguished: North Atlantic (NAtl, north of  $50^\circ\text{N}$ ), equatorial Atlantic (EqAtl,  $40^\circ\text{S}$ – $50^\circ\text{N}$ ), Southern Ocean (SO, south of  $40^\circ\text{S}$ ), equatorial Indo-Pacific (EqIPac,  $40^\circ\text{S}$ – $40^\circ\text{N}$ ), North Pacific (NPac, north of  $40^\circ\text{N}$ ). The mean **non-polar-wider tropical** ocean in the model is the mean from the equatorial boxes (eq-mean).

## 4 Conclusions

615 The CIE for  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  recorded in planktic foraminifera was first identified in laboratory experiments (Spero et al., 1997, 1999), and it was, based on theory, suggested for both isotopes that the underlying processes are directly related to the pH in the surrounding sea water during hard shell formation (Zeebe et al., 1999; Zeebe, 1999). ~~In the here relevant range of~~ However, these theoretical studies were already unable to confirm the full range of the CIE as contained in the experiments. Furthermore, according to Bijma et al. (1999) it is impossible to determine if pH around 8.0 a linear relation between pH and  $[\text{CO}_3^{2-}]$  exists (Zeebe and Wolf-Gladrow, 2001). ~~or  $[\text{CO}_3^{2-}]$  is responsible for the observed fractionation effects.~~ If this theoretical understanding is correct we would expect to see the CIE in neither or both isotopes in the our mono-specific stacks. Thus, although the interpretation of  $\delta^{18}\text{O}$  with respect to the CIE is, due to the signal-to-noise ratio, uncertain we argue, based on the clear evidence of a lack of the CIE in the recording of  $\delta^{13}\text{C}$  in *G. ruber* and *T. sacculifer*, that there is probably also no significant CIE contained in the  $\delta^{18}\text{O}$  time series of both species. ~~This finding argues against the suggestion of Spero et al. (1999), that the CIE and  $\delta^{13}\text{C}$  time series from *G. ruber* and *T. sacculifer* might be used to calculate a record of surface ocean  $[\text{CO}_3^{2-}]$ . Furthermore, we suggest to use our new stack of  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  as representative of  $\delta^{13}\text{C}_{\text{DIC}}$  in the wider tropical surface ocean.~~

~~A possible explanation~~ Various possible explanations for a lack of a CIE on orbital timescales ~~might be exist.~~ First, it might be that the isotopic fractionation during hard shell formation in *G. ruber* and *T. sacculifer* is rather insensitive to  $[\text{CO}_3^{2-}]$  in the range of interest (250–320  $\mu\text{mol kg}^{-1}$ ). Such an insensitivity has been suggested for other species (Bijma et al., 1999), but due to a lack of published data — the slopes of the CIE in *G. ruber* and *T. sacculifer* were only summarized in Spero et al. (1999), while underlying experiments have never been published in the peer-reviewed literature — it cannot be properly checked for the two species investigated here. Second, not the CIE, but alternatively the incorporation of respired  $\text{CO}_2$  (depleted in  $\delta^{13}\text{C}$ ) during shell formation might be responsible for the observed isotope data in laboratory experiments performed with *Orbulina* *universa* and *Globigerina bulloides* (Bijma et al., 1999). This process might also play a role in *G. ruber* and *T. sacculifer*, but would only explain observed effects in  $\delta^{13}\text{C}$ , but not in  $\delta^{18}\text{O}$ . However, since our stacks are inconclusive with respect to the CIE and  $\delta^{18}\text{O}$ , they might be of relevance here. A third explanation might be related to homeostasis. In symbiont-bearing planktic foraminifera, such as *G. ruber* and *T. sacculifer*, the pH at the shell surface critically depends on photosynthesis and hence light levels and symbiont density (Jørgensen et al., 1985). In order to facilitate calcification, *G. ruber* and *T. sacculifer* may actively influence the pH at the shell surface by seeking specific (optimum) light levels through vertical migration, thereby keeping the CIE constant over time. Planktic foraminifera are known to move vertically in the water column (e.g. Kimoto, 2015). Vertical migration to optimise both nutrient uptake and light has been proposed to play an important role in phytoplankton by modelling (Wirtz et al., 2022), an effect which recently has been supported by field data (Zheng et al., 2023). We speculate similar behaviour could occur in the two planktic foraminifera species.

645 It is too early to able able to generalise our finding that on orbital timescales the CIE plays no role for the interpretation of signals in planktic foraminifera in paleo records. For that effort more mono-specific stacks are necessary, preferable from conceptually different foraminifera species without symbionts or spines, as these might potentially show a different behaviour

with respect to light (and pH) optimisation. However, our findings might suggest that previous studies on planktic  $\delta^{13}\text{C}$ , which ignored the CIE (e.g. Lynch-Stieglitz et al., 2019; Lund et al., 2019) might not be biased.

650 Our carbon cycle simulations confirm that atmospheric  $\delta^{13}\text{CO}_2$  and mean surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  are tightly related to each other, highlighting the importance of air-sea gas exchange for carbon isotopes. This is not entirely new and has already been discussed before (e.g. Lynch-Stieglitz et al., 2019; Shao et al., 2021; Pinho et al., 2023). However, the  $^{13}\text{C}$  cycle is more complex than stated previously (Lynch-Stieglitz et al., 2019; Hu et al., 2020; Pinho et al., 2023) which suggest that one might calculate a mean surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  as function of atmospheric  $\delta^{13}\text{CO}_2$  and a temperature-dependent fractionation  
655 during gas exchange. We here assumed, based on modern data from Verwega et al. (2021), that species composition and therefore isotopic fractionation during marine photosynthesis might also be temperature-dependent having an important impact on surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$ . Furthermore, our simulation results show that  $\delta^{13}\text{C}_{\text{DIC}}$  in polar and ~~non-polar~~ wider tropical surface ocean have a different and time-dependent relation to atmospheric  $\delta^{13}\text{CO}_2$ .

Finally, since our simulations were forced by atmospheric carbon records we are unable to identify specific processes being  
660 responsible for the simulated changes in the  $^{13}\text{C}$  cycle. Recent climate simulations (Yun et al., 2023) emphasise the importance of the 405 kyr eccentricity cycle in ~~tropical~~ tropical hydroclimate. It therefore seems reasonable that the missing long-term variability in  $\delta^{13}\text{C}$  in our setup might indeed be connected to weathering fluxes as proposed before (e.g. Schneider et al., 2013; Wang et al., 2014), something which needs to be tested in more detail in future carbon cycle simulation studies.

*Code and data availability.* PaleoDataView, used for data processing (Langner and Mulitza, 2019), is available at <https://www.marum.de/Dr-stefan-mulitza/PaleoDataView.html> (last access 16 Nov 2023). In Table S1 meta data on the data selection are contained, which includes  
665 references to the original publications. The reference list based on citations in the Supplements (Table S1) is separately attached to the end of the main text. Most of the data from the planktic foraminifera *G. ruber* and *T. sacculifer* are already contained in the World Atlas of late Quaternary Foraminiferal Oxygen and Carbon Isotope Ratios (Mulitza et al., 2021; Mulitza et al., 2022). The data sets not yet contained in the World Atlas are Duplessy (1982); CLIMAP Project Members (1994); Meinecke (1999) and from three theses (Zahn-Knoll, 1986;  
670 Slowey, 1990; Romahn, 2014), from which data have been manually extracted from Tables within the theses. Simulation results and the data contributing to our data compilation including raw data, the Bacon settings and a netCDF file of the PaleoDataView Collection are available from PANGAEA (Köhler and Mulitza, 2023). Data for atmospheric  $\text{CO}_2$  and  $\delta^{13}\text{CO}_2$  are found in Eggleston et al. (2016b); Köhler et al. (2017b); Menking et al. (2022a). The stack of deep Pacific benthic  $\delta^{13}\text{C}$  is contained in Köhler (2022).

*Author contributions.* PK designed the study, performed the simulations, analysed the data and led the writing of the draft. SM compiled  
675 marine  $\delta^{13}\text{C}$  data and contributed to the writing of the draft.

*Competing interests.* The authors declare no competing interests.

Scatter plots between atmospheric and surface ocean  $\delta^{13}\text{C}_{\text{DIC}}$  (left: global mean; right: non-polar only) for scenarios SEi (a,b), C1 (c,d), C1CO2 (e,f) during the last 150 kyr of the simulations ( $\delta t = 100$  yr).

1180 Scatter plots between 150 kyr simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in three different scenarios (a,b: SEi, c,d: C1; e,f: C1CO2) and our new mono-specific stacks (left)  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and (right)  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  with  $\delta t = 100$  yr.

Scatter plots between 150 kyr simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in the deep Indo-Pacific in three different scenarios (a: SEi, b: C1; c: C1CO2) and a stack of deep Pacific  $\delta^{13}\text{C}_{\text{benthic}}$  from Lisiecki (2014) (L2014) with  $\delta t = 100$  yr.

Scatter plots between atmospheric and surface ocean (left: global mean; right: non-polar only) in scenarios (top) C1 and (bottom) C1CO2 for the last 150 kyr of the simulations ( $\delta t = 100$  yr).

1185 Scatter plots between 150 kyr simulated  $\delta^{13}\text{C}_{\text{DIC}}$  in scenario C1CO2 corrected by a hypothetical CIE against our new mono-specific stacks (a)  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  and (b)  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  with  $\delta t = 100$  yr.

Scatter plot of how isotope data should be recorded in planktic foraminifera if surface ocean data are corrected for the CIE. (a) Potential  $\Delta(\delta^{13}\text{C}_{\text{rub}})$  (non-polar surface ocean  $\delta^{13}\text{C}_{\text{DIC}} + \text{CIE}$  for *G. ruber*) versus potential  $\Delta(\delta^{13}\text{C}_{\text{sac}})$  (non-polar surface ocean  $\delta^{13}\text{C}_{\text{DIC}} + \text{CIE}$  for *T. sacculifer*) based on 150 kyr of simulation results of scenario C1CO2 and CIE corrections as calculated in Figure 8a–d. (b) Potential  $\Delta(\delta^{18}\text{O}_{\text{rub}})$  (mean ocean + CIE for *G. ruber*) versus potential  $\Delta(\delta^{18}\text{O}_{\text{sac}})$  (mean ocean + CIE for *T. sacculifer*) based on global ocean as calculated in Lisiecki and Stern (2016) (L2016) and CIE corrections as calculated in Figure 8e–h. The analysis contains data from the last 150 kyr with  $\delta t$  of 100 yr and 500 yr for  $\delta^{13}\text{C}$  and, respectively.
